Functions impeded by security technology. One of the reasons that participants noted for why they have not tried or do not regularly use certain security technologies is that they interfere with some component of the journalistic process. As reflected in Table 6, 3 of 15 participants mentioned this reason. Taking a closer look at which functions are impeded by existing security technologies (and should be considered in future tools for journalists), our participants mentioned the following problems:

- Anonymous communications may make it difficult for journalists to authenticate sources, or to authenticate themselves to sources.
- Using security tools may impede communications with colleagues who don't use or understand them.
- Constraints on communications with sources may reduce the quality of information journalists can get.

For example, P13 described the tension between anonymous sources and authenticity:

> *If I don't know who they are and can't check their background, I'm not going to use the information they give. Anonymous sourcing is fine if I know who they are, and I've checked who they are, and my editor knows who they are, but they can't keep that from me and then expect me to use the information they provide.*

In other words, a source's communications must be anonymous to everyone but the journalist with whom they are communicating, and that journalist must be able to prove the authenticity of that source to others (e.g., their editor). This need suggests that tools like SecureDrop [26], which supports anonymous document drops for journalists, are unlikely to be widely adopted in isolation — highlighting the need for the computer security community to interface with the journalism community.

On the flip side, P6 discussed the need for sources to authenticate him when he attempts to reach them, describing how sources are unlikely to answer the phone if they cannot see who is calling them.

In order to develop computer security technologies that will be widely adopted by journalists, the computer security community must understand such failures of existing tools. We emphasize that these failures are not merely the result of computer security tools being hard to use (a common culprit [65]) but often arise when a tool did not sufficiently account for functions important in a journalist's process, such as the ability to authenticate sources. In Section 5, we discuss what the specific failures above mean for where technologists should focus their efforts in this space.

Security needs unfulfilled by technology. In the previous paragraphs, we described needs of journalists that we infer from their reasons for not using certain security technologies. In addition to making these inferences, we also asked participants to report specifically on any concerns or issues related to computer security to which they have not yet found a good technical solutions (i.e., "I wish somebody would build a tool that does X"). From the responses to this question, we extract several technical security-related needs currently unaddressed.

Usability, education, and adoption. As discussed above, several participants mentioned usability concerns (the need for more usable security tools) and education concerns (the need for education about these issues for both sources and journalists), both for themselves and to increase the adoption of security technologies among others. Specifically, participants asked for better and easier-to-use tools or services for encrypted email, encrypted file sharing, and encrypted phone calls, as well as ways to prevent emails from being accidentally forwarded and to keep sensitive data off the Internet (e.g., air-gapping).

Mutual authentication and first contact. Some participants discussed ad hoc strategies to authenticate sources, or to authenticate themselves to sources. As noted above, current security tools for journalists may hamper these needs, rather than addressing them. Participant P0 spoke in particular about the tension between anonymity and authentication in first contact:

> *The first contact is never or very rarely anonymous or protected. If someone wants to give me some information and we don't already know each other, how would he do it? He could send me an email, yeah, okay — but then how could I be sure it's him? Unless he contacts me with his real identity first. It's very difficult to have the first contact secure.*

In this "first contact" problem, it is nearly impossible for journalists to entirely avoid *some* metadata trail when communicating with a source, since their initial contact will almost universally take place over a channel whose metadata is associated with the journalist's professional identity (e.g. telephone, email, or social media). Given the pivotal role that metadata has played in recent leak prosecutions [54], this is a significant security concern.

Digital divide. As discussed above, several participants expressed the need for better security technologies that work across the digital divide, in order to protect their communications with sources who have low technical expertise and/or limited access to technology.

These unfulfilled needs represent immediate opportunities for future work on secure journalist-source communications within the computer security community, with varying types and degrees of challenge. We discuss these new directions further in Section 5.

Other technical needs. Though we asked participants specifically about unaddressed issues related to computer security, a few also (or instead) expressed more general technical needs that have security implications.

For example, several participants discussed the difficulty of manually transcribing audio recordings of interviews and expressed a desire for better machine transcription. Our interviews show this unaddressed need led to at least one insecure practice by a participant, who described planning to use her iPhone's or Mac's speech-to-text feature to transcribe audio recordings of interviews with sources, seemingly unaware that this might send the audio of potentially sensitive interviews to the cloud [9]. Thus, as journalists develop ad hoc workarounds for tasks where a technical solution is missing from their toolset, they may unintentionally introduce vulnerabilities into their process.

More generally, as mentioned above, several participants discussed the need for a systematic knowledge management tool for journalists. P11 was most explicit:

> *There were different kinds of litigation software that I was familiar with as a lawyer, where, let's say, you have a massive case, where you have a document dump that has 15,000 documents. [...] There are programs that help you consolidate and put them into a secure database. So it's searchable [and provides a secure place where you can see everything related to a story at once]. I don't know of anything like that for journalism.*

This absence of a dedicated knowledge management tool for journalists represents an opportunity for computer security. If such a knowledge management tool seamlessly integrated computer security techniques to protect stored data and communications without significant effort on the part of the journalist, it would significantly raise the bar for the security of journalist-source communications.

5 Discussion

We elaborate on the implications of our findings for the computer security community and make concrete recommendations for how those considering journalist-source communications can most fruitfully direct their efforts.

5.1 Key Take-Aways

From the perspective of the computer security community, we consider the following take-aways to be the most important ones from our findings:

- Journalists commonly make decisions about how to communicate with sources based on the technical access and comfort level of the sources themselves. Thus, limited adoption of technical security tools for journalist-source communications stems in large part from the limited technical access and expertise of certain vulnerable populations.
- Journalists face technical challenges unrelated to computer security, including the lack of systematic knowledge management tools and limited technical support for transcription. In developing ad hoc strategies to deal with these challenges, journalists sometimes introduce additional security vulnerabilities into their practices.
- A journalist's organization plays an important role in his or her access to and competence with computer security technologies. Organizations that restrict a journalist's ability to install security (or other software) tools, or where many employees have limited technical expertise, reduce the effectiveness and adoption of security and other technologies.
- An important reason for the failure of some security tools in the journalistic context is their incompatibility with some essential aspect of the journalistic process. A tool that increases barriers to communication or prevents a journalist from determining the authenticity of a source will see limited adoption.

5.2 Recommendations

In addition to supporting ongoing efforts at educating and training journalists with respect to existing computer security technologies (e.g., [17, 43, 47, 62]), we distill from our findings the following recommendations for where the computer security community should focus its efforts.

First contact and authentication. The challenge of securing (or retroactively protecting) a journalist's first contact with a source remains a hard problem, especially given the tension between anonymity and mutual authentication. Determining authenticity, both of sources and of journalists, is of fundamental importance in the journalistic context and should be addressed explicitly by anonymous communication tools. For instance, successful approaches might leverage existing identity networks, as with the participant who asked his source to post a specific sentence on Twitter — similar to social authenticity proofs used by Keybase (`https://keybase.io/`).

Metadata protection. Protecting metadata of journalist-source communications is crucial, especially in light of successful leak prosecutions based on metadata information [54]. In practice, metadata is both legally and technically unprotected: none of the defensive strategies described by our participants was truly foolproof, especially with respect to metadata. Protecting metadata is challenging because it requires that both journalists and sources understand the risk, because it is brittle (e.g., a single failure to communicate securely can compromise dozens or hundreds of exchanges), and because it can conflict with other journalistic needs (e.g., the need for authentication in first contact). The computer security community should consider metadata protection in this context and develop effective, usable, and transparent solutions that can account for long-term communications of varying sensitivity.

Focus on sources. Since the methods and security of journalist-source communications often depend on the technical expertise and access of sources, the computer security community should focus not only on educating and building tools for journalists but also for sources. Enabling and improving access to computer security technologies for low-income and vulnerable populations (e.g., through a collaboration with public libraries and/or by supporting "dumb" phones or other access methods) will provide benefits to these communities far beyond their interaction with journalists. Meanwhile, future studies should also interview and/or survey sources to shed light on their perspectives and needs.

Knowledge management. Our findings suggest that journalists desire — but lack — a solution for systematic knowledge management to support storing, organizing, searching, and indexing story-related data and documents. This need presents an opportunity for computer security: if security techniques and tools are seamlessly and usably integrated into a well-designed knowledge management tool for journalists, these could see wide adoption within the industry and significantly raise the bar for the security of journalistic practices. For example, given the reliance among our interviewees on third-party cloud storage, a secure (and easy-to-use) cloud storage solution integrated into such a knowledge management tool would provide significant benefits. A knowledge management tool that also supports secure communication — such as encrypted chat or email within the organization — would also benefit affiliated but non-staff members of the organization (e.g., freelancers).

Understanding the journalistic process. We encourage the technical computer security community to continue engaging closely with the journalism community. While many of the themes observed in our interviews and highlighted in this paper may be well-known within the journalism community, several of them were surprising to us. The prevalence of ad hoc defensive strategies among our participants suggests mismatches between existing computer security tools and the needs and understandings of journalists. To create technical designs that address journalists' most significant security problems without compromising necessary professional practices, the computer security community must develop a deep understanding of the journalistic process. These efforts are likely to be most valuable if they are iterative, involving the development of tools that are then evaluated and refined in the field among the target population.

Broader applicability. Finally, successful techniques for securing journalist-source communications are likely to apply to — or provide lessons for — other contexts as well, such as communications between lawyers and their clients, between doctors and patients, in government operations, among dissidents and activists, and for other everyday users of technology.

6 Conclusion

Though journalists are often considered likely users and beneficiaries of secure communication and data storage tools, their practices have not been been studied in depth by the academic computer security community. To close this gap and to inform ongoing and future work on computer security for journalists, we conducted an in-depth, qualitative study of 15 journalists at well-respected journalistic institutions in the U.S. and France.

Our findings provide insight into the general journalistic practices and specific security concerns of journalists, as well as the successes and failures of existing security technologies within the journalistic context. Perhaps most importantly, we find that existing security tools have seen limited adoption not just due to usability issues (a common culprit) but because of a mismatch between between the assumed and actual practices, priorities, and constraints of journalists. This mismatch suggests that secure journalistic practices depend on a meaningful collaboration between the computer security and the journalism communities; we take an important step towards such a collaboration in this work.

Acknowledgements

We gratefully acknowledge our anonymous reviewers for their helpful feedback. We also thank Greg Akselrod and Kelly Caine for valuable discussions; Raymong Cheng, Roxana Geambasu, Tadayoshi Kohno, and Sam Sudar for feedback on earlier drafts; and Tamara Denning for guidance on interview coding. Most importantly, we thank our interviewees very much for their participation in our study. This research is supported in part by NSF Award CNS-1463968.

Constants Count: Practical Improvements to Oblivious RAM

Abstract

Oblivious RAM (ORAM) is a cryptographic primitive that hides memory access patterns as seen by untrusted storage. This paper proposes Ring ORAM, the most bandwidth-efficient ORAM scheme for the small client storage setting in both theory and practice. Ring ORAM is the first tree-based ORAM whose bandwidth is independent of the ORAM bucket size, a property that unlocks multiple performance improvements. First, Ring ORAM's overall bandwidth is 2.3× to 4× better than Path ORAM, the prior-art scheme for small client storage. Second, if memory can perform simple untrusted computation, Ring ORAM achieves constant online bandwidth ($\sim 60\times$ improvement over Path ORAM for practical parameters). As a case study, we show Ring ORAM speeds up program completion time in a secure processor by 1.5× relative to Path ORAM. On the theory side, Ring ORAM features a tighter and significantly simpler analysis than Path ORAM.

1 Introduction

With cloud computing and storage gaining popularity, privacy of users' sensitive data has become a large concern. It is well known, however, that encryption alone is not enough to ensure data privacy. Even after encryption, a malicious server still learns a user's access pattern, e.g., how frequently each piece of data is accessed, if the user scans, binary searches or randomly accesses her data at different stages. Prior works have shown that access patterns can reveal a lot of information about encrypted files [14] or private user data in computation outsourcing [32, 18].

Oblivious RAM (ORAM) is a cryptographic primitive that *completely* eliminates the information leakage in memory access traces. In an ORAM scheme, a *client* (e.g., a local machine) accesses data blocks residing on a *server*, such that for any two logical access sequences of the same length, the observable communications between the client and the server are computationally indistinguishable.

ORAMs are traditionally evaluated by *bandwidth*—the number of blocks that have to be transferred between the client and the server to access one block, *client storage*—the amount of trusted local memory required at the client side, and *server storage*—the amount of untrusted memory required at the server side. All three metrics are measured as functions of N, the total number of data blocks in the ORAM.

A factor that determines which ORAM scheme to use is whether the client has a large (GigaBytes or larger) or small (KiloBytes to MegaBytes) storage budget. An example of large client storage setting is remote oblivious file servers [30, 17, 24, 3]. In this setting, a user runs on a local desktop machine and can use its main memory or disk for client storage. Given this large client storage budget, the preferred ORAM scheme to date is the SSS construction [25], which has about $1 \cdot \log N$ bandwidth and typically requires GigaBytes of client storage.

In the same file server application, however, if the user is instead on a mobile phone, the client storage will have to be small. A more dramatic example for small client storage is when the client is a remote secure processor — in which case client storage is restricted to the processor's scarce on-chip memory. Partly for this reason, all secure processor proposals [18, 16, 8, 31, 22, 7, 5, 6] have adopted Path ORAM [27] which allows for small (typically KiloBytes of) client storage.

The majority of this paper focuses on the small client storage setting and Path ORAM. In fact, our construction is an improvement to Path ORAM. However, in Section 7, we show that our techniques can be easily extended to obtain a competitive large client storage ORAM.

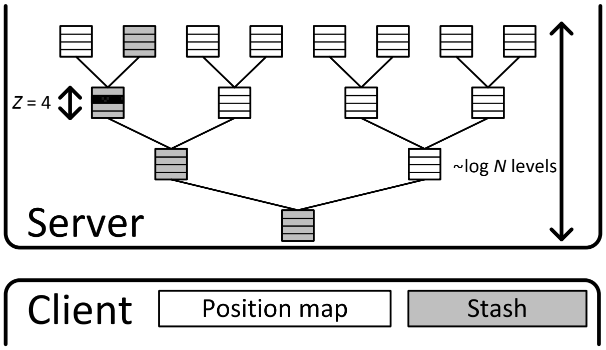

Figure 1: Path ORAM server and client storage. Suppose the **black** block is mapped to the shaded path. In that case, the block may reside in any slot along the path or in the stash (client storage).

1.1 Path ORAM and Challenges

We now give a brief overview of Path ORAM (for more details, see [27]). Path ORAM follows the tree-based ORAM paradigm [23] where server storage is structured as a binary tree of roughly $\log N$ levels. Each node in the tree is a bucket that can hold up to a small number Z of data blocks. Each path in the tree is defined as the sequence of buckets from the root of the tree to some leaf node. Each block is mapped to a random path, and must reside somewhere on that path. To access a block, the Path ORAM algorithm first looks up a position map, a table in client storage which tracks the path each block is currently mapped to, and then reads all the ($\sim Z \log N$) blocks on that path into a client-side data structure called the stash. The requested block is then remapped to a new random path and the position map is updated accordingly. Lastly, the algorithm invokes an eviction procedure which writes the same path we just read from, percolating blocks down that path. (Other tree-based ORAMs use different eviction algorithms that are less effective than Path ORAM, and hence the worse performance.)

The bandwidth of Path ORAM is $2Z \log N$ because each access reads and writes a path in the tree. To prevent blocks from accumulating in client storage, the bucket size Z has to be at least 4 (experimentally verified [27, 18]) or 5 (theoretically proven [26]).

We remind readers not to confuse the above read/write path operation with reading/writing data blocks. In ORAM, both reads and writes to a data block are served by the read path operation, which moves the requested block into client storage to be operated upon secretly. The sole purpose of the write path operation is to evict blocks from the stash and percolate blocks down the tree.

Despite being a huge improvement over prior schemes, Path ORAM is still plagued with several important challenges. First, the constant factor $2Z \geq 8$ is substantial, and brings Path ORAM's bandwidth overhead to $> 150\times$ for practical parameterizations. In contrast, the SSS construction does not have this bucket size parameter and can achieve close to $1 \cdot \log N$ bandwidth. (This bucket-size-dependent bandwidth is exactly why Path ORAM is dismissed in the large client storage setting.)

Second, despite the importance of overall bandwidth, online bandwidth—which determines response time—is equally, if not more, important in practice. For Path ORAM, half of the overall bandwidth must be incurred online. Again in contrast, an earlier work [3] reduced the SSS ORAM's online bandwidth to $O(1)$ by granting the server the ability to perform simple XOR computations. Unfortunately, their techniques do not apply to Path ORAM.

	Online Bandwidth	Overall Bandwidth
Path ORAM	$Z \log N = 4 \log N$	$2Z \log N = 8 \log N$
Ring ORAM	$\sim 1 \cdot \log N$	3-3.5$\log N$
Ring ORAM + XOR	~ 1	2-2.5$\log N$

Table 1: **Our contributions.** Overheads are relative to an insecure system. Ranges in constants for Ring ORAM are due to different parameter settings. The bandwidth cost of tree ORAM recursion [23, 26] is small ($< 3\%$) and thus excluded. XOR refers to the XOR technique from [3].

1.2 Our Contributions

In this paper, we propose Ring ORAM to address both challenges simultaneously. Our key technical achievement is to carefully re-design the tree-based ORAM such that the online bandwidth is $O(1)$, and the amortized overall bandwidth is independent of the bucket size. We compare bandwidth overhead with Path ORAM in Table 1. The major contributions of Ring ORAM include:

- **Small online bandwidth.** We provide the first tree-based ORAM scheme that achieves ~ 1 online bandwidth, relying only on very simple, untrusted computation logic on the server side. This represents at least $60\times$ improvement over Path ORAM for reasonable parameters.

- **Bucket-size independent overall bandwidth.** While all known tree-based ORAMs incur an overall bandwidth cost that depends on the bucket size, Ring ORAM eliminates this dependence, and improves overall bandwidth by $2.3\times$ to $4\times$ relative to Path ORAM.

- **Simple and tight theoretical analysis.** Using novel proof techniques based on Ring ORAM's eviction algorithm, we obtain a much simpler and tighter theoretical analysis than that of Path ORAM. Of independent interest, we note that the proof of Lemma 1 in [27], a crucial lemma for both Path ORAM and this paper, is incomplete (the lemma itself is correct). We give a rigorous proof for that lemma in this paper.

As mentioned, one main application of small client storage ORAM is for the secure processor setting. We simulate Ring ORAM in the secure processor setting and confirm that the improvement in bandwidth over Path ORAM translates to a 1.5× speedup in program completion time. Combined with all other known techniques, the average program slowdown from using an ORAM is 2.4× over a set of SPEC and database benchmarks.

Extension to larger client storage. Although our initial motivation was to design an optimized ORAM scheme under small client storage, as an interesting by-product, Ring ORAM can be easily extended to achieve competitive performance in the large client storage setting. This makes Ring ORAM a good candidate in oblivious cloud storage, because as a tree-based ORAM, Ring ORAM is easier to analyze, implement and de-amortize than hierarchical ORAMs like SSS [25]. Therefore, Ring ORAM is essentially *a united paradigm for ORAM constructions in both large and small client storage settings.*

Organization. In the rest of this introduction, we give an overview of our techniques to improve ORAM's online and overall bandwidth. Section 2 gives a formal security definition for ORAM. Section 3 explains the Ring ORAM protocol in detail. Section 4 gives a complete formal analysis for bounding Ring ORAM's client storage. Section 5 analyzes Ring ORAM's bandwidth and gives a methodology for setting parameters optimally. Section 6 compares Ring ORAM to prior work in terms of bandwidth vs. client storage and performance in a secure processor setting. Section 7 describes how to extend Ring ORAM to the large client storage setting. Section 8 gives related work and Section 9 concludes.

1.3 Overview of Techniques

We now explain our key technical insights. At a high level, our scheme also follows the tree-based ORAM paradigm [23]. Server storage is a binary tree where each node (a bucket) contains up to Z blocks and blocks percolate down the tree during ORAM evictions. We introduce the following non-trivial techniques that allow us to achieve significant savings in both online and overall bandwidth costs.

Eliminating online bandwidth's dependence on bucket size. In Path ORAM, reading a block would amount to reading and writing all Z slots in all buckets on a path. Our first goal is to *read only one block from each bucket* on the path. To do this, we randomly permute each bucket and store the permutation in each bucket as additional metadata. Then, by reading only metadata, the client can determine whether the requested block is in the present bucket or not. If so, the client relies on the stored permutation to read the block of interest from its random offset. Otherwise, the client reads a "fresh" (unread) dummy block, also from a random offset. We stress that the metadata size is typically much smaller than the block size, so the cost of reading metadata can be ignored.

For the above approach to be secure, it is imperative that each block in a bucket should be read at most once—a key idea also adopted by Goldreich and Ostrovsky in their early ORAM constructions [11]. Notice that any real block is naturally read only once, since once a real block is read, it will be invalidated from the present bucket, and relocated somewhere else in the ORAM tree. But dummy blocks in a bucket can be exhausted if the bucket is read many times. When this happens (which is public information), Ring ORAM introduces an *early reshuffle* procedure to reshuffle the buckets that have been read too many times. Specifically, suppose that each bucket is guaranteed to have S dummy blocks, then a bucket must be reshuffled every S times it is read.

We note that the above technique also gives an additional nice property: out of the $O(\log N)$ blocks the client reads, only 1 of them is a real block (i.e., the block of interest); all the others are dummy blocks. If we allow some simple computation on the memory side, we can immediately apply the XOR trick from Burst ORAM [3] to get $O(1)$ online bandwidth. In the XOR trick, the server simply XORs these encrypted blocks and sends a single, XOR'ed block to the client. The client can reconstruct the ciphertext of all the dummy blocks, and XOR them away to get back the encrypted real block.

Eliminating overall bandwidth's dependence on bucket size. Unfortunately, naïvely applying the above strategy will dramatically increase offline and overall bandwidth. The more dummy slots we reserve in each bucket (i.e., a large S), the more expensive ORAM evictions become, since they have to read and write all the blocks in a bucket. But if we reserve too few dummy slots, we will frequently run out of dummy blocks and have to call *early reshuffle*, also increasing overall bandwidth.

We solve the above problem with several additional techniques. First, we design a new eviction procedure that improves eviction quality. At a high level, Ring

ORAM performs evictions on a path in a similar fashion as Path ORAM, but eviction paths are selected based on a reverse lexicographical order [9], which evenly spreads eviction paths over the entire tree. The improved eviction quality allows us to perform evictions less frequently, only once every A ORAM accesses, where A is a new parameter. We then develop a proof that crucially shows A can approach $2Z$ while still ensuring negligible ORAM failure probability. The proof may be of independent interest as it uses novel proof techniques and is significantly simpler than Path ORAM's proof. The **amortized offline bandwidth** is now roughly $\frac{2Z}{A}\log N$, which **does not depend on the bucket size Z either**.

Second, bucket reshuffles can naturally piggyback on ORAM evictions. The balanced eviction order further ensures that every bucket will be reshuffled regularly. Therefore, we can set the reserved dummy slots S in accordance with the eviction frequency A, such that early reshuffles contribute little ($< 3\%$) to the overall bandwidth.

Putting it all Together. None of the aforementioned ideas would work alone. Our final product, Ring ORAM, stems from intricately combining these ideas in a non-trivial manner. For example, observe how our two main techniques act like two sides of a lever: (1) permuted buckets such that only 1 block is read per bucket; and (2) high quality and hence less frequent evictions. While permuted buckets make reads cheaper, they require adding dummy slots and would dramatically increase eviction overhead without the second technique. At the same time, less frequent evictions require increasing bucket size Z; without permuted buckets, ORAM reads blow up and nullify any saving on evictions. Additional techniques are needed to complete the construction. For example, early reshuffles keep the number of dummy slots small; piggyback reshuffles and load-balancing evictions keep the early reshuffle rate low. Without all of the above techniques, one can hardly get any improvement.

2 Security Definition

We adopt the standard ORAM security definition. Informally, the server should not learn anything about: 1) which data the client is accessing; 2) how old it is (when it was last accessed); 3) whether the same data is being accessed (linkability); 4) access pattern (sequential, random, etc); or 5) whether the access is a read or a write. Like previous work, we do not consider information leakage through the timing channel, such as when or how frequently the client makes data requests.

Notation	Meaning
N	Number of real data blocks in ORAM
L	Depth of the ORAM tree
Z	Maximum number of real blocks per bucket
S	Number of slots reserved for dummies per bucket
B	Data block size (in bits)
A	Eviction rate (larger means less frequent)
$\mathcal{P}(l)$	Path l
$\mathcal{P}(l,i)$	The i-th bucket (towards the root) on $\mathcal{P}(l)$
$\mathcal{P}(l,i,j)$	The j-th slot in bucket $\mathcal{P}(l,i)$

Table 2: ORAM parameters and notations.

Definition 1. (ORAM Definition) *Let*

$$\overleftarrow{y} = ((\mathsf{op}_M, \mathsf{addr}_M, \mathsf{data}_M), \ldots, (\mathsf{op}_1, \mathsf{addr}_1, \mathsf{data}_1))$$

denote a data sequence of length M, where op_i *denotes whether the i-th operation is a read or a write,* addr_i *denotes the address for that access and* data_i *denotes the data (if a write). Let* $\mathsf{ORAM}(\overleftarrow{y})$ *be the resulting sequence of operations between the client and server under an ORAM algorithm. The ORAM protocol guarantees that for any* $\overleftarrow{y}$ *and* $\overleftarrow{y}'$, $\mathsf{ORAM}(\overleftarrow{y})$ *and* $\mathsf{ORAM}(\overleftarrow{y}')$ *are computationally indistinguishable if* $|\overleftarrow{y}| = |\overleftarrow{y}'|$, *and also that for any* $\overleftarrow{y}$ *the data returned to the client by ORAM is consistent with* $\overleftarrow{y}$ *(i.e., the ORAM behaves like a valid RAM) with overwhelming probability.*

We remark that for the server to perform computations on data blocks [3], $\mathsf{ORAM}(\overleftarrow{y})$ and $\mathsf{ORAM}(\overleftarrow{y}')$ include those operations. To satisfy the above security definition, it is implied that these operations also cannot leak any information about the access pattern.

3 Ring ORAM Protocol

3.1 Overview

We first describe Ring ORAM in terms of its server and client data structures. All notation used throughout the rest of the paper is summarized in Table 2.

Server storage is organized as a binary tree of buckets where each bucket has a small number of slots to hold blocks. Levels in the tree are numbered from 0 (the root) to L (inclusive, the leaves) where $L = O(\log N)$ and N is the number of blocks in the ORAM. Each bucket has $Z + S$ slots and a small amount of metadata. Of these slots, up to Z slots may contain real blocks and the remaining S slots are reserved for dummy blocks as described in Section 1.3. Our theoretical analysis in Section 4 will show that to store N blocks in Ring ORAM, the physical ORAM tree needs roughly $6N$ to $8N$ slots. Experiments show that server storage in practice for both Ring ORAM and Path ORAM can be $2N$ or even smaller.

Client storage is made up of a position map and a stash. The position map is a dictionary that maps each block in the ORAM to a random leaf in the ORAM tree (each leaf is given a unique identifier). The stash buffers blocks that have not been evicted to the ORAM tree and additionally stores $Z(L+1)$ blocks on the eviction path during an eviction operation. We will prove in Section 4 that stash overflow probability decreases exponentially as stash capacity increases, which means our required stash size is the same as Path ORAM. The position map stores $N * L$ bits, but can be squashed to constant storage using the standard recursion technique (Section 3.7).

Main invariants. Ring ORAM has two main invariants:

1. (Same as Path ORAM): Every block is mapped to a leaf chosen uniformly at random in the ORAM tree. If a block a is mapped to leaf l, block a is contained either in the stash or in some bucket along the path from the root of the tree to leaf l.
2. **(Permuted buckets)** For every bucket in the tree, the physical positions of the $Z+S$ dummy and real blocks in each bucket are randomly permuted with respect to all past and future writes to that bucket.

Since a leaf uniquely determines a path in a binary tree, we will use leaves/paths interchangeably when the context is clear, and denote path l as $\mathcal{P}(l)$.

Access and Eviction Operations. The Ring ORAM access protocol is shown in Algorithm 1. Each access is broken into the following four steps:

1.) Position Map lookup (Lines 3-5): Look up the position map to learn which path l the block being accessed is currently mapped to. Remap that block to a new random path l'.

This first step is identical to other tree-based ORAMs [23, 27]. But the rest of the protocol differs substantially from previous tree-based schemes, and we highlight our key innovations in **bold**.

2.) Read Path (Lines 6-15): The ReadPath(l,a) operation reads all buckets along $\mathcal{P}(l)$ to look for the block of interest (block a), and then reads that block into the stash. The block of interest is then updated in stash on a write, or is returned to the client on a read. We remind readers again that both reading and writing a data block are served by a ReadPath operation.

Unlike prior tree-based schemes, our ReadPath operation **only reads one block from each bucket—the block of interest if found or a previously-unread dummy block otherwise.** This is safe because of Invariant 2, above: each bucket is permuted randomly, so the slot being read looks random to an observer. This lowers the bandwidth overhead of ReadPath (i.e., online bandwidth) to $L+1$ blocks (the number of levels in the tree) or even a single block if the XOR trick is applied (Section 3.2).

Algorithm 1 Non-recursive Ring ORAM.

```
1:  function ACCESS($a$, op, data$'$)
2:      Global/persistent variables: round

3:      $l' \leftarrow$ UniformRandom$(0, 2^L - 1)$
4:      $l \leftarrow$ PositionMap$[a]$
5:      PositionMap$[a] \leftarrow l'$

6:      data $\leftarrow$ ReadPath$(l, a)$
7:      if data $= \perp$ then
8:          $\triangleright$ If block $a$ is not found on path $l$, it must
9:          be in Stash $\triangleleft$
10:         data $\leftarrow$ read and remove $a$ from Stash
11:     if op $=$ read then
12:         return data to client
13:     if op $=$ write then
14:         data $\leftarrow$ data$'$
15:     Stash $\leftarrow$ Stash $\cup (a, l', \text{data})$

16:     round $\leftarrow$ round $+ 1 \mod A$
17:     if round $\overset{?}{=} 0$ then
18:         EvictPath()

19:     EarlyReshuffle$(l)$
```

3.) Evict Path (Line 16-18): The EvictPath operation reads Z blocks (all the remaining real blocks, and potentially some dummy blocks) from each bucket along a path into the stash, and then fills that path with blocks from the stash, trying to push blocks as far down towards the leaves as possible. The sole purpose of an eviction operation is to push blocks back to the ORAM tree to keep the stash occupancy low.

Unlike Path ORAM, eviction in Ring ORAM **selects paths in the reverse lexicographical order, and does not happen on every access. Its rate is controlled by a public parameter A: every A ReadPath operations trigger a single EvictPath operation.** This means Ring ORAM needs much fewer eviction operations than Path ORAM. We will theoretically derive a tight relationship between A and Z in Section 4.

4.) Early Reshuffles (Line 19): Finally, we perform **a maintenance task called** EarlyReshuffle **on** $\mathcal{P}(l)$**, the path accessed by** ReadPath**.** This step is crucial in maintaining blocks randomly shuffled in each bucket, which enables ReadPath to securely read only one block from each bucket.

We will present details of ReadPath, EvictPath and EarlyReshuffle in the next three subsections. We defer low-level details for helper functions needed in these three subroutines to Appendix A. We explain the security for each subroutine in Section 3.5. Finally, we discuss additional optimizations in Section 3.6 and recursion in Section 3.7.

3.2 Read Path Operation

Algorithm 2 ReadPath procedure.

```
1: function ReadPath($l, a$)
2:     data ← $\perp$
3:     for $i \leftarrow 0$ to $L$ do
4:         offset ← GetBlockOffset($\mathcal{P}(l,i), a$)
5:         data′ ← $\mathcal{P}(l,i,$offset$)$
6:         Invalidate $\mathcal{P}(l,i,$offset$)$
7:         if data′ $\neq \perp$ then
8:             data ← data′
9:         $\mathcal{P}(l,i)$.count ← $\mathcal{P}(l,i)$.count $+ 1$
       return data
```

The ReadPath operation is shown in Algorithm 2. For each bucket along the current path, ReadPath selects a *single* block to read from that bucket. For a given bucket, if the block of interest lives in that bucket, we read and invalidate the block of interest. Otherwise, we read and invalidate a randomly-chosen dummy block that is still valid at that point. The index of the block to read (either real or random) is returned by the GetBlockOffset function whose detailed description is given in Appendix A.

Reading a single block per bucket is crucial for our bandwidth improvements. In addition to reducing online bandwidth by a factor of Z, it allows us to use larger Z and A to decrease overall bandwidth (Section 5). Without this, read bandwidth is proportional to Z, and the cost of larger Z on reads outweighs the benefits.

Bucket Metadata. Because the position map only tracks the *path* containing the block of interest, the client does not know where in each bucket to look for the block of interest. Thus, for each bucket we must store the permutation in the bucket metadata that maps each real block in the bucket to one of the $Z+S$ slots (Lines 4, GetBlockOffset) as well as some additional metadata. Once we know the offset into the bucket, Line 5 reads the block in the slot, and invalidates it. We describe all metadata in Appendix A, but make the important point that the metadata is small and independent of the block size.

One important piece of metadata to mention now is a counter which tracks how many times it has been read since its last eviction (Line 9). If a bucket is read too many (S) times, it may run out of dummy blocks (i.e., all the dummy blocks have been invalidated). On future accesses, if additional dummy blocks are requested from this bucket, we cannot re-read a previously invalidated dummy block: doing so reveals to the adversary that the block of interest is not in this bucket. Therefore, we need to reshuffle single buckets on-demand as soon as they are touched more than S times using EarlyReshuffle (Section 3.4).

XOR Technique. We further make the following key observation: during our ReadPath operation, each block returned to the client is a dummy block except for the block of interest. This means our scheme can also take advantage of the XOR technique introduced in [3] to reduce online bandwidth overhead to $O(1)$. To be more concrete, on each access ReadPath returns $L+1$ blocks in ciphertext, one from each bucket, $\mathsf{Enc}(b_0, r_0), \mathsf{Enc}(b_2, r_2), \cdots, \mathsf{Enc}(b_L, r_L)$. Enc is a randomized symmetric scheme such as AES counter mode with nonce r_i. With the XOR technique, ReadPath will return *a single ciphertext* — the ciphertext of all the blocks XORed together, namely $\mathsf{Enc}(b_0, r_0) \oplus \mathsf{Enc}(b_2, r_2) \oplus \cdots \oplus \mathsf{Enc}(b_L, r_L)$. The client can recover the encrypted block of interest by XORing the returned ciphertext with the encryptions of all the dummy blocks. To make computing each dummy block's encryption easy, the client can set the plaintext of all dummy blocks to a fixed value of its choosing (e.g., 0).

3.3 Evict Path Operation

Algorithm 3 EvictPath procedure.

```
function EvictPath
    Global/persistent variables $G$ initialized to 0
    $l \leftarrow G \mod 2^L$
    $G \leftarrow G + 1$
    for $i \leftarrow 0$ to $L$ do
        Stash ← Stash $\cup$ ReadBucket($\mathcal{P}(l,i)$)
    for $i \leftarrow L$ to $0$ do
        WriteBucket($\mathcal{P}(l,i)$, Stash)
        $\mathcal{P}(l,i)$.count ← 0
```

The EvictPath routine is shown in Algorithm 3. As mentioned, evictions are scheduled statically: one evic-

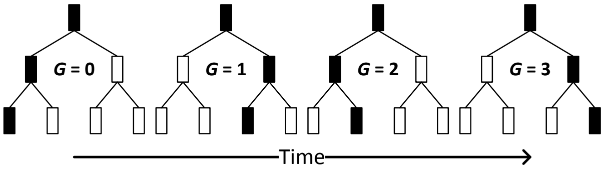

Figure 2: Reverse-lexicographic order of paths used by EvictPath. After path $G = 3$ is evicted to, the order repeats.

tion operation happens after every A reads. At a high level, an eviction operation reads all remaining real blocks on a path (in a secure fashion), and tries to push them down that path as far as possible. The leaf-to-root order in the writeback step (Lines 7) reflects that we wish to fill the deepest buckets as fully as possible. (For readers who are familiar with Path ORAM, EvictPath is like a Path ORAM access where no block is accessed and therefore no block is remapped to a new leaf.)

We emphasize two unique features of Ring ORAM eviction operations. First, evictions in Ring ORAM are performed to paths in a specific order called the *reverse-lexicographic order*, first proposed by Gentry et al. [9] and shown in Figure 2. The reverse-lexicographic order eviction aims to minimize the overlap between consecutive eviction paths, because (intuitively) evictions to the same bucket in consecutive accesses are less useful. This improves eviction quality and allows us to reduce the frequency of eviction. Evicting using this static order is also a key component in simplifying our theoretical analysis in Section 4.

Second, buckets in Ring ORAM need to be randomly shuffled (Invariant 2), and we mostly rely on EvictPath operations to keep them shuffled. An EvictPath operation reads Z blocks from each bucket on a path into the stash, and writes out $Z+S$ blocks (only up to Z are real blocks) to each bucket, randomly permuted. The details of reading/writing buckets (ReadBucket and WriteBucket) are deferred to Appendix A.

3.4 Early Reshuffle Operation

Algorithm 4 EarlyReshuffle procedure.

```
function EarlyReshuffle($l$)
    for $i \leftarrow 0$ to $L$ do
        if $\mathcal{P}(l,i)$.count $\geq S$ then
            Stash $\leftarrow$ Stash $\cup$ ReadBucket($\mathcal{P}(l,i)$)
            WriteBucket($\mathcal{P}(l,i)$, Stash)
            $\mathcal{P}(l,i)$.count $\leftarrow 0$
```

Due to randomness, a bucket can be touched $> S$ times by ReadPath operations before it is reshuffled by the scheduled EvictPath. If this happens, we call EarlyReshuffle on that bucket to reshuffle it before the bucket is read again (see Section 3.2). More precisely, after each ORAM access EarlyReshuffle goes over all the buckets on the read path, and reshuffles all the buckets that have been accessed more than S times by performing ReadBucket and WriteBucket. ReadBucket and WriteBucket are the same as in EvictPath: that is, ReadBucket reads exactly Z slots in the bucket and WriteBucket re-permutes and writes back $Z+S$ real/dummy blocks. We note that though S does not affect security (Section 3.5), it clearly has an impact on performance (how often we shuffle, the extra cost per reshuffle, etc.). We discuss how to optimally select S in Section 5.

3.5 Security Analysis

Claim 1. ReadPath *leaks no information.*

The path selected for reading will look random to any adversary due to Invariant 1 (leaves are chosen uniformly at random). From Invariant 2, we know that every bucket is randomly shuffled. Moreover, because we invalidate any block we read, we will never read the same slot. Thus, any sequence of reads (real or dummy) to a bucket between two shuffles is indistinguishable. Thus the adversary learns nothing during ReadPath. □

Claim 2. EvictPath *leaks no information.*

The path selected for eviction is chosen statically, and is public (reverse-lexicographic order). ReadBucket always reads exactly Z blocks from random slots. WriteBucket similarly writes $Z+S$ encrypted blocks in a data-independent fashion. □

Claim 3. EarlyShuffle *leaks no information.*

To which buckets EarlyShuffle operations occur is publicly known: the adversary knows how many times a bucket has been accessed since the last EvictPath to that bucket. ReadBucket and WriteBucket are secure as per observations in Claim 2. □

The three subroutines of the Ring ORAM algorithm are the only operations that cause externally observable behaviors. Claims 1, 2, and 3 show that the subroutines are secure. We have so far assumed that path remapping and bucket permutation are truly random, which gives unconditional security. If pseudorandom numbers are used instead, we have computational security through similar arguments.

3.6 Other Optimizations

Minimizing roundtrips. To keep the presentation simple, we wrote the ReadPath (EvictPath) algorithms to process buckets one by one. In fact, they can be performed for all buckets on the path in parallel which reduces the number of roundtrips to 2 (one for metadata and one for data blocks).

Tree-top caching. The idea of tree-top caching [18] is simple: we can reduce the bandwidth for ReadPath and EvictPath by storing the top t (a new parameter) levels of the Ring ORAM tree at the client as an extension of the stash[1]. For a given t, the stash grows by approximately $2^t Z$ blocks.

De-amortization. We can de-amortize the expensive EvictPath operation through a period of A accesses, simply by reading/writing a small number of blocks on the eviction path after each access. After de-amortization, worst-case overall bandwidth equals average overall bandwidth.

3.7 Recursive Construction

With the construction given thus far, the client needs to store a large position map. To achieve small client storage, we follow the standard recursion idea in tree-based ORAMs [23]: instead of storing the position map on the client, we store the position map on a smaller ORAM on the server, and store only the position map for the smaller ORAM. The client can recurse until the final position map becomes small enough to fit in its storage. For reasonably block sizes (e.g., 4 KB), recursion contributes very little to overall bandwidth (e.g., $< 5\%$ for a 1 TB ORAM) because the position map ORAMs use much smaller blocks [26]. Since recursion for Ring ORAM behaves in the same way as all the other tree-based ORAMs, we omit the details.

4 Stash Analysis

In this section we analyze the stash occupancy for a non-recursive Ring ORAM. Following the notations in Path ORAM [27], by $\mathsf{ORAM}_L^{Z,A}$ we denote a non-recursive Ring ORAM with $L+1$ levels, bucket size Z and one eviction per A accesses. The root is at level 0 and the leaves are at level L. We define the stash occupancy $\mathsf{st}(\mathcal{S}_Z)$ to be the number of real blocks in the stash after a sequence of ORAM sequences (this notation will be further explained later). We will prove that $\Pr[\mathsf{st}(\mathcal{S}_Z) > R]$ decreases exponentially in R for certain Z and A combinations. As it turns out, the deterministic eviction pattern in Ring ORAM dramatically simplifies the proof.

We note here that the reshuffling of a bucket does not affect the occupancy of the bucket, and is thus irrelevant to the proof we present here.

4.1 Proof outline

The proof consists of the two steps. The first step is the same as Path ORAM, and needs Lemma 1 and Lemma 2 in the Path ORAM paper [27], which we restate in Section 4.2. We introduce ∞-ORAM, which has an infinite bucket size and after a post-processing step has exactly the same distribution of blocks over all buckets and the stash (Lemma 1). Lemma 2 says the stash occupancy of ∞-ORAM after post-processing is greater than R if and only if there exists a subtree T in ∞-ORAM whose "occupancy" exceeds its "capacity" by more than R. We note, however, that the Path ORAM [27] paper only gave intuition for the proof of Lemma 1, and unfortunately did not capture of all the subtleties. We will rigorously prove that lemma, which turns out to be quite tricky and requires significant changes to the post-processing algorithm.

The second step (Section 4.3) is much simpler than the rest of Path ORAM's proof, thanks to Ring ORAM's static eviction pattern. We simply need to calculate the expected occupancy of subtrees in ∞-ORAM, and apply a Chernoff-like bound on their actual occupancy to complete the proof. We do not need the complicated eviction game, negative association, stochastic dominance, etc., as in the Path ORAM proof [26].

For readability, we will defer the proofs of all lemmas to Appendix B.

4.2 ∞-ORAM

We first introduce ∞-ORAM, denoted as $\mathsf{ORAM}_L^{\infty,A}$. Its buckets have infinite capacity. It receives the same input request sequence as $\mathsf{ORAM}_L^{Z,A}$. We then label buckets linearly such that the two children of bucket b_i are b_{2i} and b_{2i+1}, with the root bucket being b_1. We define the stash to be b_0. We refer to b_i of $\mathsf{ORAM}_L^{\infty,A}$ as b_i^∞, and b_i of $\mathsf{ORAM}_L^{Z,A}$ as b_i^Z. We further define ORAM *state*, which consists of the states of all the buckets in the ORAM, i.e., the blocks contained by each bucket. Let $\mathcal{S}_\infty$ be the state of $\mathsf{ORAM}_L^{\infty,A}$ and $\mathcal{S}_Z$ be the state of $\mathsf{ORAM}_L^{Z,A}$.

We now propose a new greedy post-processing algorithm G (different from the one in [27]), which by reassigning blocks in buckets makes each bucket b_i^∞ in ∞-ORAM contain the same set of blocks as b_i^Z. Formally, G takes as input $\mathcal{S}_\infty$ and $\mathcal{S}_Z$ after the same access sequence with the same randomness. For i from $2^{L+1}-1$ down to

[1] We call this optimization tree-top caching following prior work. But the word cache is a misnomer: the top t levels of the tree are *permanently* stored by the client.

1 (note that the decreasing order ensures that a parent is always processed later than its children), G processes the blocks in bucket b_i^∞ in the following way:

1. For those blocks that are also in b_i^Z, keep them in b_i^∞.
2. For those blocks that are not in b_i^Z but in some ancestors of b_i^Z, move them from b_i^∞ to $b_{i/2}^\infty$ (the parent of b_i^∞, and note that the division includes flooring). If such blocks exist and the number of blocks remaining in b_i^∞ is less than Z, raise an error.
3. If there exists a block in b_i^∞ that is in neither b_i^Z nor any ancestor of b_i^Z, raise an error.

We say $G_{\mathcal{S}_Z}(\mathcal{S}_\infty) = \mathcal{S}_Z$, if no error occurs during G and b_i^∞ after G contains the same set of blocks as b_i^Z for $i = 0, 1, \cdots 2^{L+1}$.

Lemma 1. *$G_{\mathcal{S}_Z}(\mathcal{S}_\infty) = \mathcal{S}_Z$ after the same ORAM access sequence with the same randomness.*

Next, we investigate what state $\mathcal{S}_\infty$ will lead to the stash occupancy of more than R blocks in a post-processed ∞-ORAM. We say a subtree T is a rooted subtree, denoted as $T \in \mathsf{ORAM}_L^{\infty,A}$ if T contains the root of $\mathsf{ORAM}_L^{\infty,A}$. This means that if a node in $\mathsf{ORAM}_L^{\infty,A}$ is in T, then so are all its ancestors. We define $n(T)$ to be the total number of nodes in T. We define $c(T)$ (the capacity of T) to be the maximum number of blocks T can hold; for Ring ORAM $c(T) = n(T) \cdot Z$. Lastly, we define $X(T)$ (the occupancy of T) to be the actual number of real blocks that are stored in T. The following lemma characterizes the stash size of a post-processed ∞-ORAM:

Lemma 2. *$\mathsf{st}(G_{\mathcal{S}_Z}(\mathcal{S}_\infty)) > R$ if and only if $\exists T \in \mathsf{ORAM}_L^{\infty,A}$ s.t. $X(T) > c(T) + R$ before post-processing.*

By Lemma 1 and Lemma 2, we have

$$\begin{aligned}
&\Pr[\mathsf{st}(\mathcal{S}_Z) > R] = \Pr[\mathsf{st}(G_{\mathcal{S}_Z}(\mathcal{S}_\infty)) > R] \\
&\le \sum_{T \in \mathsf{ORAM}_L^{\infty,A}} \Pr[X(T) > c(T) + R] \\
&< \sum_{n \ge 1} 4^n \max_{T : n(T) = n} \Pr[X(T) > c(T) + R]
\end{aligned} \tag{1}$$

The above inequalities used a union bound and a bound on Catalan sequences.

4.3 Bounding the Stash Size

We first give a bound on the expected bucket load:

Lemma 3. *For any rooted subtree T in $\mathsf{ORAM}_L^{\infty,A}$, if the number of distinct blocks in the ORAM $N \le A \cdot 2^{L-1}$, the expected load of T has the following upper bound:*

$$\forall T \in \mathsf{ORAM}_L^{\infty,A}, E[X(T)] \le n(T) \cdot A/2.$$

Let $X(T) = \sum_i X_i(T)$, where each $X_i(T) \in \{0, 1\}$ and indicates whether the i-th block (can be either real or stale) is in T. Let $p_i = \Pr[X_i(T) = 1]$. $X_i(T)$ is completely determined by its time stamp i and the leaf label assigned to block i, so they are independent from each other (refer to the proof of Lemma 3). Thus, we can apply a Chernoff-like bound to get an exponentially decreasing bound on the tail distribution. To do so, we first establish a bound on $E\left[e^{tX(T)}\right]$ where $t > 0$,

$$\begin{aligned}
E\left[e^{tX(T)}\right] &= E\left[e^{t\sum_i X_i(T)}\right] = E\left[\Pi_i e^{tX_i(T)}\right] \\
&= \Pi_i E\left[e^{tX_i(T)}\right] \qquad \text{(by independence)} \\
&= \Pi_i \left(p_i(e^t - 1) + 1\right) \\
&\le \Pi_i \left(e^{p_i(e^t-1)}\right) = e^{(e^t-1)\Sigma_i p_i} \\
&= e^{(e^t-1)E[X(T)]}
\end{aligned} \tag{2}$$

For simplicity, we write $n = n(T)$ and $a = A/2$. By Lemma 3, $E[X(T)] \le n \cdot a$. By the Markov Inequality, we have for all $t > 0$,

$$\begin{aligned}
\Pr[X(T) > c(T) + R] &= \Pr\left[e^{tX(T)} > e^{t(nZ+R)}\right] \\
&\le E\left[e^{tX(T)}\right] \cdot e^{-t(nZ+R)} \\
&\le e^{(e^t-1)an} \cdot e^{-t(nZ+R)} \\
&= e^{-tR} \cdot e^{-n[tZ - a(e^t-1)]}
\end{aligned}$$

Let $t = \ln(Z/a)$,

$$\Pr[X(T) > c(T) + R] \le (a/Z)^R \cdot e^{-n[Z\ln(Z/a) + a - Z]} \tag{3}$$

Now we will choose Z and A such that $Z > a$ and $q = Z\ln(Z/a) + a - Z - \ln 4 > 0$. If these two conditions hold, from Equation (1) we have $t = \ln(Z/a) > 0$ and that the stash overflow probability decreases exponentially in the stash size R:

$$\Pr[\mathsf{st}(\mathcal{S}_Z) > R] \le \sum_{n \ge 1} (a/Z)^R \cdot e^{-qn} < \frac{(a/Z)^R}{1 - e^{-q}}.$$

4.4 Stash Size in Practice

Now that we have established that $Z\ln(2Z/A) + A/2 - Z - \ln 4 > 0$ ensures an exponentially decreasing stash overflow probability, we would like to know how tight this requirement is and what the stash size should be in practice.

We simulate Ring ORAM with $L = 20$ for over 1 Billion accesses in a random access pattern, and measure the stash occupancy (excluding the transient storage of a path). For several Z values, we look for the maximum A that results in an exponentially decreasing stash overflow

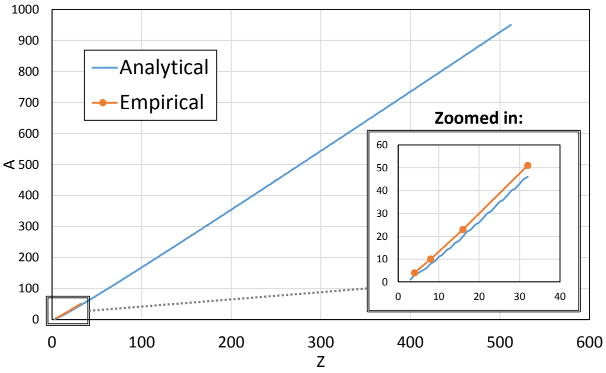

Figure 3: For each Z, determine analytically and empirically the maximum A that results in an exponentially decreasing stash failure probability.

		Z,A Parameters				
		4,3	8,8	16,20	32,46	16,23
		Max Stash Size				
λ	80	32	41	65	113	197
	128	51	62	93	155	302
	256	103	120	171	272	595

Table 3: Maximum stash occupancy for realistic security parameters (stash overflow probability $2^{-\lambda}$) and several choices of A and Z. $A = 23$ is the maximum achievable A for $Z = 16$ according to simulation.

probability. In Figure 3, we plot both the empirical curve based on simulation and the theoretical curve based on the proof. In all cases, the theoretical curve indicates a only slightly smaller A than we are able to achieve in simulation, indicating that our analysis is tight.

To determine required stash size in practice, Table 3 shows the extrapolated required stash size for a stash overflow probability of $2^{-\lambda}$ for several realistic λ. We show $Z = 16, A = 23$ for completeness: this is an aggressive setting that works for $Z = 16$ according to simulation but does not satisfy the theoretical analysis; observe that this point requires roughly 3× the stash occupancy for a given λ.

5 Bandwidth Analysis

In this section, we answer an important question: how do Z (the maximum number of real blocks per bucket), A (the eviction rate) and S (the number of extra dummies per bucket) impact Ring ORAM's performance (bandwidth)? By the end of the section, we will have a theoretically-backed analytic model that, given Z, selects optimal A and S to minimize bandwidth.

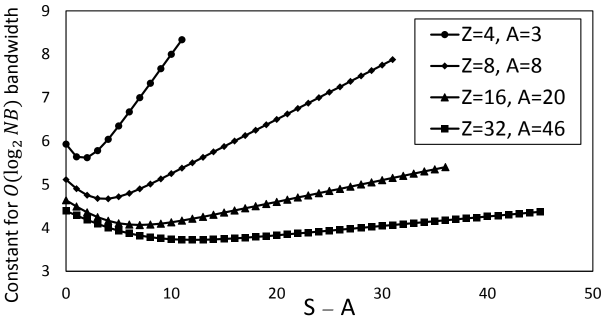

Figure 4: For different Z, and the corresponding optimal A, vary S and plot bandwidth overhead. We only consider $S \geq A$

We first state an intuitive trade-off: for a given Z, increasing A causes stash occupancy to increase and bandwidth overhead to decrease. Let us first ignore early reshuffles and the XOR technique. Then, the overall bandwidth of Ring ORAM consists of ReadPath and EvictPath. ReadPath transfers $L+1$ blocks, one from each bucket. EvictPath reads Z blocks per bucket and writes $Z+S$ blocks per bucket, $(2Z+S)(L+1)$ blocks in total, but happens every A accesses. From the requirement of Lemma 3, we have $L = \log(2N/A)$, so the ideal amortized overall bandwidth of Ring ORAM is $(1+(2Z+S)/A)\log(4N/A)$. Clearly, a larger A improves bandwidth for a given Z as it reduces both eviction frequency and tree depth L. So we simply choose the largest A that satisfies the requirement from the stash analysis in Section 4.3.

Now we consider the extra overhead from early reshuffles. We have the following trade-off in choosing S: as S increases, the early reshuffle rate decreases (since we have more dummies per bucket) but the cost to read+write buckets during an EvictPath and EarlyReshuffle increases. This effect is shown in Figure 4 through simulation: for S too small, early shuffle rate is high and bandwidth increases; for S too large, eviction bandwidth dominates.

To analytically choose a good S, we analyze the early reshuffle rate. First, notice a bucket at level l in the Ring ORAM tree will be processed by EvictPath *exactly* once for every $2^l A$ ReadPath operations, due to the reverse-lexicographic order of eviction paths (Section 3.3). Second, each ReadPath operation is to an independent and uniformly random path and thus will touch any bucket in level l with equal probability of 2^{-l}. Thus, the distribution on the expected number of times ReadPath operations touch a given bucket in level l, between two consecutive EvictPath calls, is given by a binomial distribution of $2^l A$ trials and success probability 2^{-l}. The probability that a bucket needs to be early reshuffled before an EvictPath is given by a binomial distribution cumula-

Find largest $A \leq 2Z$ such that
$Z\ln(2Z/A) + A/2 - Z - \ln 4 > 0$ holds.
Find $S \geq 0$ that minimizes
$(2Z+S)(1+\mathsf{Poiss\_cdf}(S,A))$
Ring ORAM offline bandwidth is
$\frac{(2Z+S)(1+\mathsf{Poiss\_cdf}(S,A))}{A} \cdot \log(4N/A)$

Table 4: Analytic model for choosing parameters, given Z.

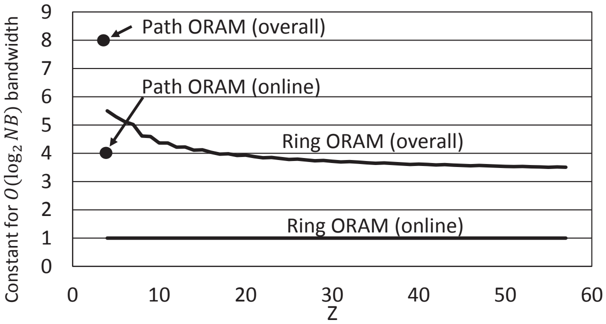

Figure 5: Overall bandwidth as a function of Z. Kinks are present in the graph because we always round A to the nearest integer. For Path ORAM, we only study $Z = 4$ since a larger Z strictly hurts bandwidth.

tive density function $\mathsf{Binom\_cdf}(S, 2^l A, 2^{-l})$.[2] Based on this analysis, the expected number of times any bucket is involved in ReadPath operations between consecutive EvictPath operations is A. Thus, we will only consider $S \geq A$ as shown in Figure 4 ($S < A$ is clearly bad as it needs too much early reshuffling).

We remark that the binomial distribution quickly converges to a Poisson distribution. So the amortized overall bandwidth, taking early reshuffles into account, can be accurately approximated as $(L+1) + (L+1)(2Z+S)/A \cdot (1 + \mathsf{Poiss\_cdf}(S,A))$. We should then choose the S that minimizes the above formula. This method always finds the optimal S and perfectly matches the overall bandwidth in our simulation in Figure 4.

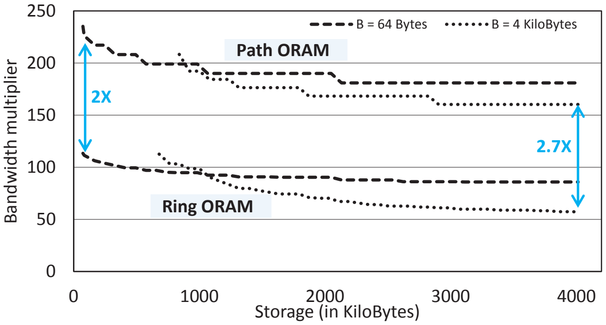

Figure 6: Bandwidth overhead vs. data block storage for 1 TB ORAM capacities and ORAM failure probability 2^{-80}.

We recap how to choose A and S for a given Z in Table 4. For the rest of the paper, we will choose A and S this way unless otherwise stated. Using this method to set A and S, we show online and overall bandwidth as a function of Z in Figure 5. In the figure, Ring ORAM does not use the XOR technique on reads. For $Z = 50$, we achieve $\sim 3.5 \log N$ bandwidth; for very large Z, bandwidth approaches $3 \log N$. Applying the XOR technique, online bandwidth overhead drops to close to 1 which reduces overall bandwidth to $\sim 2.5 \log N$ for $Z = 50$ and $2 \log N$ for very large Z.

6 Evaluation

6.1 Bandwidth vs. Client Storage

To give a holistic comparison between schemes, Figure 6 shows the best achievable bandwidth, for different client storage budgets, for Path ORAM and Ring ORAM. For each scheme in the figure, we apply all known optimizations and tune parameters to minimize overall bandwidth given a storage budget. For Path ORAM we choose $Z = 4$ (increasing Z strictly hurts bandwidth) and tree-top cache to fill remaining space. For Ring ORAM we adjust Z, A and S, tree-top cache and apply the XOR technique.

To simplify the presentation, "client storage" includes all ORAM data structures except for the position map – which has the same space/bandwidth cost for both Path ORAM and Ring ORAM. We remark that applying the recursion technique (Section 3.7) to get a small on-chip position map is cheap for reasonably large blocks. For example, recursing the on-chip position map down to 256 KiloBytes of space when the data block size is 4 KiloBytes increases overall bandwidth for Ring ORAM and Path ORAM by $< 3\%$.

The high order bit is that across different block sizes and client storage budgets, Ring ORAM consistently reduces overall bandwidth relative to Path ORAM by 2-2.7×. We give a summary of these results for several representative client storage budgets in Table 5. We remark that for smaller block sizes, Ring ORAM's improvement over Path ORAM ($\sim 2\times$ for 64 Byte blocks) is smaller relative to when we use larger blocks ($2.7\times$ for 4 KiloByte blocks). The reason is that with small blocks, the cost to read bucket metadata cannot be ignored, forcing Ring ORAM to use smaller Z.

[2] The possibility that a bucket needs to be early reshuffled twice before an eviction is negligible.

		Online, Overall Bandwidth overhead		
Block Size (Bytes)	Z, A (Ring ORAM only)	**Ring ORAM**	**Ring ORAM (XOR)**	Path ORAM
64	$10, 11$	$48\times, 144\times$	$24\times, 118\times$	$120\times, 240\times$
4096	$33, 48$	$20\times, 82\times$	$\sim 1\times, 60\times$	$80\times, 160\times$

Table 5: Breakdown between online and offline bandwidth given a client storage budget of 1000× the block size for several representative points (Section 6.1). Overheads are relative to an insecure system. Parameter meaning is given in Table 2.

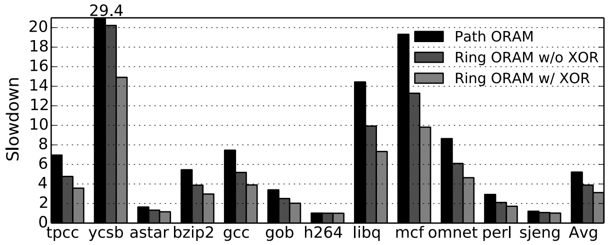

Figure 7: SPEC benchmark slowdown.

6.2 Case Study: Secure Processors

In this study, we show how Ring ORAM improves the performance of secure processors over Path ORAM. We assume the same processor/cache architecture as [5], given in Table 4 of that work. We evaluate a 4 GigaByte ORAM with 64-Byte block size (matching a typical processor's cache line size). Due to the small block size, we parameterize Ring ORAM at $Z = 5, A = 5, X = 2$ to reduce metadata overhead. We use the optimized ORAM recursion techniques [22]: we apply recursion three times with 32-Byte position map block size and get a 256 KB final position map. We evaluate performance for SPEC-int benchmarks and two database benchmarks, and simulate 3 billion instructions for each benchmark. We assume a flat 50-cycle DRAM latency, and compute ORAM latency assuming 128 bits/cycle processor-memory bandwidth. We do not use tree-top caching since it proportionally benefits both Ring ORAM and Path ORAM. Today's DRAM DIMMs cannot perform any computation, but it is not hard to imagine having simple XOR logic either inside memory, or connected to $O(\log N)$ parallel DIMMs so as not to occupy processor-memory bandwidth. Thus, we show results with and without the XOR technique.

Figure 7 shows program slowdown over an insecure DRAM. The high order bit is that using Ring ORAM with XOR results in a geometric average slowdown of 2.8× relative to an insecure system. This is a 1.5× improvement over Path ORAM. If XOR is not available, the slowdown over an insecure system is 3.2×.

We have also repeated the experiment with the unified ORAM recursion technique and its parameters [5]. The geometric average slowdown over an insecure system is 2.4× (2.5× without XOR).

7 Ring ORAM with Large Client Storage

If given a large client storage budget, we can first choose very large A and Z for Ring ORAM, which means bandwidth approaches $2\log N$ (Section 5).[3] Then remaining client storage can be used to tree-top cache (Section 3.6). For example, tree-top caching $t = L/2$ levels requires $O(\sqrt{N})$ storage and bandwidth drops by a factor of 2 to $1 \cdot \log N$—which roughly matches the SSS construction [25].

Burst ORAM [3] extends the SSS construction to handle millions of accesses in a short period, followed by a relatively long idle time where there are few requests. The idea to adapt Ring ORAM to handle bursts is to delay multiple (potentially millions of) EvictPath operations until after the burst of requests. Unfortunately, this strategy means we will experience a much higher early reshuffle rate in levels towards the root. The solution is to coordinate tree-top caching with delayed evictions: For a given tree-top size t, we allow at most 2^t delayed EvictPath operations. This ensures that for levels $\geq t$, the early reshuffle rate matches our analysis in Section 5. We experimentally compared this methodology to the dataset used by Burst ORAM and verified that it gives comparable performance to that work.

8 Related Work

ORAM was first proposed by Goldreich and Ostrovsky [10, 11]. Since then, there have been numerous follow-up works that significantly improved ORAM's efficiency in the past three decades [21, 20, 2, 1, 29, 12, 13, 15, 25, 23, 9, 27, 28]. We have already reviewed two state-of-the-art schemes with different client storage requirements: Path ORAM [27] and the SSS ORAM [25]. Circuit ORAM [28] is another recent tree-based ORAM, which requires only $O(1)$ client storage, but its bandwidth is a constant factor worse than Path ORAM.

Reducing online bandwidth. Two recent works [3, 19] have made efforts to reduce online bandwidth (response time). Unfortunately, the techniques in Burst ORAM [3] do not work with Path ORAM (or more generally any existing tree-based ORAMs). On the

[3] We assume the XOR technique because large client storage implies a file server setting.

other hand, Path-PIR [19], while featuring a tree-based ORAM, employs heavy primitives like Private Information Retrieval (PIR) or even FHE, and thus requires a significant amount of server computation. In comparison, our techniques efficiently achieve $O(1)$ online cost for tree-based ORAMs without resorting to PIR/FHE, and also improve bursty workload performance similar to Burst ORAM.

Subsequent work. Techniques proposed in this paper have been adopted by subsequent works. For example, Tiny ORAM [6] and Onion ORAM [4] used part of our eviction strategy in their design for different purposes.

9 Conclusion

This paper proposes Ring ORAM, the most bandwidth-efficient ORAM scheme for the small (constant or polylog) client storage setting. Ring ORAM is simple, flexible and backed by a tight theoretic analysis.

Ring ORAM is the first tree-based ORAM whose online and overall bandwidth are independent of tree ORAM bucket size. With this and additional properties of the algorithm, we show that Ring ORAM improves online bandwidth by 60× (if simple computation such as XOR is available at memory), and overall bandwidth by 2.3× to 4× relative to Path ORAM. In a secure processor case study, we show that Ring ORAM's bandwidth improvement translates to an overall program performance improvement of 1.5×. By increasing Ring ORAM's client storage, Ring ORAM is competitive in the cloud storage setting as well.

A Bucket Structure

Table 6 lists all the fields in a Ring ORAM bucket and their size. We would like to make two remarks. First, only the data fields are permuted and that permutation is stored in ptrs. Other bucket fields do not need to be permuted because when they are needed, they will be read in their entirety. Second, count and valids are stored in plaintext. There is no need to encrypt them since the server can see which bucket is accessed (deducing count for each bucket), and which slot is accessed in each bucket (deducing valids for each bucket). In fact, if the server can do computation and is trusted to follow the protocol faithfully, the client can let the server update count and valids. All the other structures should be probabilistically encrypted.

Algorithm 5 Helper functions.

```
count, valids, addrs, leaves, ptrs, data are fields of the
input bucket in each of the following three functions

function GetBlockOffset(bucket, $a$)
    read in valids, addrs, ptrs
    decrypt addrs, ptrs
    for $j \leftarrow 0$ to $Z-1$ do
        if $a =$ addrs[$j$] and valids[ptrs[$j$]] then
            return ptrs[$j$]                ▷ block of interest
    return a pointer to a random valid dummy

function ReadBucket(bucket)
    read in valids, addrs, leaves, ptrs
    decrypt addrs, leaves, ptrs
    $z \leftarrow 0$            ▷ track # of remaining real blocks
    for $j \leftarrow 0$ to $Z-1$ do
        if valids[ptrs[$j$]] then
            data$'$ $\leftarrow$ read and decrypt data[ptrs[$j$]]
            $z \leftarrow z+1$
            if addrs[$j$] $\neq \perp$ then
                block $\leftarrow$ (addr[$j$], leaf[$j$], data$'$)
                Stash $\leftarrow$ Stash $\cup$ block
    for $j \leftarrow z$ to $Z-1$ do
        read a random valid dummy

function WriteBucket(bucket, Stash)
    find up to $Z$ blocks from Stash that can reside
    in this bucket, to form addrs, leaves, data$'$
    ptrs $\leftarrow$ PRP($0, Z+S$)              ▷ or truly random
    for $j \leftarrow 0$ to $Z-1$ do
        data[ptrs[$j$]] $\leftarrow$ data$'$[$j$]
    valids $\leftarrow \{1\}^{Z+S}$
    count $\leftarrow 0$
    encrypt addrs, leaves, ptrs, data
    write out count, valids, addrs, leaves, ptrs, data
```

Having defined the bucket structure, we can be more specific about some of the operations in earlier sections. For example, in Algorithm 2 Line 5 means reading $\mathcal{P}(l,i)$.data[offset], and Line 6 means setting $\mathcal{P}(l,i)$.valids[offset] to 0.

Now we describe the helper functions in detail. GetBlockOffset reads in the valids, addrs, ptrs field, and looks for the block of interest. If it finds the block of interest, meaning that the address of a still valid block matches the block of interest, it returns the permuted location of that block (stored in ptrs). If it does not find the block of interest, it returns the permuted location of a random valid dummy block.

Notation	Size (bits)	Meaning
count	$\log(S)$	# of times this bucket has been touched by ReadPath since it was last shuffled
valids	$(Z+S)*1$	Indicates whether each of the $Z+S$ blocks is valid
addrs	$Z*\log(N)$	Address for each of the Z (potentially) real blocks
leaves	$Z*L$	Leaf label for each of the Z (potentially) real blocks
ptrs	$Z*\log(Z+S)$	Offset in the bucket for each of the Z (potentially) real blocks
data	$(Z+S)*B$	Data field for each of the $Z+S$ blocks, **permuted** according to ptrs
EncSeed	λ (security parameter)	Encryption seed for the bucket; count and valids are stored in the clear

Table 6: Ring ORAM bucket format. All logs are taken to their ceiling.

ReadBucket reads all of the remaining real blocks in a bucket into the stash. For security reasons, ReadBucket always reads *exactly* Z blocks from that bucket. If the bucket contains less than Z valid real blocks, the remaining blocks read out are random valid dummy blocks. Importantly, since we allow at most S reads to each bucket before reshuffling it, it is guaranteed that there are at least Z valid (real + dummy) blocks left that have not been touched since the last reshuffle.

WriteBucket evicts as many blocks as possible (up to Z) from the stash to a certain bucket. If there are $z' \leq Z$ real blocks to be evicted to that bucket, $Z+S-z'$ dummy blocks are added. The $Z+S$ blocks are then randomly shuffled based on either a truly random permutation or a Pseudo Random Permutation (PRP). The permutation is stored in the bucket field ptrs. Then, the function resets count to 0 and all valid bits to 1, since this bucket has just been reshuffled and no blocks have been touched. Finally, the permuted data field along with its metadata are encrypted (except count and valids) and written out to the bucket.

B Proof of the Lemmas

To prove Lemma 1, we made a little change to the Ring ORAM algorithm. In Ring ORAM, a ReadPath operation adds the block of interest to the stash and replaces it with a dummy block in the tree. Instead of making the block of interest in the tree dummy, we turn it into a *stale* block. On an EvictPath operation to path l, all the stale blocks that are mapped to leaf l are turned into dummy blocks. Stale blocks are treated as real blocks in both $\mathsf{ORAM}_L^{Z,A}$ and $\mathsf{ORAM}_L^{\infty,A}$ (including G_Z) until they are turned into dummy blocks. Note that this trick of stale blocks is only to make the proof go through. It hurts the stash occupancy and we will not use it in practice. With the stale block trick, we can use induction to prove Lemma 1.

Proof of Lemma 1. Initially, the lemma obviously holds. Suppose $G_{\mathcal{S}_Z}(\mathcal{S}_\infty) = \mathcal{S}_Z$ after some accesses. We need to show that $G_{\mathcal{S}'_Z}(\mathcal{S}_\infty) = \mathcal{S}'_Z$ where $\mathcal{S}'_Z$ and $\mathcal{S}'_\infty$ are the states after the next operation (either ReadPath or EvictPath). A ReadPath operation adds a block to the stash (the root bucket) for both $\mathsf{ORAM}_L^{Z,A}$ and $\mathsf{ORAM}_L^{\infty,A}$, and does not move any blocks in the tree except turning a real block into a stale block. Since stale blocks are treated as real blocks, $G_{\mathcal{S}'_Z}(\mathcal{S}_\infty) = \mathcal{S}'_Z$ holds.

Now we show the induction holds for an EvictPath operation. Let EP_l^Z be an EvictPath operation to $\mathcal{P}(l)$ (path l) in $\mathsf{ORAM}_L^{Z,A}$ and EP_l^∞ be an EvictPath operation to $\mathcal{P}(l)$ in $\mathsf{ORAM}_L^{\infty,A}$. Then, $\mathcal{S}'_Z = \mathsf{EP}_l^Z(\mathcal{S}_Z)$ and $\mathcal{S}'_\infty = \mathsf{EP}_l^\infty(\mathcal{S}_\infty)$. Note that EP_l^Z has the same effect as EP_l^∞ followed by post-processing, so

$$\begin{aligned}\mathcal{S}'_Z = \mathsf{EP}_l^Z(\mathcal{S}_Z) &= G_{\mathcal{S}'_Z}(\mathsf{EP}_l^\infty(\mathcal{S}_Z)) \\ &= G_{\mathcal{S}'_Z}(\mathsf{EP}_l^\infty(G_{\mathcal{S}_Z}(\mathcal{S}_\infty)))\end{aligned}$$

The last equation is due to the induction hypothesis.

It remains to show that

$$G_{\mathcal{S}'_Z}(\mathsf{EP}_l^\infty(G_{\mathcal{S}_Z}(\mathcal{S}_\infty))) = G_{\mathcal{S}'_Z}(\mathsf{EP}_l^\infty(\mathcal{S}_\infty)),$$

which is $G_{\mathcal{S}'_Z}(\mathcal{S}'_\infty)$. To show this, we decompose G into steps for each bucket, i.e., $G_{\mathcal{S}_Z}(\mathcal{S}_\infty) = g_1 g_2 \cdots g_{2^{L+1}}(\mathcal{S}_\infty)$ where g_i processes bucket b_i^∞ in reference to b_i^Z. Similarly, we decompose $G_{\mathcal{S}'_Z}$ into $g'_1 g'_2 \cdots g'_{2^{L+1}}$ where each g'_i processes bucket $b_i'^\infty$ of $\mathcal{S}'_\infty$ in reference to $b_i'^Z$ of $\mathcal{S}'_Z$. We now only need to show that for any $0 < i < 2^{L+1}$, $G_{\mathcal{S}'_Z}(\mathsf{EP}_l^\infty(g_1 g_2 \cdots g_i(\mathcal{S}_\infty))) = G_{\mathcal{S}'_Z}(\mathsf{EP}_l^\infty(g_1 g_2 \cdots g_{i-1}(\mathcal{S}_\infty)))$. This is obvious if we consider the following three cases separately:

1. If $b_i \in \mathcal{P}(l)$, then g_i before EP_l^∞ has no effect since EP_l^∞ moves all blocks on $\mathcal{P}(l)$ into the stash before evicting them to $\mathcal{P}(l)$.
2. If $b_i \notin \mathcal{P}(l)$ and $b_{i/2} \notin \mathcal{P}(l)$ (neither b_i nor its parent is on Path l), then g_i and EP_l^∞ touch non-overlapping buckets and do not interfere with each other. Hence, their order can be swapped, $G_{\mathcal{S}'_Z}(\mathsf{EP}_l^\infty(g_0 g_1 g_2 \cdots g_i(\mathcal{S}_\infty))) = G_{\mathcal{S}'_Z} g_i(\mathsf{EP}_l^\infty(g_0 g_1 g_2 \cdots g_{i-1}(\mathcal{S}_\infty)))$. Furthermore,

$b_i^Z = b_i'^Z$ (since EP_l^∞ does not change the content of b_i), so g_i has the same effect as g_i' and can be merged into $G_{\mathcal{S}_Z'}$.

3. If $b_i \notin \mathcal{P}(l)$ but $b_{i/2} \in \mathcal{P}(l)$, the blocks moved into $b_{i/2}$ by g_i will stay in $b_{i/2}$ after EP_l^∞ since $b_{i/2}$ is the highest intersection (towards the leaf) that these blocks can go to. So g_i can be swapped with EP_l^∞ and can be merged into $G_{\mathcal{S}_Z'}$ as in the second case.

We remind the readers that because we only remove stale blocks that are mapped to $\mathcal{P}(l)$, the first case is the only case where some stale blocks in b_i may turn into dummy blocks. And the same set of stale blocks are removed from $\mathsf{ORAM}_L^{Z,A}$ and $\mathsf{ORAM}_L^{\infty,A}$.

This shows

$$\begin{aligned} G_{\mathcal{S}_Z'}\left(\mathsf{EP}_l^\infty\left(G_{\mathcal{S}_Z}\left(\mathcal{S}_\infty\right)\right)\right) &= G_{\mathcal{S}_Z'}\left(\mathsf{EP}_l^\infty\left(\mathcal{S}_\infty\right)\right) \\ &= G_{\mathcal{S}_Z'}\left(\mathcal{S}_\infty'\right) \end{aligned}$$

and completes the proof. □

The proof of Lemma 2 remains unchanged from the Path ORAM paper [27], and is replicated here for completeness.

Proof of Lemma 2. If part: Suppose $T \in \mathsf{ORAM}_L^{\infty,A}$ and $X(T) > c(T) + R$. Observe that G can assign the blocks in a bucket only to an ancestor bucket. Since T can store at most $c(T)$ blocks, more than R blocks must be assigned to the stash by G.

Only if part: Suppose that $\mathsf{st}\left(G_{\mathcal{S}_Z}\left(\mathcal{S}_\infty\right)\right) > R$. Let T be the maximal rooted subtree such that all the buckets in T contain exactly Z blocks after post-processing G. Suppose b is a bucket not in T. By the maximality of T, there is an ancestor (not necessarily proper ancestor) bucket b' of b that contains less than Z blocks after post-processing, which implies that no block from b can go to the stash. Hence, all blocks that are in the stash must have originated from T. Therefore, it follows that $X(T) > c(T) + R$. □

Proof of Lemma 3. For a bucket b in $\mathsf{ORAM}_L^{\infty,A}$, define $Y(b)$ to be the number of blocks in b before post-processing. It suffices to prove that $\forall b \in \mathsf{ORAM}_L^{\infty,A}$, $E[Y(b)] \leq A/2$.

If b is a leaf bucket, the blocks in it are put there by the last EvictPath operation to that leaf/path. Note that only real blocks could be put in b by that operation, although some of them may have turned into stale blocks. Stale blocks can never be moved into a leaf by an EvictPath operation, because that EvictPath operation would remove all the stale blocks mapped to that leaf. There are at most N distinct real blocks and each block has a probability of 2^{-L} to be mapped to b independently. Thus $E[Y(b)] \leq N \cdot 2^{-L} \leq A/2$.

If b is not a leaf bucket, we define two variables m_1 and m_2: the last EvictPath operation to b's left child is the m_1-th EvictPath operation, and the last EvictPath operation to b's right child is the m_2-th EvictPath operation. Without loss of generality, assume $m_1 < m_2$. We then time-stamp the blocks as follows. When a block is accessed and remapped, it gets time stamp m^*, which is the number of EvictPath operations that have happened. Blocks with $m^* \leq m_1$ will not be in b as they will go to either the left child or the right child of b. Blocks with $m^* > m_2$ will not be in b as the last access to b (m_2-th) has already passed. Therefore, only blocks with time stamp $m_1 < m^* \leq m_2$ will be put in b by the m_2-th access. (Some of them may be accessed again after the m_2-th access and become stale, but this does not affect the total number of blocks in b as stale blocks are treated as real blocks.) There are at most $d = A|m_1 - m_2|$ such blocks, and each goes to b independently with a probability of $2^{-(i+1)}$, where i is the level of b. The deterministic nature of evictions in Ring ORAM ensures $|m_1 - m_2| = 2^i$. (One way to see this is that a bucket b at level i will be written every 2^i EvictPath operations, and two consecutive EvictPath operations to b always travel down the two different children of b.) Therefore, $E[Y(b)] \leq d \cdot 2^{-(i+1)} = A/2$ for any non-leaf bucket as well. □

Raccoon: Closing Digital Side-Channels through Obfuscated Execution

Abstract

Side-channel attacks monitor some aspect of a computer system's behavior to infer the values of secret data. Numerous side-channels have been exploited, including those that monitor caches, the branch predictor, and the memory address bus. This paper presents a method of defending against a broad class of side-channel attacks, which we refer to as *digital side-channel attacks*. The key idea is to obfuscate the program at the source code level to provide the illusion that many extraneous program paths are executed. This paper describes the technical issues involved in using this idea to provide confidentiality while minimizing execution overhead. We argue about the correctness and security of our compiler transformations and demonstrate that our transformations are safe in the context of a modern processor. Our empirical evaluation shows that our solution is 8.9× faster than prior work (GhostRider [20]) that specifically defends against memory trace-based side-channel attacks.

1 Introduction

It is difficult to keep secrets during program execution. Even with powerful encryption, the values of secret variables can be inferred through various side-channels, which are mechanisms for observing the program's execution at the level of the operating system, the instruction set architecture, or the physical hardware. Side-channel attacks have been used to break AES [26] and RSA [27] encryption schemes, to break the Diffie-Hellman key exchange [15], to fingerprint software libraries [46], and to reverse-engineer commercial processors [18].

```
function SQUARE_AND_MULTIPLY($m, s, n$)
    $z \leftarrow 1$
    for bit $b$ in $s$ from left to right do
        if $b = 1$ then
            $z \leftarrow m \cdot z^2 \bmod n$
        else
            $z \leftarrow z^2 \bmod n$
        end if
    end for
return $z$
end function
```

Figure 1: Source code to compute $m^s \bmod n$.

To understand side-channel attacks, consider the pseudocode in Figure 1, which is found in old implementations of both the encryption and decryption steps of RSA, DSA, and other cryptographic systems. In this function, s is the secret key, but because the Taken branch is computationally more expensive than the Not Taken branch, an adversary who can measure the time it takes to execute an iteration of the loop can infer whether the branch was Taken or Not Taken, thereby inferring the value of s one bit at a time [31, 5]. This particular block of code has also been attacked using side-channels involving the cache [44], power [16], fault injection [3, 41], branch predictor [1], electromagnetic radiation [11], and sound [32].

Over the past five decades, numerous solutions [20, 30, 21, 42, 35, 22, 40, 14, 43, 37, 39, 38, 23, 45, 25, 34, 9, 33, 10] have been proposed for defending against side-channel attacks. Unfortunately, these defenses provide point solutions that leave the program open to other side-channel attacks. Given the vast number of possible side-channels, and given the high overhead that comes from composing multiple solutions, we ideally would find a single solution that simultaneously closes a broad class of side-channels.

In this paper, we introduce a technique that does just this, as we focus on the class of *digital side-channels*, which we define as side-channels that carry information over discrete bits. These side-channels are visible to the adversary at the level of both the program state and the instruction set architecture (ISA). Thus, address traces, cache usage, and data size are examples of digital side-channels, while power draw, electromagnetic radiation, and heat are not.

Our key insight is that *all* digital side-channels emerge from variations in program execution, so while other solutions attempt to hide the symptoms—for example, by normalizing the number of instructions along two paths of a branch—we instead attack the root cause by executing extraneous program paths, which we refer to as *decoy* paths. Intuitively, after obfuscation, the adversary's view through any digital side-channel appears the same as if the program were run many times with different inputs. Of course, we must ensure that our system records the output of only the real path and not the decoy paths, so our solution uses a transaction-like system to update memory. On the real paths, each `store` operation first reads the old value of a memory location before writing the new value, while the decoy paths read the old value and write the same old value.

The only distinction between real and decoy paths lies in the values written to memory: Decoy and real paths will write different values, but unless an adversary can break the data encryption, she cannot distinguish decoy from real paths by monitoring digital side-channels. Our solution does *not* defend against non-digital side-channel attacks, because analog side-channels might reveal the difference between the encrypted values that are stored. For example, a decoy path might "increment" some variable x multiple times, and an adversary who can precisely monitor some non-digital side-channel, such as power-draw, might be able to detect that the "increments" to x all write the same value, thereby revealing that the code belongs to a decoy path.

Nevertheless, our new approach offers several advantages. First, it defends against almost all digital side-channel attacks.[1] Second, it does not require that the programs themselves be secret, just the data. Third, it obviates the need for special-purpose hardware. Thus, standard processor features such as caches, branch predictors and prefetchers do not need to be disabled. Finally, in contrast with previous solutions for hiding specific side channels, it places few fundamental restrictions on the set of supported language features.

This paper makes the following contributions:

1. We design a set of mechanisms, embodied in a system that we call Raccoon,[2] that closes digital side-channels for programs executing on commodity hardware. Raccoon works for both single- and multi-threaded programs.

2. We evaluate the security aspects of these mechanisms in several ways. First, we argue that the obfuscated data- and control-flows are correct and are always kept secret. Second, we use information flows over inference rules to argue that Raccoon's own code does not leak information. Third, as an example of Raccoon's defense, we show that Raccoon protects against a simple but powerful side-channel attack through the OS interface.

3. We evaluate the performance overhead of Raccoon and find that its overhead is 8.9× smaller than that of GhostRider, which is the most similar prior work [20].[3] Unlike GhostRider, Raccoon defends against a broad range of side-channel attacks and places many fewer restrictions on the programming language, on the set of applicable compiler optimizations, and on the underlying hardware.

This paper is organized as follows. Section 2 describes background and related work, and Section 3 describes our assumed threat model. We then describe our solution in detail in Section 4 before presenting our security evaluation and our performance evaluation in Sections 5 and 6, respectively. We discuss the implications of Raccoon's design in Section 7, and we conclude in Section 8.

2 Background and Related Work

Side-channel attacks through the OS, the underlying hardware, or the processor's output pins have been a subject of vigorous research. Formulated as the "confinement problem" by Lampson in 1973 [19], such attacks have become relevant for cloud infrastructures where the adversary and victim VMs can be co-resident [29] and also for settings where adversaries have physical access to the processor-DRAM interface [46, 22].

Side-Channels through OS and Microarchitecture. Some application-level information leaks are beyond the application's control, for example, an adversary reading a victim's secrets through the `/proc` filesystem [13], or a victim's floating point registers that are not cleared on a context switch [2]. In addition to such *explicit* information leaks, *implicit* flows rely on *contention* for shared resources, as observed by Wang and Lee [39] for cache channels and extended by Hunger et al. [37] to all microarchitectural channels.

Defenses against such attacks either partition resources [40, 14, 43, 37], add noise [39, 38, 23, 45], or

[1] Section 3 (Threat Model) clarifies the specific side-channels closed by our approach.

[2] Raccoons are known for their clever ability to break their scent trails to elude predators. Raccoons introduce spurious paths as they climb and descend trees, jump into water, and create loops.

[3] GhostRider [20] was evaluated with non-optimized programs executing on embedded CPUs, which results in an unrealistically low overhead (∼10×). Our measurements instead use a modern CPU with an aggressively optimized binary as the baseline.

normalize the channel [17, 20] to curb side-channel capacity. Raccoon's defenses complement prior work that modifies the hardware and/or OS. Molnar et al. [25] describe a transformation that prevents control-flow side-channel attacks, but their approach does not apply to programs that contain function calls and it does not protect against data-flow-based side-channel attacks.

Physical Access Attacks and Secure Processors. Execute-only Memory (XOM) [36] encrypts portions of memory to prevent the adversary from reading secret data or instructions from memory. The AEGIS [35] secure processor provides the notion of tamper-evident execution (recognizing integrity violations using a merkle tree) and tamper-resistant computing (preventing an adversary from learning secret data using memory encryption). Intel's Software Guard Extensions (SGX) [24] create "enclaves" in memory and limit accesses to these enclaves. Both XOM and SGX are only partially successful in prevent the adversary from accessing code because an adversary can still disassemble the program binary that is stored on the disk. In contrast, Raccoon permits release of the transformed code to the adversary. Hence Raccoon never needs to encrypt code memory.

Oblivious RAM. AEGIS, XOM, and Intel SGX do not prevent information leakage via memory address traces. Memory address traces can be protected using Oblivious RAM, which re-encrypts and re-shuffles data after each memory access. The Path ORAM algorithm [34] is a tree-based ORAM scheme that adds two secret on-chip data structures, the *stash* and *position map*, to piggyback multiple writes to the in-memory data structure. While Raccoon uses a modified version of the Path ORAM algorithm, the specific ORAM implementation is orthogonal to the Raccoon design.

The Ascend [9] secure processor encrypts memory contents and uses the ORAM construct to hide memory access traces. Similarly, Phantom [22] implements ORAM to hide memory access traces. Phantom's memory controller leverages parallelism in DRAM banks to reduce overhead of ORAM accesses. However, both Phantom and Ascend assume that the adversary can only access code by reading the contents of memory. By contrast, Raccoon hides memory access traces via control flow obfuscation and software ORAM while still permitting the adversary to read the code. Ascend and Phantom rely on custom memory controllers whereas Memory Trace Oblivious systems that build on Phantom [20] rely on a new, deterministic processor pipeline. In contrast, Raccoon protects off-chip data on commodity hardware.

Memory Trace Obliviousness. GhostRider [20, 21] is a set of compiler and hardware modifications that transforms programs to satisfy Memory Trace Obliviousness (MTO). MTO hides control flow by transforming programs to ensure that the memory access traces are the same no matter which control flow path is taken by the program. GhostRider's transformation uses a type system to check whether the program is fit for transformation and to identify security-sensitive program values. It also pads execution paths along both sides of a branch so that the length of the execution does not reveal the branch predicate value.

However, unlike Raccoon, GhostRider cannot execute on generally-available processors and software environments because GhostRider makes strict assumptions about the underlying hardware and the user's program. Specifically, GhostRider (1) requires the use of new instructions to load and store data blocks, (2) requires substantial on-chip storage, (3) disallows the use of dynamic branch prediction, (4) assumes in-order execution, and (5) does not permit use of the hardware cache (it instead uses a scratchpad memory controlled by the compiler). GhostRider also does not permit the user code to contain pointers or to contain function calls that use or return secret information. By contrast, Raccoon runs on SGX-enabled Intel processors (SGX is required to encrypt values on the data bus) and permits user programs to contain pointers, permits the use of possibly unsafe arithmetic statements, and allows the use of function calls that use or return secret information.

3 Threat Model and System Guarantees

This section describes our assumptions about the underlying hardware and software, along with Raccoon's obfuscation guarantees.

Hardware Assumptions. We assume that the adversary can monitor and tamper with any digital signals on the processor's I/O pins. We also assume that the processor is a sealed chip [35], that all off-chip resources (including DRAM, disks, and network devices) are untrusted, that all read and written values are encrypted, and that the integrity of all reads and writes is checked.

Software Assumptions. We assume that the adversary can run malicious applications on the same operating system and/or hardware as the victim's application. We allow malicious applications to probe the victim application's run-time statistics exposed by the operating system (*e.g.* the stack pointer in `/proc/pid/stat`). However, we assume that the operating system is trusted, so Iago attacks [7] are out of scope.

The Raccoon design assumes that the input program is free of errors, *i.e.* (1) the program does not contain bugs that will induce application crashes, (2) the program does not exhibit undefined behavior, and (3) if multi-threaded, then the program is data-race free. Under these assumptions, Raccoon does not introduce new termination-channel leaks, and Raccoon correctly obfuscates multi-threaded programs.

Raccoon statically transforms the user code into an obfuscated binary; we assume that the adversary has access to this transformed binary code and to any symbol table and debug information that may be present.

In its current implementation, Raccoon does not support all features of the C99 standard. Specifically, Raccoon cannot obfuscate I/O statements[4] and non-local `goto` statements. While `break` and `continue` statements do not present a fundamental challenge to Raccoon, our current implementation does not obfuscate these statements. Raccoon cannot analyze libraries since their source code is not available when compiling the end-user's application.

As with related solutions [30, 20, 21], Raccoon does not protect information leaks from loop trip counts, since naïvely obfuscating loop back-edges would create infinite loops. For the same reason, Raccoon does not obfuscate branches that represent terminal cases of recursive function calls. However, to address these issues, it is possible to adapt complementary techniques designed to close timing channels [42], which can limit information leaks from loop trip counts and recursive function calls.

Raccoon includes static analyses that check if the input program contains these unsupported language constructs. If such constructs are found in the input program, the program is rejected.

System Guarantees. Within the constraints listed above, Raccoon protects against all digital side-channel attacks. Raccoon guarantees that an adversary monitoring the digital signals of the processor chip cannot differentiate between the real path execution and the decoy path executions. Even after executing multiple decoy program paths, Raccoon guarantees the same final program output as the original program.

Raccoon guarantees that its obfuscation steps will not introduce new program bugs or crashes, so Raccoon does not introduce new information leaks over the termination channel.

Assuming that the original program is race-free, Raccoon's code transformations respect the original program's control and data dependences. Moreover, Raccoon's obfuscation code uses thread-local storage. Thus, Raccoon's obfuscation technique works seamlessly with multi-threaded applications because it does not introduce new data dependences.

```
1: $p \leftarrow \&a$;
2: if $secret$ = true then
3:     ...                                   ▷ Real path.
4: else
5:     ...                                   ▷ Decoy path.
6:     $p \leftarrow \&b$;        ▷ Dummy instructions do not update $\boldsymbol{p}$.
7:     $*p \leftarrow 10$;          ▷ Accesses variable $\boldsymbol{a}$ instead of $\boldsymbol{b}$!
8: end if
```

Figure 2: Illustrating the importance of Property 2. This code fragment shows how solutions that do not update memory along decoy paths may leak information. If the decoy path is not allowed to update memory, then the dereferenced pointer in line 7 will access $\boldsymbol{a}$ instead of accessing $\boldsymbol{b}$, which reveals that the statement was part of a decoy path.

4 Raccoon Design

This section describes the design and implementation of Raccoon from the bottom-up. We start by describing the two critical properties of Raccoon that distinguish it from other obfuscation techniques. Then, after describing the key building block upon which higher-level oblivious operations are built, we describe each of Raccoon's individual components: (1) a taint analysis that identifies program statements that require obfuscation (Section 4.3), (2) a runtime transaction-like memory mechanism for buffering intermediate results along decoy paths (Section 4.4), (3) a program transformation that obfuscates control-flow statements (Section 4.5), and (4) a code transformation that uses software Path ORAM to hide array accesses that depend on secrets (Section 4.6). We then describe Raccoon's program transformations that ensure crash-free execution (Section 4.7). Finally, we illustrate with a simple example the synergy among Raccoon's various obfuscation steps (Section 4.8).

4.1 Key Properties of Our Solution

Two key properties of Raccoon distinguish it from other branch-obfuscating solutions [20, 21, 25, 8]:

- **Property 1:** Both real and decoy paths execute actual program instructions.
- **Property 2:** Both real and decoy paths are allowed to update memory.

Property 1 produces decoy paths that—from the perspective of an adversary monitoring a digital side-channel—are indistinguishable from from real paths.

[4] Various solutions have been proposed that allow limited use of "transactional" I/O statements through runtime systems [6], operating systems [28], or the underlying hardware [4].

Without this property, previous solutions can close one side-channel while leaving other side-channels open. To understand this point, we refer back to Figure 1 and consider a solution that normalizes execution time along the two branch paths in the Figure by adding NOP instructions to the Not Taken path. This solution closes the timing channel but introduces different instruction counts along the two branch paths. On the other hand, the addition of dummy instructions to normalize instruction counts will likely result in different execution time along the two branch paths, since (on commodity hardware) the NOP instructions will have a different execution latency than the multiply instruction.

Property 2 is a special case of Property 1, but we include it because the ability to update memory is critical to Raccoon's ability to obfuscate execution. For example, Figure 2 shows that if the decoy path does not update the pointer ***p***, then the subsequent decoy statement will update ***a*** instead of ***b***, revealing that the assignment to ****p*** was part of a decoy path.

4.2 Oblivious Store Operation

Raccoon's key building block is the oblivious store operation, which we implement using the CMOV x86 instruction. This instruction accepts a condition code, a source operand, and a destination operand; if the condition is true, it moves the source operand to the destination. When both the source and the destination operands are in registers, the execution of this instruction does not reveal information about the branch predicate (hence the name *oblivious* store operation).[5] As we describe shortly, many components in Raccoon leverage the oblivious store operation. Figure 3 shows the x86 assembly code for the CMOV wrapper function.

4.3 Taint Analysis

Raccoon requires the user to annotate secret variables using the __attribute__ construct. With these secret variables identified, Raccoon performs inter-procedural taint analysis to identify branches and data access statements that require obfuscation. Raccoon propagates taint across both implicit and explicit flow edges. The result of the taint analysis is a list of memory accesses and branch statements that must be obfuscated to protect privacy.

```
cmov(uint8_t pred, uint32_t t_val, uint32_t f_val) {
    uint32_t result;
    __asm__ volatile (
        "mov    %2, %0;"
        "test   %1, %1;"
        "cmovz  %3, %0;"
        "test   %2, %2;"
        : "=r" (result)
        : "r" (pred), "r" (t_val), "r" (f_val)
        : "cc"
    );
    return result;
}
```

Figure 3: CMOV wrapper

4.4 Transaction Management

To support Properties 1 and 2, Raccoon executes each branch of an obfuscated if-statement in a transaction. In particular, Raccoon buffers load and store operations along each path of an if-statement, and Raccoon writes values along the real path to DRAM using the oblivious store operation. If a decoy path tries to write a value to the DRAM, Raccoon uses the oblivious store operation to read the existing value and write it back. At compile time, Raccoon transforms load and store operations so that they will be serviced from the transaction buffers. Figure 4 shows pseudocode that implements transactional loads and stores. Loads and stores that appear in non-obfuscated code do not use the transaction buffers.

4.5 Control-Flow Obfuscation

To obfuscate control flow, Raccoon forces control flow along both paths of an obfuscated branch, which requires three key facilities: (1) a method of perturbing the branch outcome, (2) a method of bringing execution control back from the end of the if-statement to the start of the if-statement so that execution can follow along the unexplored path, and (3) a method of ensuring that memory updates along decoy path(s) do not alter non-transactional memory. The first facility is implemented by the obfuscate() function (which forces sequential execution of both paths arising out of a conditional branch instruction). Although Raccoon executes both branch paths, it evaluates the (secret) branch predicate only once. This ensures that the execution of the first path does not unexpectedly change the value of the branch predicate. The second facility is implemented by the epilog() function (which transfers control-flow from the post-dominator of the if-statement to the beginning of the if-statement). Finally the third facility is implemented using the oblivious store operation described earlier. The control-flow obfuscation functions

[5] Contrary to the pseudocode describing the CMOV instruction in the Intel 64 Architecture Software Developer's Manual, our assembly code tests reveal that in 64-bit operating mode when the operand size is 16-bit or 32-bit, the instruction resets the upper 32 bits regardless of whether the predicate is true. Thus the instruction does not leak the value of the predicate via the upper 32 bits, as one might assume based on the manual.

```
// Writes a value to the transaction buffer.
tx_write(address, value) {
    if (threaded program)
        lock();

    // Write to both the transaction buffer
    // and to the non-transactional storage.
    tls->gl_buffer[address] = value;
    *address = cmov(real_idx == instance,
            value, *address);

    if (threaded program)
        unlock();
}

// Fetches a value from the transaction buffer.
tx_read(address) {
    if (threaded program)
        lock();

    value = *address;
    if (address in tls->gl_buffer)
        value = tls->gl_buffer[address];

    value = cmov(real_idx == instance,
            *address, value);

    if (threaded program)
        unlock();

    return value;
}
```

Figure 4: Pseudocode for transaction buffer accesses. Equality checks are implemented using XOR operation to prevent the compiler from introducing an explicit branch instruction.

(obfuscate() and epilog()) use the libc setjmp() and longjmp() functions to transfer control between program points.

Safety of setjmp() and longjmp() Operations. The use of setjmp() and longjmp() is safe as long as the runtime system does not destroy the activation record of the caller of setjmp() prior to calling longjmp(). Thus, the function that invokes setjmp() should not return until longjmp() is invoked. To work around this limitation, Raccoon copies the stack contents along with the register state (identified by the jmp_buff structure) and restores the stack before calling longjmp(). To avoid perturbing the stack while manipulating the stack, Raccoon manipulates the stack using C macros and global variables.

As an additional safety requirement, the runtime system must not remove the code segment containing the call to setjmp() from instruction memory before the call to longjmp(). Because both obfuscate()—which calls setjmp()—and epilog()—which calls longjmp()—are present in the same program module, we know that that the code segment will not vanish before calling longjmp().

Obfuscating Nested Branches. Nested branches are obfuscated in Raccoon by maintaining a stack of transaction buffers that mimics the nesting of transactions. Unlike traditional transactions, transactions in Raccoon are easier to nest because Raccoon can determine whether to commit the results or to store them temporarily in the transaction buffer *at the beginning of the transaction* (based on the secret value of the branch predicate).

4.6 Software Path ORAM

Raccoon's implementation of the Path ORAM algorithm builds on the oblivious store operation. Since processors such as the Intel x86 do not have a trusted memory (other than a handful of registers) for implementing the *stash*, we modify the Path ORAM algorithm from its original form [34]. Raccoon's Path ORAM implementation cannot directly index into arrays that represent the *position map* or the *stash*, so Raccoon's implementation streams over the *position map* and *stash* arrays and uses the oblivious store operation to selectively read or update array elements. Raccoon implements both recursive [33] as well as non-recursive versions of Path ORAM. Our software implementation of Path ORAM permits flexible sizes for both the *stash memory* and the *position map*.

Section 6.3 compares recursive and non-recursive ORAM implementations with an implementation that streams over the entire data array. Raccoon uses AVX vector intrinsic operations for streaming over data arrays. We find that even with large data sizes, it is faster to stream over the array than perform a single ORAM access.

4.7 Limiting Termination Channel Leaks

By executing instructions along decoy paths, Raccoon might operate on incorrect values. For example, consider the statement if (y != 0) { z = x / y; }. If $y = 0$ for a particular execution and if Raccoon executes the decoy path with $y = 0$, then the program will crash due to a division-by-zero error, and the occurrence of this crash in an otherwise bug-free program would reveal that the program was executing a decoy path (and, consequently, that $y = 0$).

To avoid such situations, Raccoon prevents the program from terminating abnormally due to exceptions. For each integer division that appears in a transaction (along both real and decoy paths), Raccoon instruments the operation so that it obliviously (using cmov) replaces

```
/* Sample user code. */
01: int array[512] __attribute__((annotate ("secret")));
02: if (array[mid] <= x) {
03:     l = mid;
04: } else {
05:     r = mid;
06: }

/* Transformed pseudocode. */
07: r1 = stream_load(array, mid);
08: r2 = r1 <= x;
09: key = obfuscate(r2, r3);

10: if (r3) {
11:     tx_write(l, mid);
12: } else {
13:     tx_write(r, mid);
14: }

15: epilog(key);
```

Figure 5: Sample code and transformed pseudocode.

the divisor with a non-zero value. To prevent integer division overflow, Raccoon checks whether the dividend is equal to INT_MIN and whether the divisor is equal to -1; if so, Raccoon obliviously substitutes the divisor to prevent a division overflow. Raccoon also disables floating point exceptions using `fedisableexcept()`. Similarly, array `load` and `store` operations appearing on the decoy path are checked (again, obliviously, using `cmov`) for out-of-bounds accesses. Thus, to ensure that the execution of decoy paths does not crash the program, Raccoon patches unsafe operations. Section 5.3 demonstrates that this process of patching unsafe operations does not leak secret information to the adversary.

4.8 Putting It All Together

We now explain how Raccoon transforms the code shown in Figure 5. Here, the `secret` annotation informs Raccoon that the contents of `array` are secret.

Static taint analysis then reveals that the branch predicate (line 2) depends on the secret value, so Raccoon obfuscates this branch. Similarly, implicit flow edges from the branch predicate to the two assignment statements (at lines 3 and 5) indicate that Raccoon should use the oblivious `store` operation for both assignment statements.

Accordingly, Raccoon replaces direct memory stores for `l` and `r` with function calls that write into transaction buffers in lines 11 and 13 of the transformed pseudocode. The access to `array` in line 1 is replaced by an oblivious streaming operation in line 7. Finally, the branch in line 2 is obfuscated by inserting the `obfuscate()` and `epilog()` function calls. The `epilog()` and `obfuscate()` function calls are coordinated over the `key` variable. To prevent the compiler from deleting or optimizing security-sensitive code sections, Raccoon marks security-sensitive functions, variables, and memory access operations as `volatile` (not shown in the transformed IR).[6]

At runtime, the transformed code executes the following steps:

1. Line 7 streams over the array and uses ORAM to load a single element (identified by `mid`) of the array.

2. Line 8 calculates the actual value of the branch predicate.

3. The key to this obfuscation lies in the `epilog()` function on line 15, which forces the transformed code to execute twice. The first time this function is called, it transfers control back to line 9. The second time this function is called, it simply returns, and program execution proceeds to other statements in the user's code.

4. Line 9 obfuscates the branch outcome. The first time the `obfuscate()` function returns, it stores 0 in `r3`, and control is transferred to the statement at line 13, where the `tx_write()` function call updates the transaction buffer. Non-transactional memory is updated only if this path corresponds to the real path.

   The second time the `obfuscate()` function returns, it stores 1 in `r3`, and control is transferred to the statement at line 11, again calling the `tx_write()` function to update the transaction buffer. Again, non-transactional memory is updated only if this path corresponds to the real path.

5 Security Evaluation

In this section, we first demonstrate that the control-flows and data-flows in obfuscated programs are correct and that they are independent of the secret value. Then, using type-rules that track information flows, we argue that Raccoon's own code does not leak secret information. We then illustrate Raccoon's defenses against termination channels by reasoning about exceptions in x86 processors. Finally, we evaluate Raccoon's ability to prevent side-channel attacks via the `/proc` filesystem.

5.1 Security of Obfuscated Code

In this section, we argue that the obfuscated control-flows and data-flows (1) preserve the original program's

[6] The C99 standard states that any "any expression referring to [a volatile object] shall be evaluated *strictly* according to the rules of the abstract machine", and the abstract machine is defined in a manner that considers that "issues of optimization are irrelevant".

dependences and (2) do not reveal any secret information. We only describe scalar loads and stores, since all array-loads and array-stores are obfuscated by simply streaming over the array. To simplify the explanation, the following arguments describe a top-level (*i.e.* a non-nested) branch. The same arguments can be extended to nested branches by maintaining a stack of transaction buffers.

Correctness of Obfuscated Data-Flow. To ensure correct data-flow, Raccoon uses a combination of transaction buffers and non-transactional storage (*i.e.* main memory). Raccoon sets up a fresh transaction buffer for each thread that executes a new path. Figure 4 shows the implementation of buffered `load` and `store` operations for use with transactions. The `store` operations along real paths write to both transaction buffers and non-transactional storage (since threads cannot share data that is stored in thread-local transaction buffers).

Consider a non-obfuscated program that stores a value to a memory location *m* in line 10 and loads a value from the same location in line 20. We now consider four possible arrangements of these two `load` and `store` operations in the obfuscated program, where each operation may reside either inside or outside a transaction. Our goal is to ensure that the `load` operation always reads the correct value, whether the correct value resides in a transactional buffer or in non-transactional storage.

- **`store` outside transaction, `load` inside transaction:** This implies that there is no `store` operation on *m* within the transaction. Thus, the transaction buffer does not contain an entry for *m*, and the `load` operation reads the value from the non-transactional storage.

- **`store` inside transaction, `load` inside transaction:** Since the transaction has previously written to *m*, the transaction buffer contains an entry for *m*, and the `load` operation fetches the value from the transaction buffer.

- **`store` inside transaction, `load` outside transaction:** This implies that the `store` operation must lie along the real path. Real-path execution updates non-transactional storage. Since `load` operations outside of transactions always fetch from non-transactional storage, the `load` operation reads the correct value of *m*.

- **`store` outside transaction, `load` outside transaction:** Raccoon does not change `load` or `store` operations that are located outside of the transactions. Hence the non-obfuscated reaching definition remains unperturbed.

Raccoon correctly obfuscates multi-threaded code as well. In programs obfuscated by Raccoon, decoy paths only update transactional buffers. Thus, only the `store` operations on real path affect reaching definitions of the obfuscated program. Furthermore, `store` (or `load`) operations along real path immediately update (or fetch) non-transactional storage and do not wait until the transaction execution ends. Thus, memory updates from execution of real paths are immediately visible to all threads, ensuring that inter-thread dependences are not masked by transactional execution. Finally, all transactional `load` and `store` operations use locks to ensure that these accesses are atomic. Put together, `load` and `store` operations on real paths are atomic and globally-visible, whereas `store` operations on decoy paths are only locally-visible and get discarded upon transaction termination. We thus conclude that the obfuscated code maintains correct data-flows for both single- and multi-threaded programs.

Concealing Obfuscated Data-Flow. Raccoon always performs two `store` operations for every transactional write operation, regardless of whether the write operation belongs to a real path or a decoy path. Moreover, by leveraging the oblivious `store` operation, Raccoon hides the specific value written to the transactional buffer or to the non-transactional storage. Although the `tx_read()` function uses an `if`-statement, the predicate of the `if`-statement is not secret, since an adversary can simply inspect the code and differentiate between repeated and first-time memory accesses. Thus, we conclude that the data-flows exposed to the adversary do not leak secret information.

Concealing Obfuscated Control-Flow. Raccoon converts control flow that depends on secret values into static (*i.e.* deterministically repeatable) control-flow that does not depend on secret values. Given a conditional branch instruction and two branch targets in the LLVM Intermediate Representation (IR), Raccoon always forces execution along the first target and then the second target. Thus, the sequence of executed branch targets depends on the (static) encoding of the branch instruction and not on the secret predicate.

5.2 Security of Obfuscation Code

Raccoon's own code should never leak secret information, so in this section, we demonstrate the security of the secret information maintained by Raccoon. Because the Raccoon code exposes only a handful of APIs (Table 1) to user applications, we can perform a detailed analysis of the code's entry- and exit-points to ensure that these

$$\text{T-LOAD}\quad \frac{l_r(p) = \mathsf{L}, A = pts(p), m = \max_{a \in A} l_a(a)}{\langle x = \mathbf{load} p; c, l_a, l_r\rangle \rightarrow \langle c, l_a, l_r[x \mapsto m]\rangle}$$

$$\text{T-STORE}\quad \frac{l_r(p) = \mathsf{L}, A = pts(p)}{\langle \mathbf{store}(x,p); c, l_a, l_r\rangle \rightarrow \langle c, \bigcup_{a \in A} l_a[a \mapsto max(l_a(a), l_r(x)), l_r]\rangle}$$

$$\text{T-BINOP}\quad \frac{}{\langle v = \textbf{binary-op}(x,y); c, l_a, l_r\rangle \rightarrow \langle c, l_a, l_r[v \mapsto \mathbf{max}(l_r(x), l_r(y))]\rangle}$$

$$\text{T-UNOP}\quad \frac{}{\langle v = \textbf{unary-op}(x); c, l_a, l_r\rangle \rightarrow \langle c, l_a, l_r[v \mapsto l_r(x)]\rangle}$$

$$\text{T-BRANCH}\quad \frac{l_r(p) = \mathsf{L}, \langle c_t; c, l_a, l_r\rangle \rightarrow \langle c, l_a', l_r'\rangle, \langle c_f; c, l_a, l_r\rangle \rightarrow \langle c, l_a'', l_r''\rangle}{\langle \mathbf{branch}(p, c_t, c_f); c, l_a, l_r\rangle \rightarrow \langle c, M(l_a', l_a''), M(l_r', l_r'')\rangle}$$

$$\text{T-CMOV}\quad \frac{}{\langle v = \mathbf{cmov}(p,t,f); c, l_a, l_r\rangle \rightarrow \langle c, l_a, l_r[v \mapsto \mathsf{L}]\rangle}$$

$$\text{T-SKIP}\quad \frac{}{\langle v = \mathbf{skip}; c, l_a, l_r\rangle \rightarrow \langle c, l_a, l_r\rangle}$$

$$\text{T-SEQUENCE}\quad \frac{\langle c_0, l_a, l_r\rangle \rightarrow \langle c_0', l_a', l_r'\rangle}{\langle c_0; c_1, l_a, l_r\rangle \rightarrow \langle c_0'; c_1, l_a', l_r'\rangle}$$

$$M(l', l'') = \forall_{x \,\in\, \{K(l') \,\cup\, K(l'')\}}\ (x,\ max(l'(x), l''(x))) \qquad K(l) = \{x \mid (x,s)\ \in\ l\}$$

interfaces never spill secret information outside of Raccoon's own code.

Type System for Tracking Information Flows. Figure 6 shows a subset of the typing rules used for checking the IR of Raccoon's own code. These rules express small-step semantics that track security labels. We assume the existence of a functions $l_r : v \rightarrow \gamma$ and $l_a : \Delta \rightarrow \gamma$ that map LLVM's virtual registers (v) and addresses (Δ) to security labels (γ), respectively. Security labels can be of two types: `L` represents low-context (or public) information, while `H` represents high-context (or secret) information. Secret information listed in Table 1 is assigned the `H` security label, while all other information is assigned the `L` security label. We also assume the existence of a function $pts : r \rightarrow \{\Delta\}$ that returns the points-to set for a given virtual register r.

Our goal is to ensure that Raccoon does not leak secret information either through control-flow (`branch` instructions) or data-flow (`load` and `store` instructions). The typing rules in Figure 6 verify that information labeled as secret never appears as an address in a `load` or `store` instruction and never appears as a predicate in a `branch` instruction. Otherwise, the typing rules would result in a stuck transition. To prevent information leaks, Raccoon passes the secret information through the declassifier (`cmov`) before executing a `load`, `store`, or `branch` operation with a secret value. Due to its oblivious nature, the `cmov` operation resets the security label of its destination to `L`.

Security Evaluation of the `cmov` Operation. The tiny code size of the `cmov` operation (Figure 3) permits us to thoroughly inspect each instruction for possible information leaks. We use the Intel 64 Architecture Software Developer's Manual to understand the side-effects of each instruction.

Since the code operates on the processor registers only and never accesses memory, it operates within the (trusted) boundary of the sealed processor chip. The secret predicate is loaded into the `%1` register. The `mov` instruction in line 4 initializes the destination register with `t_val`. The `test` instruction at line 5 checks if `pred` is zero and updates the Zero flag (`ZF`), Sign flag (`SF`), and the Parity flag (`PF`) to reflect the comparison. The subsequent `cmovz` instruction copies `f_val` into the destination register *only if* `pred` is zero. At this point, `ZF`, `SF`, and `PF` still contain the results of the comparison. The `test` instruction at line 7 overwrites these flags by comparing known non-secret values.

Since none of the instructions ever accesses memory, these instructions can never raise a General Protection Fault, Page Fault, Stack Exception Fault, Segment Not Present exception, or Alignment Check exception. None of these instructions uses the `LOCK` prefix, so they will never generate an Invalid Opcode (#UD) exception. As per the Intel Software Developer's Manual, the above instructions cannot raise any other exception besides the ones listed above. Through a manual analysis of the descriptions of 253 performance events[7] supported

[7] Intel 64 and IA-32 Architectures Software Developers Manual, Section 19.5.

by our target platform, we discovered that only two performance events are directly relevant to the code in Figure 3: `PARTIAL_RAT_STALLS.FLAGS_MERGE_UOP` and `UOPS_RETIRED.ALL`. The first event (`FLAGS_MERGE_UOP`), which counts the number of performance-sensitive flags-merging micro-operations, produces the same value for our code, no matter whether the predicate is true or false. The second event (`UOPS_RETIRED.ALL`) counts the number of retired micro-operations. Since details of micro-operation counts for x86 instructions are not publicly available, we used an unofficial source of instruction tables[8] to verify that the micro-operation count for a `cmov` instruction is independent of the instruction's predicate. We thus conclude that the code in Figure 3 does not leak the secret predicate value.

Category	Interrupt list
Arithmetic errors	Division by zero, invalid operands, overflow, underflow, inexact results.
Memory access interrupts	Stack exception fault, general protection fault, page fault.
Debugging interrupts	Single-step, breakpoint.
Privileged operations	Invalid TSS, segment not present.
Coprocessor (legacy) interrupts	No coprocessor, coprocessor overrun, coprocessor error.
Other	Non-maskable interrupt, invalid opcode, double-fault abort.

Table 2: Categorized list of x86 hardware exceptions.

5.3 Termination Leaks

In Section 4.7, we explained how Raccoon patches division operations and memory access instructions to prevent the program from crashing along decoy paths. We now explain why these patches are sufficient in preventing the introduction of new termination leaks. Table 2 shows a categorized list of exception conditions arising in Intel x86 processors[9] that may terminate programs. Among these interrupts, Raccoon transparently handles arithmetic and memory access interrupts.

Debugging interrupts are irrelevant for the program safety discussion because they do not cause the program to terminate. Our threat model does not apply obfuscation to OS or kernel code. Since we do not expect user programs to contain privileged instructions, Raccoon does not need to mask interrupts from privileged operations. Coprocessor interrupts are relevant to Numeric Processor eXtensions (NPX), which are no longer used today. Non-maskable interrupts are not caused by software events and thus need not be hidden by Raccoon. Branches in Raccoon always jump to the start of valid basic blocks, so invalid opcodes can never occur in an obfuscated version of a correct program. A double-fault exception occurs when the processor encounters an exception while invoking the handler for a previous exception. Aborts due to double-fault need not be hidden by Raccoon because none of the primary exceptions in an obfuscated program will leak secret information. In conclusion, Raccoon prevents abnormal program termination, thus guaranteeing that Raccoon's execution of decoy paths will never cause information leaks over the termination channel.

5.4 Defense Against Side-Channel Attacks

We have argued in Sections 5.1 and 5.2 that Raccoon closes digital side-channels. We now show a concrete example of a simple but powerful side-channel attack, and we use basic machine-learning techniques to visually illustrate Raccoon's defense against this attack. We model the adversary as a process that observes the instruction pointer (IP) values of the victim process. Both the victim process and the adversary process run on the same machine. The `driver` process starts the `victim` process and immediately pauses the `victim` process by sending a `SIGSTOP` signal. The `driver` process then starts the `adversary` process and sends it the process ID of the paused `victim` process. This `adversary` process polls for the instruction pointer of the `victim` process every 5ms via the `kstkeip` field in `/proc/pid/stat`. When the `victim` process finishes execution, the `driver` process sends a `SIGINT` signal to the `adversary` process, signalling it to save its collection of instruction pointers to a file. We run the `victim` programs with various secret inputs and each run produces a (sampled) trace of instruction pointers. Each such trace is labelled with the name of the program and an identifier for the secret input. We collect 300 traces for each label. For the sake of brevity, we show results for only three programs from our benchmark suite.

The labelled traces are then passed through a Support Vector Machine for k-fold cross-validation (we choose $k = 10$) using LIBSVM v3.18. Using the prediction data, we construct a confusion matrix for each program, which conveys the accuracy of a classification system by counting the number of correctly-predicted and mis-predicted values (see Figure 7). The confusion matrices show that for the non-secure executions, the classifier is able to label instruction pointer traces with high accuracy. By contrast, when using traces from obfuscated execution, the classifier's accuracy is significantly lower.

6 Performance Evaluation

Methodology. Raccoon is implemented in the LLVM compiler framework v3.6. In our test setup, the host op-

erating system is CentOS 6.3. To evaluate performance, we use 15 programs (eight small kernels and seven small applications). Table 3 summarizes their characteristics and the associated input data sizes. The bottom eight programs in the table are the same programs used to evaluate GhostRider [20, 21], and we use these to compare Raccoon's overhead against that of GhostRider. To simplify the comparison between Raccoon and GhostRider, we use data sizes that are similar to those used to evaluate GhostRider [20]. Raccoon uses the `__attribute__` construct to mark secret variables—which mandates that the input programs are written in C/C++. However the rest of Raccoon operates entirely on the LLVM IR and does not use any source-language features. Thus, Raccoon can easily be ported to work with any language that can be compiled to the LLVM IR. All tests use the LLVM/Clang compiler toolchain.

We run all experiments on a machine with two Intel Xeon (Sandy Bridge) processors and with 32 GB (8 × 4 GB) DDR3 memory. Each processor has eight cores with 256 KB private L2 caches. The eight cores on a processor chip share a 20 MB L3 cache. Streaming encryption/decryption hardware makes the cost of accessing memory from encrypted RAM banks almost the same as the cost of accessing a DRAM bank. The underlying hardware does not support encrypted RAM banks, but we do not separately add any encryption-related overhead to our measurements because the streaming access cost is almost the same with or without encryption.

Performance measurements of our simulated ORAM use the native hardware performance event—`UNHALTED_CORE_CYCLES`. We measure overhead using `clock_gettime()`. Our software Path ORAM implementation is configured with a block size of 64 bytes. Each node in the Path ORAM tree stores 10 blocks. The stash size is selected at ORAM initialization time and is set to $\frac{\textit{ORAM block count}}{100}$ or 64 entries, whichever is higher.

Name	Lines	Data size
Classifier	86	5 features, 5 records
IP resolver	247	3,500 records
Medical risk analysis	92	3,200 records
CRC32	76	10 KB

Table 3: Benchmark programs used for performance evaluation of Raccoon. The bottom eight programs are also used to evaluate GhostRider. The remaining seven programs cannot be transformed by GhostRider because these programs use pointers and invoke functions in the secret context.

6.1 Obfuscation Overhead

There are two main sources of Raccoon overhead: (1) the cost of the ORAM operations (or streaming) and (2) the cost of control-flow obfuscation (including the cost of buffering transactional memory accesses, the cost of copying program stack and CPU registers, and the cost of obliviously patching arithmetic and memory access instructions). We account for ORAM/streaming overhead over both real and decoy paths. Of course, the overhead varies with program characteristics, such as size of the input data, number of obfuscated statements, and number of memory access statements. Figure 8 shows the obfuscation overhead for the benchmark programs when compared with an aggressively optimized (compiled with `-O3`) non-obfuscated binary executable. The geometric mean of the overhead is ∼16.1×. Applications closer to the left end of the spectrum had low overheads due to Raccoon's ability to leverage existing compiler optimizations (if-conversion, automatic loop unrolling, and memory to register promotion). In most applications with high obfuscation overhead, a majority of the overhead arises from transactional execution in control-flow obfuscation.

6.2 Comparison with GhostRider

To place our work in the context of similar solutions to side-channel defenses, we compare Raccoon with the

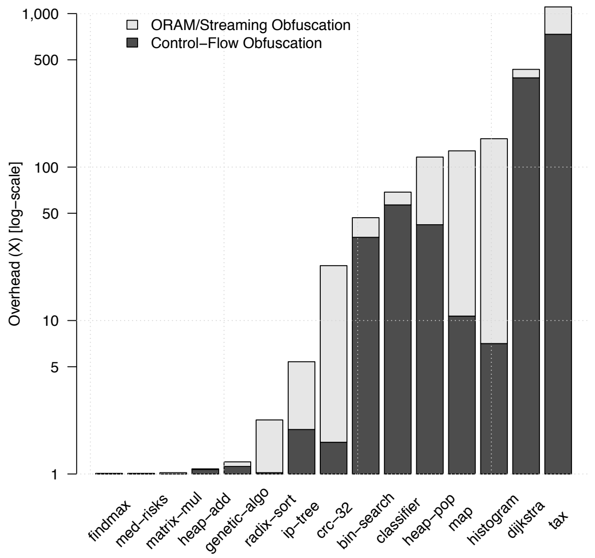

Figure 8: Sources of obfuscation overhead.

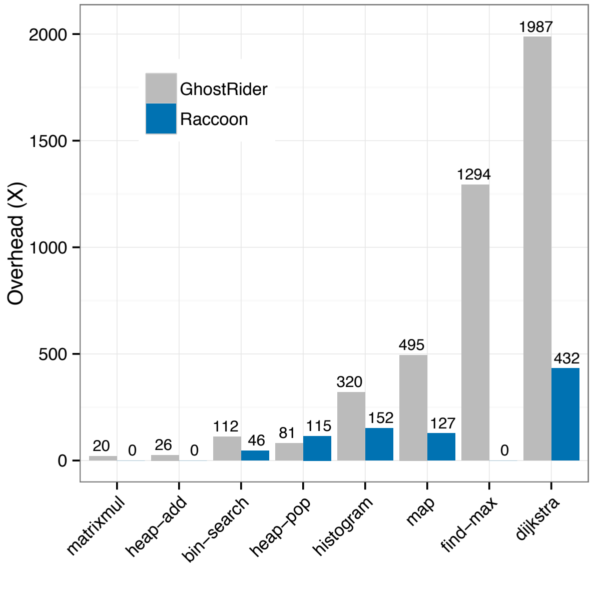

Figure 9: Overhead comparison on GhostRider's benchmarks. Even when we generously underestimate GhostRider's overhead, GhostRider sees an average overhead of 195×, while Raccoon's overhead is 21.8×.

GhostRider hardware/software framework [20, 21] that implements Memory Trace Obliviousness. This section focuses on the performance aspects of the two systems, but as mentioned in Section 2, Raccoon provides significant benefits over GhostRider beyond performance. First, Raccoon provides a broad coverage against many different side-channel attacks. Second, the dynamic obfuscation scheme used in Raccoon strengthens the threat model, since it allows the transformed code to be released to the adversary. Third, Raccoon does not require special-purpose hardware. Finally, since GhostRider adds instructions to mimic address traces in both branch paths, it requires that address traces from obfuscated code be known at compile-time, which significantly limits the programs that GhostRider can obfuscate. Raccoon relaxes this requirement by executing actual code, so Raccoon can transform more complex programs than GhostRider.

Methodology. We now describe our methodology for simulating the GhostRider solution. As with our Raccoon setup, we compare GhostRider's obfuscated program with an aggressively optimized (compiled with `-O3`) non-obfuscated version of the same program. Various compiler optimizations (dead code elimination, vectorization, constant merging, constant propagation, global value optimizations, instruction combining, loop-invariant code motion, and promotion of memory to registers) interfere with GhostRider's security guarantees, so we disable optimizations for the obfuscated program. We manually apply the transformations implemented in the GhostRider compiler. We simulate a processor that is modelled after the GhostRider processor, so we use a single-issue in-order processor that does not allow prefetching into the cache.

There are four reasons why our methodology significantly underestimates GhostRider's overhead. The first three reasons stem from our inability to faithfully simulate all features of the GhostRider processor: (1) We simulate variable-latency instructions, (2) we simulate the use of a dynamic branch predictor, and (3) we simulate a perfect cache for non-ORAM memory accesses. All three of these discrepancies give GhostRider an unrealistically fast hardware platform. The fourth reason arises because our simulator does not support AVX vector instructions, so we are unable to compare GhostRider against a machine that can execute AVX vector instructions.

The non-obfuscated execution uses a 4-issue, out-of-order core with support for Access Map Pattern Matching prefetching scheme [12] for the L1, L2 and L3 data caches. In all other respects, the two processor configurations are identical. Both processors are clocked at 1 GHz. The processor configuration closely matches the configuration described by Fletcher et al. [10], and based on their measurements, we assume that the latency to all ORAM banks is 1,488 cycles per cache line. We run GhostRider's benchmarks on this modified Marss86 simulator and manually add the cost of each ORAM access to the total program execution latency.

Performance Comparison. Figure 9 compares the overhead of GhostRider on the simulated processor and the overhead of Raccoon. Only those benchmark programs that meet GhostRider's assumptions are used in this comparison. The remaining seven applications cannot be transformed by the GhostRider solution because they use pointers or because they invoke functions in the secret context. We see that Raccoon's overhead (geometric mean of 16.1× over all 15 benchmarks, geometric mean of 21.8× over GhostRider-only benchmarks) is significantly lower than GhostRider's overhead (geometric mean of 195×), even when giving GhostRider's processor substantial benefits (perfect caching, lack of AVX-vector support in the baseline processor, and dynamic branch prediction).

6.3 Software Path ORAM

This section considers choices for Raccoon's ORAM implementation. In particular, to run on typical general-purpose processors, we need to modify the Path ORAM algorithm to assume just a tiny amount of trusted memory, which forces us to stream the *position map* and *stash* multiple times to obliviously copy or update elements.

We thus consider three possible implementations. The first, recursive ORAM [33], places the *position map* in a smaller ORAM until the *position map* of the smallest ORAM fits in the CPU registers. The second is a non-recursive solution that streams over a single large *position map*. The third uses AVX intrinsic operations and streams over the entire array to access a single element.

Figure 10(a) compares the cost of ORAM initialization for different ORAM sizes in our recursive and non-recursive ORAM implementations. On this log-log scale, we see that the non-recursive ORAM is significantly faster than the recursive ORAM for all sizes. Figure 10(b) compares our non-recursive ORAM implementation against the streaming approach. In particular, it measures the cost of accessing a single element and the cost of 64 single-element random accesses using ORAM and streaming. We see that the streaming implementation is orders of magnitude faster than our non-recursive ORAM.

In summary, our software implementation of Path ORAM requires non-trivial changes to the original Path ORAM algorithm. Unfortunately, these changes impose a prohibitively large memory bandwidth requirement, making the modified software Path ORAM far costlier than streaming over arrays. Raccoon's obfuscation technique is compatible with the use of dedicated ORAM memory controllers, and Raccoon's overhead can be further reduced by using such special purpose hardware [22].

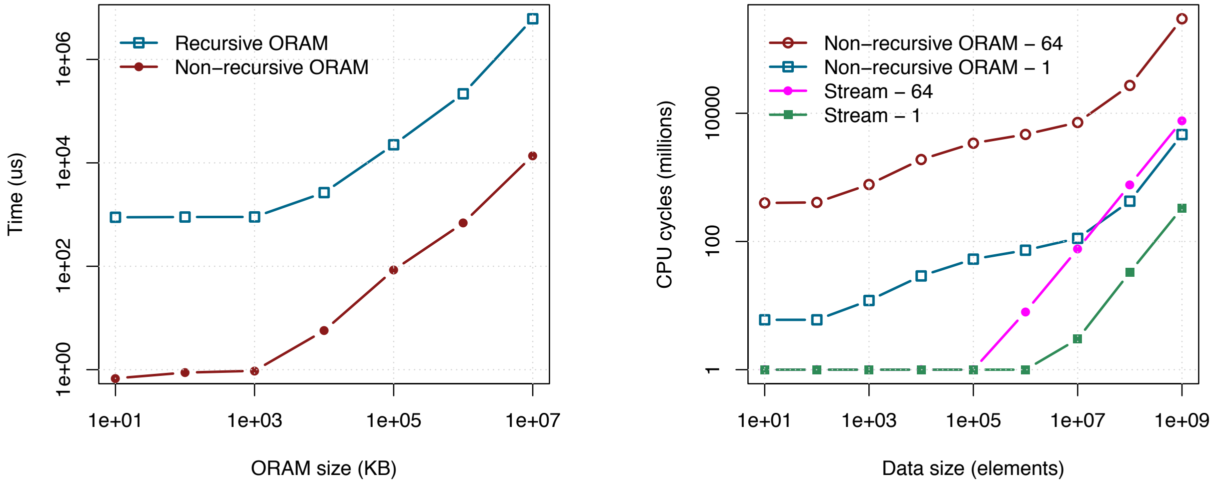
7 Discussion

Closing Other Side-Channels. The existing Raccoon implementation does not defend against kernel-space side-channel attacks. However, many of Raccoon's obfuscation principles can be applied to OS kernels as well. Memory updates in systems such as TxOS [28] can be made oblivious using Raccoon's `cmov` operation. By contrast, non-digital side-channels appear to be fundamentally beyond Raccoon's scope since physical characteristics (power, temperature, EM radiation) of hardware devices make it possible to differentiate between real values and decoy values.

Multi-threaded Programs. Raccoon's data structures are stored in thread-local storage (TLS), so Raccoon can access internal data structures without using locks. Raccoon initializes these data-structures at thread entry-points (identified by `pthread_create()`) and frees them at thread destruction-points (identified by `pthread_exit()`). Raccoon prevents race conditions on the user program's memory by using locks where necessary. Most importantly, as long as the user program is race-free, Raccoon maintains the correct data-flow dependences in both single-threaded and multi-threaded programs, as described in Section 5.1.

Taint Analysis. Raccoon's taint analysis is sound but not complete, so it over-approximates the amount of code that must be obfuscated. For large programs, this over-approximation is a significant source of overhead. Raccoon's taint analysis is flow-insensitive, path-insensitive, and context-insensitive, and Raccoon uses a rudimentary alias analysis technique that assumes two pointers alias if they have the same type. We believe that more precise static analysis techniques can be used to greatly shrink Raccoon's taint graph, thus reducing the obfuscation overhead.

Limitations Imposed by Hardware. Various x86 instructions (`DIV`, `SQRT`, etc.) consume different cycles depending on their operand values. Such operand-dependent instruction execution latency introduces the biggest hurdle in ensuring the security of Raccoon-obfuscated programs. We also believe that the performance overhead of obfuscated programs would be substantially smaller than the current overhead if processors came equipped with (small) scratchpad memory. Based on these conjectures, we plan to explore the impact of modified hardware designs in the near future.



(a) Initialization cost of recursive and non-recursive ORAM implementation (median of 10 measurements for each sample).

(b) Performance comparison of software Path ORAM and streaming over the entire array.

8 Conclusions

In this paper, we have introduced the notion of digital side-channel attacks, and we have presented a system named Raccoon to defend against such attacks. We have evaluated Raccoon's performance against 15 programs to show that its overhead is significantly less than that of the best prior work and that it has several additional benefits: it expands the threat model, it removes special-purpose hardware, it permits the release of the transformed code to the adversary, and it also expands the set of supported language features. In comparing Raccoon against GhostRider, we find that Raccoon's overhead is 8.9× lower.

Raccoon's obfuscation technique can be enhanced in several ways. First, while the performance overhead of Raccoon-obfuscated programs is high enough to preclude immediate practical deployment, we believe that this overhead can be substantially reduced by employing deterministic or special-purpose hardware. Second, Raccoon's technique of transactional execution and oblivious memory update can be applied to the operating system (OS) kernel, thus paving the way for protection against OS-based digital side-channel attacks. Finally, in addition to defending against side-channel attacks, we believe that Raccoon can be strengthened to defend against covert-channel communication.

Acknowledgments. We thank our shepherd, David Evans, and the anonymous reviewers for their helpful feedback. We also thank Casen Hunger and Akanksha Jain for their help in using machine learning techniques and microarchitectural simulators. Abstract

New big-data analysis platforms can enable distributed computation on encrypted data by utilizing trusted computing primitives available in commodity server hardware. We study techniques for ensuring privacy-preserving computation in the popular MapReduce framework. In this paper, we first show that protecting only individual units of distributed computation (e.g. map and reduce units), as proposed in recent works, leaves several important channels of information leakage exposed to the adversary. Next, we analyze a variety of design choices in achieving a stronger notion of private execution that is the analogue of using a distributed oblivious-RAM (ORAM) across the platform. We develop a simple solution which avoids using the expensive ORAM construction, and incurs only an additive logarithmic factor of overhead to the latency. We implement our solution in a system called $\mathtt{M}^2\mathtt{R}$, which enhances an existing Hadoop implementation, and evaluate it on seven standard MapReduce benchmarks. We show that it is easy to port most existing applications to $\mathtt{M}^2\mathtt{R}$ by changing fewer than 43 lines of code. $\mathtt{M}^2\mathtt{R}$ adds fewer than 500 lines of code to the TCB, which is less than 0.16% of the Hadoop codebase. $\mathtt{M}^2\mathtt{R}$ offers a factor of 1.3× to 44.6× lower overhead than extensions of previous solutions with equivalent privacy. $\mathtt{M}^2\mathtt{R}$ adds a total of 17% to 130% overhead over the insecure baseline solution that ignores the leakage channels $\mathtt{M}^2\mathtt{R}$ addresses.

1 Introduction

The threat of data theft in public and private clouds from insiders (e.g. curious administrators) is a serious concern. Encrypting data on the cloud storage is one standard technique which allows users to protect their sensitive data from such insider threats. However, once the data is encrypted, enabling computation on it poses a significant challenge. To enable privacy-preserving computation, a range of security primitives have surfaced recently, including trusted computing support for hardware-isolated computation [2, 5, 38, 40] as well as purely cryptographic techniques [20,21,47]. These primitives show promising ways for running computation securely on a single device running an untrusted software stack. For instance, *trusted computing* primitives can isolate units of computation on an untrusted cloud server. In this approach, the hardware provides a confidential and integrity-protected execution environment to which encryption keys can be made available for decrypting the data before computing on it. Previous works have successfully demonstrated how to securely execute a unit of user-defined computation on an untrusted cloud node, using support from hardware primitives available in commodity CPUs [8, 14, 38, 39, 49] .

In this paper, we study the problem of enabling privacy-preserving *distributed computation* on an untrusted cloud. A sensitive distributed computation task comprises many units of computation which are scheduled to run on a multi-node cluster (or cloud). The input and output data between units of computation are sent over channels controlled by the cloud provisioning system, which may be compromised. We assume that each computation node in the cluster is equipped with a CPU that supports trusted computing primitives (for example, TPMs or Intel SGX). Our goal is to enable a privacy-preserving execution of a distributed computation task. Consequently, we focus on designing privacy in the popular MapReduce framework [17]. However, our techniques can be applied to other distributed dataflow frameworks such as Spark [62], Dryad [26], and epiC [27].

Problem. A MapReduce computation consists of two types of units of computation, namely *map* and *reduce*, each of which takes key-value tuples as input. The MapReduce provisioning platform, for example Hadoop [1], is responsible for scheduling the map/reduce operations for the execution in a cluster and for providing a data channel between them [31]. We aim to achieve a strong level of security in the distributed execution of a MapReduce task (or job) — that is, the adversary learns nothing beyond the execution time and the number of input and output of each computation unit. If we view each unit of computation as one atomic operation of a larger distributed program, the execution can be thought of as running a set of operations on data values passed via a data channel (or a global "RAM") under the adversary's control. That is, our definition of privacy is analogous to the strong level of privacy offered by the well-known oblivious RAM protocol in the monolithic processor case [22].

We assume that the MapReduce provisioning platform is compromised, say running malware on all nodes in the cluster. Our starting point in developing a defense is a baseline system which runs each unit of computation (map/reduce instance) in a hardware-isolated process, as proposed in recent systems [49, 59]. Inputs and outputs of each computation unit are encrypted, thus the adversary observes only encrypted data. While this baseline offers a good starting point, merely encrypting data in-transit between units of computation is not sufficient (see Section 3). For instance, the adversary can observe the pattern of data reads/writes between units. As another example, the adversary can learn the synchronization between map and reduce units due to the scheduling structure of the provisioning platform. Further, the adversary has the ability to duplicate computation, or tamper with the routing of encrypted data to observe variations in the execution of the program.

Challenges. There are several challenges in building a practical system that achieves our model of privacy. First, to execute map or reduce operations on a single computation node, one could run all computation units — including the entire MapReduce platform — in an execution environment that is protected by use of existing trusted computing primitives. However, such a solution would entail little trust given the large TCB, besides being unwieldy to implement. For instance, a standard implementation of the Hadoop stack is over 190K lines of code. The scope of exploit from vulnerabilities in such a TCB is large. Therefore, the first challenge is to enable practical privacy by minimizing the increase in platform TCB and without requiring any algorithmic changes to the original application.

The second challenge is in balancing the needs of privacy and performance. Addressing the leakage channels discussed above using generic methods easily yields a solution with poor practical efficiency. For instance, hiding data read/write patterns between specific map and reduce operations could be achieved by a generic oblivious RAM (ORAM) solution [22, 55]. However, such a solution would introduce a slowdown proportional to polylog in the size of the intermediate data exchange, which could degrade performance by over 100× when gigabytes of data are processed.

Our Approach. We make two observations that enable us to achieve our model of privacy in a MapReduce implementation. First, on a single node, most of the MapReduce codebase can stay outside of the TCB (i.e. code performing I/O and scheduling related tasks). Thus, we design four new components that integrate readily to the existing MapReduce infrastructure. These components which amount to fewer than 500 lines of code are the only pieces of trusted logic that need to be in the TCB, and are run in a protected environment on each computation node. Second, MapReduce computation (and computation in distributed dataflow frameworks in general) has a specific structure of data exchange and execution between map and reduce operations; that is, the map writes the data completely before it is consumed by the reduce. Exploiting this structure, we design a component called *secure shuffler* which achieves the desired security but is much less expensive than a generic ORAM solution, adding only a $O(\log N)$ additive term to the latency, where N is the size of the data.

Results. We have implemented a system called $\mathtt{M}^2\mathtt{R}$ based on Hadoop [1]. We ported 7 applications from a popular big-data benchmarks [25] and evaluated them on a cluster. The results confirm three findings. First, porting MapReduce jobs to $\mathtt{M}^2\mathtt{R}$ requires small development effort: changing less than 45 lines of code. Second, our solution offers a factor of $1.3\times$ to $44.6\times$ (median $11.2\times$) reduction in overhead compared to the existing solutions with equivalent privacy, and a total of $17\% - 130\%$ of overhead over the baseline solution which protects against none of the attacks we focus on in this paper. Our overhead is moderately high, but $\mathtt{M}^2\mathtt{R}$ has high compatibility and is usable with high-sensitivity big data analysis tasks (e.g. in medical, social or financial data analytics). Third, the design is scalable and adds a TCB of less than 0.16% of the original Hadoop codebase.

Contributions. In summary, our work makes three key contributions:

- *Privacy-preserving distributed computation.* We define a new pragmatic level of privacy which can be achieved in the MapReduce framework requiring no algorithmic restructuring of applications.
- *Attacks.* We show that merely encrypting data in enclaved execution (with hardware primitives) is insecure, leading to significant privacy loss.
- *Practical Design.* We design a simple, non-intrusive architectural change to MapReduce. We implement it in a real Hadoop implementation and benchmark its performance cost for privacy-sensitive applications.

2 The Problem

Our goal is to enable privacy-preserving computation for distributed dataflow frameworks. Our current design and

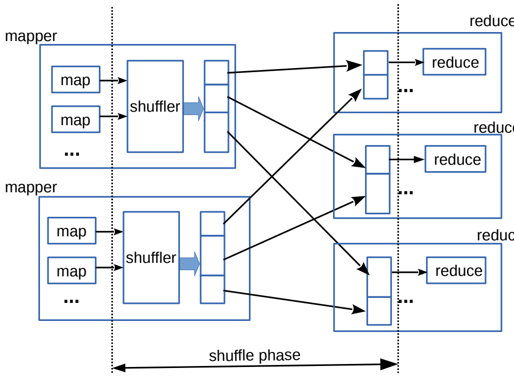

Figure 1: The MapReduce computation model.

implementation are specific to MapReduce framework, the computation structure of which is nevertheless similar to other distributed dataflow engines [26, 27, 62], differing mainly in supported operations.

Background on MapReduce. The MapReduce language enforces a strict structure: the computation task is split into map and reduce operations. Each instance of a map or reduce, called a *computation unit* (or unit), takes a list of key-value tuples[1]. A MapReduce task consists of sequential phases of map and reduce operations. Once the map step is finished, the intermediate tuples are grouped by their key-components. This process of grouping is known as *shuffling*. All tuples belonging to one group are processed by a reduce instance which expects to receive tuples sorted by their key-component. Outputs of the reduce step can be used as inputs for the map step in the next phase, creating a chained MapReduce task. Figure 1 shows the dataflow from the map to the reduce operations via the shuffling step. In the actual implementation, the provisioning of all map units on one cluster node is locally handled by a *mapper* process, and similarly, by a *reducer* process for reduce units.

2.1 Threat Model

The adversary is a malicious insider in the cloud, aiming to subvert the confidentiality of the client's computation running on the MapReduce platform. We assume that the adversary has complete access to the network and storage back-end of the infrastructure and can tamper with the persistent storage or network traffic. For each computation node in the cluster, we assume that the adversary can corrupt the entire software stack, say by installing malware.

We consider an adversary that perpetrates both passive and active attacks. A passive or *honest-but-curious* attacker passively observes the computation session, behaving honestly in relaying data between computation units, but aims to infer sensitive information from the observed data. This is a pragmatic model which includes adversaries that observe data backed up periodically on disk for archival, or have access to performance monitoring interfaces. An active or *malicious* attacker (e.g. an installed malware) can deviate arbitrarily from the expected behavior and tamper with any data under its control. Our work considers both such attacks.

There are at least two direct attacks that an adversary can mount on a MapReduce computation session. First, the adversary can observe data passing between computation units. If the data is left unencrypted, this leads to a direct breach in confidentiality. Second, the adversary can subvert the computation of each map/reduce instance by tampering with its execution. To address these basic threats, we start with a baseline system described below.

Baseline System. We consider the *baseline system* in which each computation unit is hardware-isolated and executed privately. We assume that the baseline system guarantees that the program can only be invoked on its entire input dataset, or else it aborts in its first map phase. Data blocks entering and exiting a computation unit are encrypted with authenticated encryption, and all side-channels from each computation unit are assumed to be masked [51]. Intermediate data is decrypted only in a hardware-attested computation unit, which has limited memory to securely process up to T inputs tuples. Systems achieving this baseline have been previously proposed, based on differing underlying hardware mechanisms. VC^3 is a recent system built on Intel SGX [49].

Note that in this baseline system, the MapReduce provisioning platform is responsible for invoking various trusted units of computation in hardware-isolated processes, passing encrypted data between them. In Section 3, we explain why this baseline system leaks significant information, and subsequently define a stronger privacy objective.

2.2 Problem Definition

Ideally, the distributed execution of the MapReduce program should leak nothing to the adversary, except the total size of the input, total size of the output and the running time. The aforementioned baseline system fails to achieve the ideal privacy. It leaks two types of information: (a) the input and output size, and processing time of individual computation unit, and (b) dataflow among the computation units.

We stress that the leakage of (b) is significant in many applications since it reveals relationships among the input. For instance, in the well-known example of computing Pagerank scores for an encrypted graph [44], flows from a computation unit to another correspond to edges

[1] To avoid confusion of the tuple key with cryptographic key, we refer to the first component in the tuple as *key-component*.

in the input graph. Hence, leaking the dataflow essentially reveals the whole graph edge-structure!

Techniques for hiding or reducing the leakage in (a) by padding the input/output size and introducing timing delays are known [35, 41]. Such measures can often require algorithmic redesign of the application [9] or use of specialized programming languages or hardware [33,34], and can lead to large overheads for applications where the worst case running time is significantly larger than the average case. We leave incorporating these orthogonal defenses out-of-scope.

Instead, in this work, we advocate focusing on eliminating leakage on (b), while providing a formulation that clearly captures the information that might be revealed. We formulate the admissible leakage as Ψ which captures the information (a) mentioned above, namely the input/output size and running time of each trusted computation unit invoked in the system. We formalize this intuition by defining the execution as a protocol between trusted components and the adversary, and define our privacy goal as achieving *privacy modulo-*Ψ.

Execution Protocol. Consider an honest execution of a program on input $I = \langle x_1, x_2, \ldots, x_n \rangle$. For a given map-reduce phase, let there be n map computation units. Let us label the map computation units such that the unit with label i takes x_i as input. Recall that the tuples generated by the map computation units are to be shuffled, and divided into groups according to the key-components. Let K to be the set of unique key-components and let $\pi : [n+1, n+m] \rightarrow K$ be a randomly chosen permutation, where $m = |K|$. Next, m reduce computation units are to be invoked. We label them starting from $n+1$, such that the computation unit i takes tuples with key-component $\pi(i)$ as input.

Let I_i, O_i, T_i be the respective input size (measured by number of tuples), output size, and processing time of the computation unit i, and call $\Psi_i = \langle I_i, O_i, T_i \rangle$ the *IO-profile* of computation unit i. The profile Ψ of the entire execution on input I is the sequence of Ψ_i for all computation units $i \in [1, \ldots, n+m]$ in the execution protocol. If an adversary $\widetilde{\mathscr{A}}$ can initiate the above protocol and observe Ψ, we say that the adversary has access to Ψ.

Now, let us consider the execution of the program on the same input $I = \langle x_1, x_2, \ldots, x_n \rangle$ under a MapReduce provisioning protocol by an adversary $\mathscr{A}$. A semi-honest adversary $\mathscr{A}$ can obtain information on the value of the input, output and processing time of every trusted instance, including information on trusted instances other than the map and reduce computation units. If the adversary is malicious, it can further tamper with the inputs and invocations of the instances. In the protocol, the adversary controls 6 parameters:

(C1) the start time of each computation instance,
(C2) the end time of each instance,
(C3) the encrypted tuples passed to its inputs,
(C4) the number of computation instances,
(C5) order of computation units executed,
(C6) the total number of map-reduce phases executed.

Since the adversary $\mathscr{A}$ can obtain "more" information and tamper the execution, a question to ask is, can the adversary $\mathscr{A}$ gain more knowledge compared to an adversary $\widetilde{\mathscr{A}}$ who only has access to Ψ? Using the standard notions of indistinguishability[2] and adversaries [28], we define a secure protocol as follows:

Definition 1 (**Privacy modulo-Ψ**). *A provisioning protocol for a program is modulo-Ψ private if, for any adversary $\mathscr{A}$ executing the MapReduce protocol, there is a adversary $\widetilde{\mathscr{A}}$ with access only to Ψ, such that the output of $\mathscr{A}$ and $\widetilde{\mathscr{A}}$ are indistinguishable.*

The definition states that the output of the adversaries can be directly seen as deduction made on the information available. The fact that all adversaries have output indistinguishable from the one which knows Ψ suggests that no additional information can be gained by any $\mathscr{A}$ beyond that implied by knowledge of Ψ.

Remarks. First, our definition follows the scenario proposed by Canneti [11], which facilitates universal composition. Hence, if a protocol is private module-Ψ for one map-reduce phase, then an entire sequence of phases executed is private module-Ψ. Note that our proposed M^{2}R consists of a sequence of map, shuffle, and reduce phases where each phase starts only after the previous phase has completed, and the chain of MapReduce jobs are carried out sequentially. Thus, universal composition can be applied. Second, we point out that if the developer restructures the original computation to make the IO-profile the same for all inputs, then Ψ leaks nothing about the input. Therefore, the developer can consider using orthogonal techniques to mask timing latencies [41], hiding trace paths and IO patterns [34] to achieve ideal privacy, if the performance considerations permit so.

2.3 Assumptions

In this work, we make specific assumptions about the baseline system we build upon. First, we assume that the underlying hardware sufficiently protects each computation unit from malware and snooping attacks. The range of threats that are protected against varies based on the underlying trusted computing hardware. For instance,

[2] non-negligible advantage in a distinguishing game

traditional TPMs protect against software-only attacks but not against physical access to RAM via attacks such as cold-boot [24]. More recent trusted computing primitives, such as Intel SGX [40], encrypt physical memory and therefore offer stronger protection against adversaries with direct physical access. Therefore, we do not focus on the specifics of how to protect each computation unit, as it is likely to change with varying hardware platform used in deployment. In fact, our design can be implemented in any virtualization-assisted isolation that protects user-level processes on a malicious guest OS [12, 52, 57], before Intel SGX becomes available on the market.

Second, an important assumption we make is that of information leakage via side-channels (e.g. cache latencies, power) from a computation unit is minimal. Indeed, it is a valid concern and an area of active research. Both software and hardware-based solutions are emerging, but they are orthogonal to our techniques [18, 29].

Finally, to enable arbitrary computation on encrypted data, decryption keys need to be made made available to each hardware-isolated computation unit. This provisioning of client's keys to the cloud requires a set of trusted administrator interfaces and privileged software. We assume that such trusted key provisioning exists, as is shown in recent work [49, 65].

3 Attacks

In this section, we explain why a baseline system that merely encrypts the output of each computation unit leaks significantly more than a system that achieves privacy modulo-Ψ. We explain various subtle attack channels that our solution eliminates, with an example.

Running Example. Let us consider the canonical example of the Wordcount job in MapReduce, wherein the goal is to count the number of occurrences of each word in a set of input files. The map operation takes one file as input, and for each word w in the file, outputs the tuple $\langle w, 1\rangle$. All outputs are encrypted with standard authenticated encryption. Each reduce operation takes as input all the tuples with the same tuple-key, i.e. the same word, and aggregates the values. Hence the output of reduce operations is an encrypted list of tuples $\langle w, w_c\rangle$, where w_c is the frequency of word w for all input files. For simplicity, we assume that the input is a set of files $F = \{F_1, \ldots, F_n\}$, each file has the same number of words and is small enough to be processed by a map operation[3].

What does Privacy modulo-Ψ Achieve? Here all the map computation units output same size tuples, and after grouping, each reduce unit receives tuples grouped by words. The size of map outputs and group sizes constitute Ψ, and a private modulo-Ψ execution therefore leaks some statistical information about the collection of files in aggregate, namely the frequency distribution of words in F. However, it leaks nothing about the contents of words in the individual files — for instance, the frequency of words in any given file, and the common words between any pair of files are not leaked. As we show next, the baseline system permits a lot of inference attacks as it fails to achieve privacy modulo-Ψ. In fact, eliminating the remaining leakage in this example may not be easy, as it may assume apriori knowledge about the probability distribution of words in F (e.g. using differential privacy [48]).

Passive Attacks. Consider a semi-honest adversary that executes the provisioning protocol, but aims to infer additional information. The adversary controls 6 parameters **C1-C6** (Section 2.2) in the execution protocol. The number of units (**C4**) and map-reduce phases executed (**C6**) are dependent (and implied) by Ψ in an honest execution, and do not leak any additional information about the input. However, parameters **C1,C2,C3** and **C5** may directly leak additional information, as explained below.

- *Dataflow Patterns (Channel C3).* Assume that the encrypted tuples are of the same size, and hence do not individually leak anything about the underlying plain text. However, since the adversary constitutes the data communication channel, it can correlate the tuples written out by a map unit and read by a specific reduce unit. In the Wordcount example, the i^{th} map unit processes words in the file F_i, and then the intermediate tuples are sorted before being fed to reduce units. By observing which map outputs are grouped together to the same reduce unit, the adversary can learn that the word w_i in file F_i is the same as a word w_j in file F_j. This is true if they are received by the same reduce unit as one group. Thus, data access patterns leak significant information about overlapping words in files.
- *Order of Execution (Channel C5).* A deterministic order of execution of nodes in any step can reveal information about the underlying tuples beyond what is implied by Ψ. For instance, if the provisioning protocol always sorts tuple-keys and assigns them to reduce units in sorted order, then the adversary learns significant information. In the WordCount example, if the first reduce unit always corresponds to words appearing first in the sorted order, this would leak information about specific words processed by the reduce unit. This is not directly implied by Ψ.
- *Time-of-Access (Channel C1,C2)* Even if data access patterns are eliminated, time-of-access is an-

[3] Files can be processed in fixed size blocks, so this assumption is without any loss of generality

other channel of leakage. For instance, an optimizing scheduler may start to move tuples to the reduce units even before the map step is completed (pipelining) to gain efficiency. In such cases, the adversary can correlate which blocks written by map units are read by which reduce units. If outputs of all but the i^{th} map unit are delayed, and the j^{th} reduce unit completes, then the adversary can deduce that there is no dataflow from the i^{th} map unit to j^{th} reduce unit. In general, if computation units in a subsequent step do not synchronize to obtain outputs from all units in the previous step, the time of start and completion leaks information.

Active Attacks. While we allow the adversary to abort the computation session at any time, we aim to prevent the adversary from using active attacks to gain advantage in breaking confidentiality. We remind readers that in our baseline system, the adversary can only invoke the program with its complete input set, without tampering with any original inputs. The output tuple-set of each computation unit is encrypted with an authenticated encryption scheme, so the adversary cannot tamper with individual tuples. Despite these preliminary defenses, several channels for active attacks exist:

- *Tuple Tampering*. The adversary may attempt to duplicate or eliminate an entire output tuple-set produced by a computation unit, even though it cannot forge individual tuples. As an attack illustration, suppose the adversary wants to learn how many words are unique to an input file F_i. To do this, the adversary can simply drop the output of the i^{th} map unit. If the number of tuples in the final output reduces by k, the tuples eliminated correspond to k unique words in F_i.
- *Misrouting Tuples*. The adversary can reorder intermediate tuples or route data blocks intended for one reduce unit to another. These attacks subvert our confidentiality goals. For instance, the adversary can bypass the shuffler altogether and route the output of i^{th} map unit to a reduce unit. The output of this reduce unit leaks the number of unique words in F_i. Similar inference attacks can be achieved by duplicating outputs of tuples in the reduce unit and observing the result.

4 Design

Our goal is to design a MapReduce provisioning protocol which is private modulo-Ψ and adds a small amount of the TCB to the existing MapReduce platform. We explain the design choices available and our observations that lead to an efficient and clean security design.

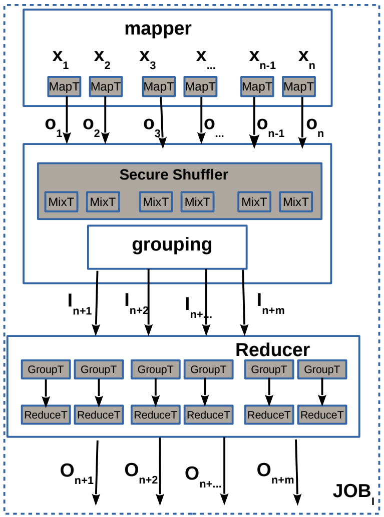

Figure 2: The data flow in $\mathtt{M}^2\mathtt{R}$. Filled components are trusted. Input, intermediate and output tuples are encrypted. The original map and reduce operations are replaced with `mapT` and `reduceT`. New components are the mixer nodes which use `mixT`, and another trusted component called `groupT`.

4.1 Architecture Overview

The computation proceeds in phases, each consisting of a map step, a shuffle step, and a reduce step. Figure 2 depicts the 4 new trusted components our design introduces into the dataflow pipeline of MapReduce. These four new TCB components are `mapT`, `reduceT`, `mixT` and `groupT`. Two of these correspond to the execution of map and reduce unit. They ensure that output tuples from the map and reduce units are encrypted and each tuple is of the same size. The other 2 components implement the critical role of *secure shuffling*. We explain our non-intrusive mechanism for secure shuffling in Section 4.2. Further, all integrity checks to defeat active attacks are designed to be distributed requiring minimal global synchronization. The shuffler in the MapReduce platform is responsible for grouping tuples, and invoking reduce units on disjoint ranges of tuple-keys. On each cluster node, the reducer checks the grouped order and the expected range of tuples received using the trusted `groupT` component. The outputs of the reduce units are then fed back into the next round of map-reduce phase.

Minimizing TCB. In our design, a major part of the MapReduce's software stack deals with job scheduling and I/O operations, hence it can be left outside of the TCB. Our design makes no change to the grouping and scheduling algorithms, and they are outside our TCB as shown in the Figure 2. Therefore, the design is conceptually simple and requires no intrusive changes to be implemented over existing MapReduce implementations. Developers need to modify their original applications to prepare them for execution in a hardware-protected process in our baseline system, as proposed in previous systems [38, 39, 49]. Beyond this modification made by the baseline system to the original MapReduce, M^{2}R requires a few additional lines of code to invoke the new privacy-enhancing TCB components. That is, MapReduce applications need modifications only to invoke components in our TCB. Next, we explain how our architecture achieves privacy and integrity in a MapReduce execution, along with the design of these four TCB components.

4.2 Privacy-Preserving Execution

For any given execution, we wish to ensure that each computation step in a phase is private modulo-Ψ. If the map step, the shuffle step, and the reduce step are individually private modulo-Ψ, by the property of serial composibility, the entire phase and a sequence of phases can be shown to be private. We discuss the design of these steps in this section, assuming a honest-but-curious adversary limited to passive attacks. The case of malicious adversaries is discussed in Section 4.3.

4.2.1 Secure Shuffling

As discussed in the previous section, the key challenge is performing secure shuffling. Consider the naive approach in which we simply move the entire shuffler into the platform TCB of each cluster node. To see why this is insecure, consider the grouping step of the shuffler, often implemented as a distributed sort or hash-based grouping algorithm. The grouping algorithm can only process a limited number of tuples locally at each mapper, so access to intermediate tuples must go to the network during the grouping process. Here, network data access patterns from the shuffler leak information. For example, if the shuffler were implemented using a standard merge sort implementation, the merge step leaks the relative position of the pointers in sorted sub-arrays as it fetches parts of each sub-array from network incrementally[4].

One generic solution to hide data access patterns is to employ an ORAM protocol when communicating with the untrusted storage backend. The grouping step will then access data obliviously, thereby hiding all correlations between grouped tuples. This solution achieves strong privacy, but with an overhead of $O(\log^k N)$ for each access when the total number of tuples is N [55]. Advanced techniques can be employed to reduce the overhead to $O(\log N)$, i.e. $k = 1$ [43]. Nevertheless, using a sorting algorithm for grouping, the total overhead becomes $O(N \log^{k+1} N)$, which translates to a factor of $30-100\times$ slowdown when processing gigabytes of shuffled data.

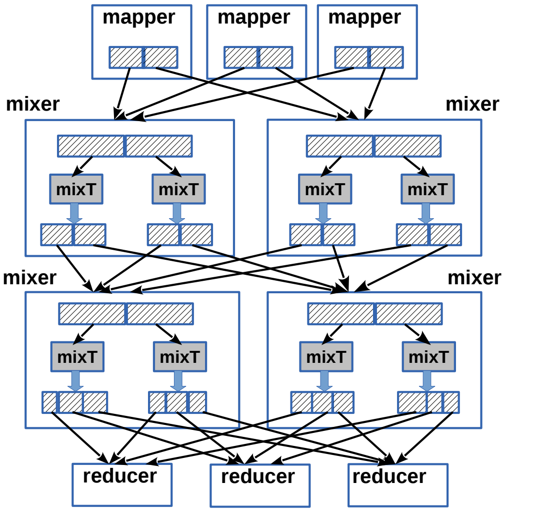

Figure 3: High level overview of the map-mix-reduce execution using a 2-round mix network.

A more advanced solution is to perform oblivious sorting using sorting networks, for example, odd-even or bitonic sorting network [23]. Such an approach hides data access patterns, but admits a $O(\log^2 N)$ latency (additive only). However, sorting networks are often designed for a fixed number of small inputs and hard to adapt to tens of gigabytes of distributed data.

We make a simple observation which yields a non-intrusive solution. Our main observation is that in MapReduce and other dataflow frameworks, the sequence of data access patterns is fixed: it consists of cycles of tuple writes followed by reads. The reduce units start reading and processing their inputs only after the map units have finished. In our solution, we rewrite intermediate encrypted tuples with re-randomized tuple keys such that there is no linkability between the re-randomized tuples and the original encrypted map output tuples. We observe that this step can be realized by secure mix networks [30]. The privacy of the computation reduces directly to the problem of secure mixing. The total latency added by our solution is an additive term of $O(\log N)$ in the worst case. Since MapReduce shuffle step is based on sorting which already admits $O(N \log N)$ overhead, our design retains the asymptotic runtime complexity of the original framework.

Our design achieves privacy using a cascaded mix network (or cascaded-mix) to securely shuffle tuples [30]. The procedure consists of a cascading of κ intermediate steps, as shown in Figure 3. It has κ identical steps (called mixing steps) each employing a number of trusted computation units called `mixT` units, the execution of which can be distributed over multiple nodes called mixers. Each `mixT` takes a fixed amount of T tuples that it can process in memory, and passes exactly the same number of encrypted tuples to all `mixT` units in the sub-

[4] This can reveal, for instance, whether the first sub-array is strictly lesser than the first element in the second sorted sub-array.

sequent step. Therefore, in each step of the cascade, the mixer utilizes N/T mixT units for mixing N tuples. At $\kappa = \log \frac{N}{T}$, the network ensures the strongest possible unlinkability, that is, the output distribution is statistically indistinguishable from a random distribution [30].

Each mixT unit decrypts the tuples it receives from the previous step, randomly permutes them using a linear-time algorithm and re-encrypts the permuted tuples with fresh randomly chosen symmetric key. These keys are known only to mixT units, and can be derived using a secure key-derivation function from a common secret. The processing time of mixT are padded to a constant. Note that the re-encryption time has low variance over different inputs, therefore such padding incurs low overhead.

Let Ω represents the number of input and output tuples of cascaded-mix with κ steps. Intuitively, when κ is sufficiently large, an semi-honest adversary who has observed the execution does not gain more knowledge than Ω. The following lemma states that indeed this is the case. We present the proof in Appendix A.

Lemma 1. *Cascaded-mix is private module-Ω under semi-honest adversary, given that the underlying encryption scheme is semantically secure.*

4.2.2 Secure Grouping

After the mixing step, the shuffler can group the randomized tuple keys using its original (unmodified) grouping algorithm, which is not in the TCB. The output of the cascaded-mix is thus fed into the existing grouping algorithm of MapReduce, which combines all tuples with the same tuple-key and forward them to reducers. Readers will notice that if the outputs of the last step of the cascaded-mix are probabilistically encrypted, this grouping step would need to be done in a trusted component. In our design, we add a last $(\kappa+1)$-th step in the cascade to accommodate the requirement for subsequent grouping. The last step in the cascade uses a deterministic symmetric encryption F_s, with a secret key s, to encrypt the key-component of the final output tuples. Specifically, the $\langle a,b \rangle$ is encrypted to a ciphertext of the form $\langle F_s(a), E(a,b) \rangle$, where $E(\cdot)$ is a probabilistic encryption scheme. This ensures that the two shuffled tuples with the same tuple-keys have the same ciphertext for the key-component of the tuple, and hence the subsequent grouping algorithm can group them without decrypting the tuples. The secret key s is randomized in each invocation of the cascaded-mix, thereby randomizing the ciphertexts across two map-reduce phases or jobs.

What the adversary gains by observing the last step of mixing is the tuples groups which are permuted using $F_s(\cdot)$. Thus, if $F_s(\cdot)$ is a pseudorandom function family, the adversary can only learn about the size of each group, which is already implied by Ψ. Putting it all together with the Lemma 1, we have:

Theorem 1. *The protocol M^{2}R is modulo-Ψ private (under semi-honest adversary), assuming that the underlying private-key encryption is semantically secure, and $F_s(\cdot)$ is a pseudorandom function family.*

4.3 Execution Integrity

So far, we have considered the privacy of the protocol against honest-but-curious adversaries. However, a malicious adversary can deviate arbitrarily from the protocol by mounting active attacks using the 6 parameters under its control. In this section, we explain the techniques necessary to prevent active attacks.

The program execution in M^{2}R can be viewed as a directed acyclic graph (DAG), where vertices denote trusted computation units and edges denote the flow of encrypted data blocks. M^{2}R has 4 kinds of trusted computation units or vertices in the DAG: mapT, mixT, groupT, and reduceT. At a high-level, our integrity-checking mechanism works by ensuring that nodes at the j^{th} level (by topologically sorted order) check the consistency of the execution at level $j-1$. If they detect that the adversary deviates or tampers with the execution or outputs from level $j-1$, then they abort the execution.

The MapReduce provisioning system is responsible for invoking trusted computation units, and is free to decide the total number of units spawned at each level j. We do not restrict the MapReduce scheduling algorithm to decide which tuples are processed by which reduce unit, and their allocation to nodes in the cluster. However, we ensure that all tuples output at level $i-1$ are processed at level i, and there is no duplicate. Note that this requirement ensures that a computation in step i starts only after outputs of previous step are passed to it, implicitly synchronizes the start of the computation units at step i. Under this constraint, it can be shown that channels **C1-C2** (start-end time of each computation node) can only allow the adversary to delay an entire step, or distinguish the outputs of units within one step, which is already implied by Ψ. We omit a detailed proof in this paper. Using these facts, we can show that the malicious adversary has no additional advantage compared to an honest-but-curious adversary, stated formally below.

Theorem 2. *The protocol M^{2}R is private modulo-Ψ under malicious adversary, assuming that the underlying authenticated-encryption is semantically secure (confidentiality) and secure under chosen message attack (integrity), and $F_s(\cdot)$ is a pseudorandom function family.*

Proof Sketch: Given a malicious adversary $\mathscr{A}$ that executes the M^{2}R protocol, we can construct an adversary

$\widetilde{\mathscr{A}}$ that simulates $\mathscr{A}$, but only has access to Ψ in the following way. To simulate $\mathscr{A}$, the adversary $\widetilde{\mathscr{A}}$ needs to fill in information not present in Ψ. For the output of a trusted unit, the simulation simply fills in random tuples, where the number of tuples is derived from Ψ. The timing information can likewise be filled-in. Whenever $\mathscr{A}$ deviates from the protocol and feeds a different input to a trusted instance, the simulation expects the instance will halt and fills in the information accordingly. Note that the input to $\mathscr{A}$ and the input constructed for the simulator $\widetilde{\mathscr{A}}$ could have the same DAG of program execution, although the encrypted tuples are different. Suppose there is a distinguisher that distinguishes $\mathscr{A}$ and $\widetilde{\mathscr{A}}$, let us consider the two cases: either the two DAG's are the same or different. If there is a non-negligible probability that they are the same, then we can construct a distinguisher to contradict the security of the encryption, or $F_s(\cdot)$. If there is a non-negligible probability that they are different, we can forge a valid authentication tag. Hence, the outputs of $\mathscr{A}$ and $\widetilde{\mathscr{A}}$ are indistinguishable. ■

Integrity Checks. Nearly all our integrity checks can be distributed across the cluster, with checking of invariants done locally at each trusted computation. Therefore, our integrity checking mechanism can largely bundle the integrity metadata with the original data. No global synchronization is necessary, except for the case of the `groupT` units as they consume data output by an untrusted grouping step. The `groupT` checks ensure that the ordering of the grouped tuples received by the designated `reduceT` is preserved. In addition, `groupT` units synchronize to ensure that each reducer processes a distinct range of tuple-keys, and that all the tuple-keys are processed by at least one of the reduce units.

4.3.1 Mechanisms

In the DAG corresponding to a program execution, the MapReduce provisioning system assigns unique *instance ids*. Let the vertex i at the level j has the designated id (i, j), and the total number of units at level j be $|V_j|$. When a computation instance is spawned, its designed instance id (i, j) and the total number of units $|V_j|$ are passed as auxiliary input parameters by the provisioning system. Each vertex with id (i, j) is an operation of type `mapT`, `groupT`, `mixT` or `reduceT`, denoted by the function $OpType(i, j)$. The basic mechanism for integrity-checking consists of each vertex emitting a *tagged-block* as output which can be checked by trusted components in the next stage. Specifically, the tagged block is 6-tuple $B = \langle O, LvlCnt, SrcID, DstID, DstLvl, DstType \rangle$, where:

O	is the encrypted output tuple-set,
$LvlCnt$	is the number of units at source level,
$SrcID$	is the instance id of the source vertex,
$DstID$	is instance id of destination vertex or `NULL`
$DstLvl$	is the level of the destination vertex,
$DstType$	is the destination operation type.

In our design, each vertex with id (i, j) fetches the tagged-blocks from all vertices at the previous level, denoted by the multiset $\mathscr{B}$, and performs the following consistency checks on $\mathscr{B}$:

1. The LvlCnt for all $b \in \mathscr{B}$ are the same (say $\ell(\mathscr{B})$).
2. The SrcID for all $b \in \mathscr{B}$ are distinct.
3. For set $S = \{SrcID(b) \mid b \in \mathscr{B}\}$, $|S| = \ell(\mathscr{B})$.
4. For all $b \in \mathscr{B}$, $DstLvl(b) = j$.
5. For all $b \in \mathscr{B}$, $DstID(b) = (i, j)$ or `NULL`.
6. For all $b \in \mathscr{B}$, $DstType(b) = OpType(i, j)$.

Conditions 1,2 and 3 ensure that tagged-blocks from *all* units in the previous level are read and that they are distinct. Thus, the adversary has not dropped or duplicated any output tuple. Condition 4 ensures that the computation nodes are ordered sequentially, that is, the adversary cannot misroute data bypassing certain levels. Condition 6 further checks that execution progresses in the expected order — for instance, the map step is followed by a mix, subsequently followed by a group step, and so on. We explain how each vertex decides the right or expected order independently later in this section. Condition 5 states that if the source vertex wishes to fix the recipient id of a tagged-block, it can verifiably enforce it by setting it to non-NULL value.

Each tagged-block is encrypted with standard authenticated encryption, protecting the integrity of all metadata in it. We explain next how each trusted computation vertex encodes the tagged-block.

Map-to-Mix DataFlow. Each `mixT` reads the output metadata of all `mapT`. Thus, each `mixT` knows the total number of tuples N generated in the entire map step, by summing up the counts of encrypted tuples received. From this, each `mixT` independently determines the total number of mixers in the system as N/T. Note that T is the pre-configured number of tuples that each `mixT` can process securely without invoking disk accesses, typically a 100M of tuples. Therefore, this step is completely decentralized and requires no co-ordination between `mixT` units. A `mapT` unit invoked with id (i, j) simply emit tagged-blocks, with the following structure: $\langle \cdot, |V_j|, (i, j), \texttt{NULL}, j+1, \texttt{mixT} \rangle$.

Mix-to-Mix DataFlow. Each `mixT` re-encrypts and permutes a fixed number (T) of tuples. In a κ-step cascaded mix network, at any step s ($s < \kappa - 1$) the `mixT` outputs T/m tuples to each one of the m `mixT` units in the step $s+1$. To ensure this, each mixT adds metadata to its tagged-block output so that it reaches only the specified mixT unit for the next stage. To do so, we use the *DstType* field, which is set to type $\mathtt{mixT}_{s+1}$ by the mixer at step s. Thus, each mixT node knows the total number of tuples being shuffled N (encoded in OpType), its step number in the cascaded mix, and the public value T. From this each mixT can determine the correct number of cascade steps to perform, and can abort the execution if the adversary tries to avoid any step of the mixing.

Mix-to-Group DataFlow. In our design, the last mix step (i,j) writes the original tuple as $\langle F_s(k),(k,v,tctr)\rangle$, where the second part of this tuple is protected with authenticated-encryption. The value $tctr$ is called a tuple-counter, which makes each tuple globally distinct in the job. Specifically, it encodes the value (i,j,ctr) where ctr is a counter unique to the instance (i,j). The assumption here is that all such output tuples will be grouped by the first component, and each group will be forwarded to reducers with no duplicates. To ensure that the outputs received are correctly ordered and untampered, the last mixT nodes send a special tagged-block to groupT nodes. This tagged-block contains the count of tuples corresponding to $F_s(k)$ generated by mixT unit with id (i,j). With this information each groupT node can locally check that:

- For each received group corresponding to $g = F_s(k)$, the count of distinct tuples $(k,\cdot,i,j,ctr)$ it receives tallies with that specified in the tagged-block received from mixT node (i,j), for all blocks in $\mathscr{B}$.

Finally, groupT units need to synchronize to check if there is any overlap between tuple-key ranges. This requires an additional exchange of tokens between groupT units containing the range of group keys and tuple-counters that each unit processes.

Group-to-Reduce Dataflow. There is a one-to-one mapping between groupT units and reduceT units, where the former checks the correctness of the tuple group before forwarding to the designated reduceT. This communication is analogous to that between mixT units, so we omit a detailed description for brevity.

5 Implementation

Baseline Setup. The design of M^{2}R can be implemented differently depending on the underlying architectural primitives available. For instance, we could implement our solution using Intel SGX, using the mechanisms of VC^3 to achieve our baseline. However, Intel SGX is not yet available in shipping CPUs, therefore we use a trusted-hypervisor approach to implement the baseline system, which minimizes the performance overheads from the baseline system. We use Intel TXT to securely boot a trusted Xen-4.4.3 hypervisor kernel, ensuring its static boot integrity[5]. The inputs ands output of map and reduce units are encrypted with AES-GCM using 256-bit keys. The original Hadoop jobs are executed as user-level processes in ring-3, attested at launch by the hypervisor, making an assumption that they are protected during subsequent execution. The MapReduce jobs are modified to call into our TCB components implemented as x86 code, which can be compiled with SFI constraints for additional safety. The hypervisor loads, verifies and executes the TCB components within its address space in ring-0. The rest of Hadoop stack runs in ring 3 and invokes the units by making hypercalls. Note that the TCB components can be isolated as user-level processes in the future, but this is only meaningful if the processes are protected by stronger solutions such as Intel SGX or other systems [12, 14, 52].

M^{2}R TCB. Our main contributions are beyond the baseline system. We add four new components to the TCB of the baseline system. We have modified a standard Hadoop implementation to invoke the mixT and groupT units before and after the grouping step. These two components add a total 90 LoC to the platform TCB. No changes are necessary to the original grouping algorithm. Each mapT and reduceT implement the trusted map and reduce operation — same as in the baseline system. They are compiled together with a static utility code which is responsible for (a) padding each tuple to a fixed size, (b) encrypting tuples with authenticated encryption, (c) adding and verifying the metadata for tagged-blocks, and (d) recording the instance id for each unit. Most of these changes are fairly straightforward to implement. To execute an application, the client encrypts and uploads all the data to M^{2}R nodes. The user then submits M^{2}R applications and finally decrypts the results.

6 Evaluation

This section describes M^{2}R performance in a small cluster under real workloads. We ported 7 data intensive jobs from the standard benchmark to M^{2}R, making less than 25% changes in number of lines of code (LoC) to the original Hadoop jobs. The applications add fewer than 500 LoC into the TCB, or less than 0.16% of the entire Hadoop software stack. M^{2}R adds $17-130\%$ overhead in running time to the baseline system. We also compare M^{2}R with another system offering the same level of privacy, in which encrypted tuples are sent back to a trusted client. We show that M^{2}R is up to 44.6× faster compared

[5] Other hypervisor solutions such as TrustVisor [39], Overshadow [14], Nova [56], SecVisor [50] could equivalently be used

Job	*LoC changed (vs. Hadoop job)*	*TCB increase (vs. Hadoop codebase)*	*Input size (vs. plaintext size)*	*Shuffled bytes*	*# App hypercalls*	*# Platform hypercall*
Wordcount	10 (15%)	370 (0.14%)	2.1G (1.06×)	4.2G	3277173	35
Index	28 (24%)	370 (0.14%)	2.5G (1.15×)	8G	3277173	59
Grep	13 (13%)	355 (0.13%)	2.1G (1.06×)	75M	3277174	10
Aggregate	16 (18%)	395 (0.15%)	2G (1.19×)	289M	18121377	12
Join	30 (22%)	478 (0.16%)	2G (1.19×)	450M	11010647	14
Pagerank	42 (20%)	429 (0.15%)	2.5G (4×)	2.6G	1750000	21
KMeans	113 (7%)	400 (0.12%)	1G (1.09×)	11K	12000064	8

Table 1: Summary of the porting effort and TCB increase for various M^{2}R applications, and the application runtime cost factors. Number of app hypercalls consists of both `mapT` and `reduceT` invocations. Number of platform hypercalls include `groupT` and `mixT` invocations.

Job	*Baseline (vs. no encryption)*	M^{2}R *(% increase vs. baseline)*	*Download-and-compute (× M^{2}R)*
Wordcount	570 (221)	1156 (100%)	1859 (1.6×)
Index	666 (423)	1549 (130%)	2061 (1.3×)
Grep	70 (48)	106 (50%)	1686 (15.9×)
Aggregate	125 (80)	205 (64%)	9140 (44.6×)
Join	422 (211)	510 (20%)	5716 (11.2×)
Pagerank	521 (334)	755 (44%)	1209 (1.6×)
KMeans	123 (71)	145 (17%)	6071 (41.9×)

Table 2: Overall running time (s) of M^{2}R applications in comparison with other systems: (1) the baseline system protecting computation only in single nodes, (2) the download-and-compute system which does not use trusted primitives but instead sends the encrypted tuples back to trusted servers when homomorphic encrypted computation is not possible [59].

to this solution.

6.1 Setup & Benchmarks

We select a standard benchmark for evaluating Hadoop under large workloads called HiBench suite [25]. The 7 benchmark applications, listed in Table 1, cover a wide range of data-intensive tasks: compute intensive (KMeans, Grep, Pagerank), shuffle intensive (Wordcount, Index), database queries (Join, Aggregate), and iterative (KMeans, Pagerank). The size of the encrypted input data is between 1 GB and 2.5 GB in these case studies. Different applications have different amount of shuffled data, ranging from small sizes (75MB in Grep, 11K in KMeans) to large sizes (4.2GB in Wordcount, 8GB in Index).

Our implementation uses the Xen-4.3.3 64-bit hypervisor compiled with trusted boot option. The rest of M^{2}R stack runs on Ubuntu 13.04 64-bit version. We conduct our experiments in a cluster of commodity servers equipped with 1 quad-core Intel CPU 1.8GHz, 1TB hard drive, 8GB RAM and 1GB Ethernet cards. We vary our setup to have between 1 to 4 compute nodes (running mappers and reducers) and between 1 to 4 mixer nodes for implementing a 2-step cascaded mix network. The results presented below are from running with 4 compute nodes and 4 mixers each reserving a 100MB buffer for mixing, averaged over 10 executions.

6.2 Results: Performance

Overheads & Cost Breakdown. We observe a linear scale-up with the number of nodes in the cluster, which confirms the scalability of M^{2}R. In our benchmarks (Table 2), we observe a total overhead of between $17\% - 130\%$ over the baseline system that simply encrypts inputs and outputs of map/reduce units, and utilizes none of our privacy-enhancing techniques. It can also be seen that in all applications except for Grep and KMeans, running time is proportional to the size of data transferred during shuffling (shuffled bytes column in Table 1). To understand the cost factors contributing to the overhead, we measure the time taken by the secure shuffler, by the `mapT` and `reduceT` units, and by the rest of the Hadoop system which comprises the time spent on I/O, scheduling and other book-keeping tasks. This relative cost breakdown is detailed in Figure 4. From the result, we observe that the cost of the secure shuffler is significant. Therefore, reducing the overheads of shuffling, by avoiding the generic ORAM solution, is well-incentivized and is critical to reducing the overall overheads. The two main benchmarks which have high overheads of over 100%, namely Wordcount and Index, incur this cost primarily due to the cost of privacy-preserving shuffling a large amount of data. In benchmarks where the shuffled data is small (Grep, KMeans), the use of `mapT`/`reduceT` adds relatively larger overheads than that from the secure shuffler. The second observation is that the total cost of the both shuffler and other trusted components is comparable to that of Hadoop, which provides evidence that M^{2}R preserves the asymptotic complexity of Hadoop.

Comparison to Previous Solutions. Apart from the baseline system, a second point of comparison are previously proposed systems that send encrypted tuples to the user for private computation. Systems such as Monomi [59] and AutoCrypt [58] employ homomorphic encryption for computing on encrypted data on the single servers. For operations that cannot be done on the server using partially homomorphic encryption, such Monomi-like systems forward the data to a trusted set of servers (or to the client's private cloud) for decryption. We refer to this approach as download-and-compute approach. We estimate the performance of a Monomi-like system extended to distributed computation tasks, for achieving privacy equivalent to ours. To compare, we assume that the system uses Paillier, ElGamal and randomized

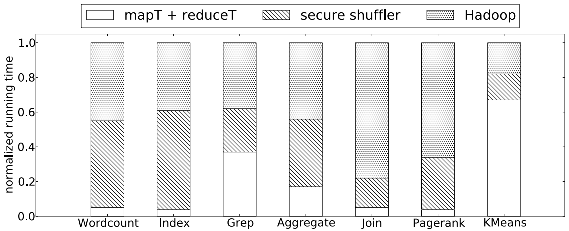

Figure 4: Normalized break-down time for M^{2}R applications. The running time consists of the time taken by mapT and reduceT, plus the time by the secure shuffler. The rest comes from the Hadoop runtime.

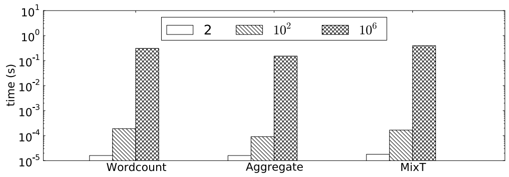

Figure 5: Cost of executing mapT instance of the Wordcount and Aggregate job, and the cost for executing mixT. Input sizes (number of ciphertexts per input) varies from 2 to 10^6.

search schemes for homomorphic computation, but not OPE or deterministic schemes (since that leaks more than M^{2}R and our baseline system do). We run operations that would fall outside such the expressiveness of the allowed homomorphic operations, including shuffling, as a separate network request to the trusted client. We batch network requests into one per MapReduce step. We assume that the network round trip latency to the client is only 1ms — an optimistic approximation since the average round trip delay in the same data center is $10-100$ms [4, 61]. We find that this download-and-compute approach is slower compared to ours by a factor of 1.3× to 44.6× (Table 2), with the median benchmark running slower by 11.2×. The overheads are low for case-studies where most of the computation can be handled by homomorphic operations, but most of the benchmarks require conversions between homomorphic schemes (thereby requiring decryption) [58, 59] or computation on plaintext values.

Platform-Specific Costs. Readers may wonder if the evaluation results are significantly affected by the choice of our implementation platform. We find that the dominant costs we report here are largely complementary to the costs incurred by the specifics of the underlying platform. We conduct a micro-benchmark to evaluate the cost of context-switches and the total time spent in the trusted components to explain this aspect. In our platform, the cost of each hypercall (switch to trusted logic) is small ($13\mu s$), and the execution of each trusted component is largely proportional to the size of its input data as shown in Figure 5. The time taken by the trusted computation grows near linearly with the input data-size, showing that the constant overheads of context-switches and other platform's specifics do not contribute to the reported results significantly. This implies that simple optimizations such as batching multiple trusted code invocations would not yield any significant improvements, since the overheads are indeed proportional to the total size of data and not the number of invocations. The total number of invocations (via hypercalls) for app-specific trusted logic (mapT, reduceT) is proportional to the total number input tuples, which amounts for less than half a second overhead even for millions of input tuples. The number of invocations to the other components (mixT and groupT) is much smaller ($8-59$) and the each invocation operates on large inputs of a few gigabytes; therefore the dominant cost is not that of context-switches, but that of the cost of multi-step shuffling operation itself and the I/O overheads.

6.3 Results: Security & Porting Effort

Porting effort. We find that the effort to adapt all benchmarks to M^{2}R is modest at best. For each benchmark, we report the number of Java LoC we changed in order to invoke the trusted components in M^{2}R, measured using the sloccount tool [6]. Table 1 shows that all applications except for KMeans need to change fewer than 43 LoC. Most changes are from data marshaling before and after invoking the mapT and reduceT units. KMeans is more complex as it is a part of the Mahout distribution and depends on many other utility classes. Despite this, the change is only 113 LoC, or merely 7% of the original KMeans implementation.

TCB increase. We define our *TCB increase* as the total size of the four trusted components. This represents the additional code running on top of a base TCB, which in our case is Xen. Note that our design can eliminate the base TCB altogether in the future by using SGX enclaves, and only retain the main trusted components we propose in M^{2}R. The TCB increase comprises the per-application trusted code and platform trusted code. The former consists of the code for loading and executing mapT, reduceT units (213 LoC) as well as the code for implementing their logic. Each map/reduce codebase itself is small, fewer than 200 LoC, and runs as trusted components in the baseline system itself. The platform trusted code includes that of mixT and groupT, which amounts to 90 LoC altogether. The entire Hadoop software stack is over 190*K* LoC and M^{2}R avoids moving all of it into the TCB. Table 1 shows that all jobs have TCB increases of fewer than 500 LoC, merely 0.16% of the Hadoop codebase.

Security. M^{2}R achieves stronger privacy than previous

[6] http://www.dwheeler.com/sloccount

Job	M^{2}R	*Baseline (additional leakage)*
Wordcount	# unique words + count	word-file relationship
Index	# unique words + count	word-file relationship
Grep	nothing	nothing
Aggregate	# groups + group size	record-group relationship
Join	# groups + group size	record-group relationship
Pagerank	node in-degree	whole input graph
KMeans	nothing	nothing

Table 3: Remaining leakage of M^{2}R applications, compared with that in the baseline system.

platforms that propose to use encrypted computation for big-data analysis. Our definition allows the adversary to observe an admissible amount of information, captured by Ψ, in the computation but hides everything else. It is possible to quantitatively analyze the increased privacy in information-theoretic terms, by assuming the probability distribution of input data [37, 53]. However, here we present a qualitative description in Table 3 highlighting how much privacy is gained by the techniques introduced in M^{2}R over the baseline system. For instance, consider the two case studies that incur most performance overhead (Wordcount, Index). In these examples, merely encrypting the map/reduce tuples leaks information about which file contains which words. This may allow adversaries to learn the specific keywords in each file in the dataset. In M^{2}R, this leakage is reduced to learning only the total number of unique words in the complete database and the counts of each, hiding information about individual files. Similarly, M^{2}R hides which records are in which group for database operations (Aggregate and Join). For Pagerank, the baseline system leaks the complete input graph edge structure, giving away which pair of nodes has an edge, whereas M^{2}R reduces this leakage to only the in-degree of graph vertices. In the two remaining case studies, M^{2}R provides no additional benefit over the baseline.

7 Related Work

Privacy-preserving data processing. One of M^{2}R's goal is to offer large-scale data processing in a privacy preserving manner on untrusted clouds. Most systems with this capability are in the database domain, i.e. supporting SQL queries processing. CryptDB [47] takes a purely cryptographic approach, showing the practicality of using partially homomorphic encryption schemes [3, 15, 45, 46, 54]. CryptDB can only work on a small set of SQL queries and therefore is unable to support arbitrary computation. Monomi [59] supports more complex queries, by adopting the download-and-compute approach for complex queries. As shown in our evaluation, such an approach incurs an order of magnitude larger overheads.

There exist alternatives supporting outsourcing of query processing to a third party via server-side trusted hardware, e.g. IBM 4764/5 cryptographic co-processors. TrustedDB [7] demonstrated that a secure outsourced database solution can be built and run at a fraction of the monetary cost of any cryptography-enabled private data processing. However, the system requires expensive hardware and a large TCB which includes the entire SQL server stack. Cipherbase improves upon TrustedDB by considering encrypting data with partially homomorphic schemes, and by introducing a trusted entity for query optimization [6]. M^{2}R differs to these systems in two fundamental aspects. First, it supports general computation on any type of data, as opposed to being restricted to SQL and structured database semantics. Second, and more importantly, M^{2}R provides confidentiality in a distributed execution environment which introduces more threats than in a single-machine environment.

VC^3 is a recent system offering privacy-preserving general-purpose data processing [49]. It considers MapReduce and utilizes Intel SGX to maintain a small TCB. This system is complementary to M^{2}R, as it focuses on techniques for isolated computation, key management, etc. which we do not consider. The privacy model in our system is stronger than that of VC^3 which does not consider traffic analysis attacks.

GraphSC offers a similar security guarantee to that of M^{2}R for specialized graph-processing tasks [42]. It provides a graph-based programming model similar to GraphLab's [36], as opposed to the dataflow model exposed by M^{2}R. GraphSC does not employ trusted primitives, but it assumes two non-colluding parties. There are two main techniques for ensuring data-oblivious and secure computation in GraphSC: sorting and garbled circuits. However, these techniques result in large performance overheads: a small Pagerank job in GraphSC is $200,000\times - 500,000\times$ slower than in GraphLab without security. M^{2}R achieves an overhead of $2\times - 5\times$ increase in running time because it leverages trusted primitives for computation on encrypted data. A direct comparison of oblivious sorting used therein instead of our secure shuffler is a promising future work.

Techniques for isolated computation. The current implementation of M^{2}R uses a trusted hypervisor based on Xen for isolated computation. Overshadow [14] and CloudVisor [63] are techniques with large TCB, whereas Flicker [38] and TrustVisor [39] reduce the TCB at the cost of performance. Recently, Minibox [32] enhances a TrustVisor-like hypervisor with two-way protection providing security for both the OS and the applications (or PALs). Advanced hardware-based techniques include Intel SGX [40] and Bastion [12] provide a hardware protected secure mode in which applications can be executed at hardware speed. All these techniques are complementary to ours.

Mix networks. The concept of mix network is first described in the design of untraceable electronic mail [13]. Since then, a body of research has concentrated on building, analyzing and attacking anonymous communication systems [16, 19]. Canetti presents the first definition of security that is preserved under composition [11], from which others have shown that the mix network is secure under Canetti's framework [10, 60]. Security properties of cascaded mix networks were studied in [30]. We use these theoretical results in our design.

8 Conclusion & Future Work

In this paper, we defined a model of privacy-preserving distributed execution of MapReduce jobs. We analyzed various attacks channels that break data confidentiality on a baseline system which employs both encryption and trusted computing primitives. Our new design realizes the defined level of security, with a significant step towards lower performance overhead while requiring a small TCB. Our experiments with M^{2}R showed that the system requires little effort to port legacy MapReduce applications, and is scalable.

Systems such as M^{2}R show evidence that specialized designs to hide data access patterns are practical alternatives to generic constructions such as ORAM. The question of how much special-purpose constructions benefit important practical systems, as compared to generic constructions, is an area of future work. A somewhat more immediate future work is to integrate our design to other distributed dataflow systems. Although having the similar structure of computation, those systems are based on different sets of computation primitives and different execution models, which presents both opportunities and challenges for reducing the performance overheads of our design. Another avenue for future work is to realize our model of privacy-preserving distributed computation in the emerging in-memory big-data platforms [64], where only very small overheads from security mechanisms can be tolerated.

Appendix A Security Analysis

Proof (Lemma 1):

Consider the “ideal mixer” that takes as input a sequence $\langle x_1, \ldots, x_N \rangle$ where each $x_i \in [1,N]$, picks a permutation $p : [1,N] \to [1,N]$ randomly and then output the sequence $\langle x_{p(1)}, x_{p(2)}, \ldots, x_{p(N)} \rangle$. Klonowski et al. [30] investigated the effectiveness of the cascaded network of mixing, and showed that $O(\log \frac{N}{T})$ steps are suffice to bring the distribution of the mixed sequence statistically close to the output of the ideal mixer, where T is the number of items an instance can process in memory. Our proof relies on the above-mentioned result.

Let us assume that κ, the number of steps carried out by cascaded-mix, is sufficiently large such that the distribution of the mixed sequence is statistically close to the ideal mixer.

Consider an adversary $\mathscr{S}$ that executes the cascaded-mix. Let us construct an adversary $\mathscr{A}$ who simulates $\mathscr{S}$ but only has access to Ω. To fill in the tuple values not present in Ω, the simulation simply fills in random tuples. Note that the number of tuples can be derived from Ω.

Now, suppose that on input $x_1, \ldots, x_N$, the output of $\mathscr{A}$ and $\mathscr{S}$ can be distinguished by $\mathscr{D}$. We want to show that this contradicts the semantic security of the underlying encryption scheme, by constructing a distinguisher $\widetilde{\mathscr{D}}$ who can distinguish multiple ciphertexts from random with polynomial-time sampling (i.e. the distinguisher sends the challenger multiple messages, and receive more than one sample).

Let $z = \langle z_1, z_2, \ldots, z_N \rangle$ be the output of the mixer on input $x_1, \ldots, x_N$. The distinguisher $\widetilde{\mathscr{D}}$ asks the challenger for a sequence of ciphertexts of z. Let $c_{i,j}$'s be the ciphertexts returned by the challenger, where $c_{i,j}$ is the i-th ciphertexts of z_j. To emulate $\mathscr{S}$, likewise, $\widetilde{\mathscr{D}}$ needs to feed the simulation with the intermediate data generated by `mixT`. Let $y_{i,j}$ be the i-th intermediate ciphertext in round j the distinguisher $\widetilde{\mathscr{D}}$ generated for the emulation. The $y_{i,j}$'s are generated as follow:

1. $\widetilde{\mathscr{D}}$ simulates the cascaded-mix by randomly picking a permutation for every `mixT`. Let $p_j : [1,N] \to [1,N]$ be the overall permutation for round j. Let $\hat{p}_j$ be the permutation that moves the i-th ciphertext in the input, to its location after j rounds. That is, $\hat{p}_j(i) = p_j(\hat{p}_{j-1}(i))$, and $\hat{p}_0(i) = i$.

2. Set $y_{i,j} = c_{\hat{p}_j(i),j}$ for each i, j.

Let v be the output of $\mathscr{D}$'s simulation. Note that if $x_{i,j}$'s are random ciphertexts, then the distribution of v is the same as the output distribution of $\mathscr{A}$. On the other hand, if $x_{i,j}$'s are ciphertexts of z, then the input to the emulation is statistically close to the input of $\mathscr{S}$, and thus distribution of v is statistically close to the output distribution of S.

Since $\mathscr{D}$ can distinguish output of $\mathscr{S}$ from $\mathscr{A}$'s, $\widetilde{\mathscr{D}}$ can distinguish the ciphertexts of z from random. □

Measuring Real-World Accuracies and Biases in Modeling Password Guessability

Abstract

Parameterized password guessability—how many guesses a particular cracking algorithm with particular training data would take to guess a password—has become a common metric of password security. Unlike statistical metrics, it aims to model real-world attackers and to provide per-password strength estimates. We investigate how cracking approaches often used by researchers compare to real-world cracking by professionals, as well as how the choice of approach biases research conclusions.

We find that semi-automated cracking by professionals outperforms popular fully automated approaches, but can be approximated by combining multiple such approaches. These approaches are only effective, however, with careful configuration and tuning; in commonly used default configurations, they underestimate the real-world guessability of passwords. We find that analyses of large password sets are often robust to the algorithm used for guessing as long as it is configured effectively. However, cracking algorithms differ systematically in their effectiveness guessing passwords with certain common features (e.g., character substitutions). This has important implications for analyzing the security of specific password characteristics or of individual passwords (e.g., in a password meter or security audit). Our results highlight the danger of relying only on a single cracking algorithm as a measure of password strength and constitute the first scientific evidence that automated guessing can often approximate guessing by professionals.

1 Introduction

Despite decades of research into alternative authentication schemes, text passwords have comparative advantages—familiarity, ease of implementation, nothing for users to carry—that make a world without text passwords unlikely in the near future [5]. Two-factor authentication, single-sign-on systems, password managers, and biometrics promise to obviate remembering a distinct password for each online account, but passwords will not disappear entirely.

Text passwords have been compromised with alarming regularity through both online and offline attacks. While online attacks are mitigated through rate-limiting password-entry attempts, faulty rate limiting contributed to the iCloud photo leak [39]. In offline attacks, including recent ones on LinkedIn [7], eHarmony [62], Gawker [2], and Adobe [48], an attacker steals a database of (usually) hashed passwords and tries to recover passwords through offline guessing. Because password reuse is common [14], recovered passwords can often be used to access accounts on other systems.

A key aspect of improving password security is making passwords more computationally expensive to guess during offline attacks. Cracking tools like the GPU-based oclHashcat [57] and distributed cracking botnets [13, 17] enable attackers to make 10^{14} guesses in hours if passwords are hashed using fast hash functions like MD5 or NTLM. These advances are offset by the development of hash functions like bcrypt [52] and scrypt [47], which make attacks more difficult by requiring many iterations or consuming lots of memory.

Unfortunately, users often create predictable passwords [7, 29], which attackers can guess quickly even if the passwords are protected by a computationally expensive hash function. In some cases, predictable passwords are a rational coping strategy [54, 60]; in other cases, users are simply unsure whether a password is secure [66]. System administrators encourage strong passwords through password-composition policies and password-strength meters. The design and effectiveness of such mechanisms hinges on robust metrics to measure how difficult passwords are to guess.

In recent years, traditional entropy metrics have fallen out of favor because they do not reflect how easily a password can be cracked in practice [3, 31, 69]. It has instead become common to measure password strength by running or simulating a particular cracking algorithm, parameterized by a set of training data [4, 31, 69]. This approach has two main advantages. First, it calculates the guessability of each password individually, enabling data-driven strength estimates during password creation [10, 33]. Second, it estimates real-world security against existing, rather than idealized, adversarial techniques. A disadvantage of this approach is that the (simulated) cracking algorithm may not be configured or trained as effectively as by a real attacker, leading to inaccurate estimates of password strength.

This paper reports on the first study of how various cracking approaches used by researchers compare to real-world cracking by professionals, as well as how the choice of approach biases research conclusions. We contracted a computer security firm specializing in password recovery to crack a set of passwords chosen for their diversity in password-composition policies. We then computed the guessability of these passwords using four popular approaches. We tested many configurations of two well-known password-cracking toolkits: John the Ripper [49] and oclHashcat [57]. We also tested two approaches popular in academia: Weir et al.'s probabilistic context-free grammar (PCFG) [70] and Ma et al.'s Markov models [40].

Unsurprisingly, a professional attacker updating his strategy dynamically during cracking outperformed fully automated, "fire-and-forget" approaches (henceforth simply referred to as *automated*), yet often only once billions or trillions of guesses had been made. We found that relying on a single automated approach to calculate guessability underestimates a password's vulnerability to an experienced attacker, but using the earliest each password is guessed by any automated approach provides a realistic and conservative approximation.

We found that each approach was highly sensitive to its configuration. Using more sophisticated configurations than those traditionally used in academic research, our comparative analysis produced far more nuanced results than prior work. These prior studies found that Markov models substantially outperform the PCFG approach [18, 40], which in turn substantially outperforms tools like John the Ripper [16, 69, 72]. We found that while Markov was marginally more successful at first, it was eventually surpassed by PCFG for passwords created under typical requirements. Furthermore, the most effective configurations of John the Ripper and Hashcat were frequently comparable to, and sometimes even more effective than, the probabilistic approaches.

Both the differences across algorithms and the sensitivity to configuration choices are particularly notable because most researchers use only a single approach as a security metric [10, 12, 19, 42, 56, 65, 69]. In addition, many researchers use adversarial cracking tools in their default configuration [11, 14, 15, 20, 21, 28, 34, 71]. Such a decision is understandable since each algorithm is very resource- and time-intensive to configure and run. This raises the question of whether considering only a single approach biases research studies and security analyses. For instance, would substituting a different cracking algorithm change the conclusions of a study?

We investigate these concerns and find that for comparative analyses of large password sets (e.g., the effect of password-composition policies on guessability), choosing one cracking algorithm can reasonably be expected to yield similar results as choosing another.

However, more fine-grained analyses—e.g., examining what characteristics make a password easy to guess—prove very sensitive to the algorithm used. We find that per-password guessability results often vary by orders of magnitude, even when two approaches are similarly effective against large password sets as a whole. This has particular significance for efforts to help system administrators ban weak passwords or provide customized guidance during password creation [10, 33]. To facilitate the analysis of password guessability across many password-cracking approaches and to further systematize passwords research, we introduce a Password Guessability Service [9] for researchers.

In summary, this paper makes the following main contributions: We show that while running a single cracking algorithm or tool relatively out-of-the-box produces only a poor estimate of password guessability, using multiple well-configured algorithms or tools in parallel can approximate passwords' vulnerability to an expert, real-world attacker. Furthermore, while comparative analyses of large password sets may be able to rely on a single cracking approach, any analysis of the strength of individual passwords (e.g., a tool to reject weak ones) or the security impact of particular characteristics (e.g., the use of digits, multiple character classes, or character substitutions) must consider many approaches in parallel.

2 Related Work

In this section, we discuss commonly used metrics of password strength (Section 2.1) and describe popular categories of password-cracking attacks (Section 2.2).

2.1 Password Security Metrics

While estimated entropy was once a leading password strength metric [8], it does not reflect what portion of a set can be cracked easily [3, 31, 69]. Two main classes of metrics have emerged in its place: statistical metrics and parameterized metrics. Both classes focus on *guess-*

ability, the number of guesses needed by an adversary to guess a given password or a fraction of a set.

Statistical metrics are particularly valuable for examining password sets as a whole. For example, Bonneau introduced partial guessing metrics [3] for estimating the number of guesses required for an idealized attacker, who can perfectly order guesses, to guess a given fraction of a set. Since password distributions are heavy-tailed, very large samples are required to determine a set's guessability accurately.

Parameterized metrics instead investigate guessability under a cracking algorithm and training data [4, 31, 69]. These metrics thus model an adversary using existing tools, rather than an idealized attack, though the metric is only as good as the chosen algorithm and training data. Parameterized metrics can also be used to compare password sets without fully running the algorithm [40].

In contrast to statistical metrics, parameterized metrics have two important properties. First, they estimate the guessability of each password individually. Estimating guessability per-password is important for security audits (e.g., identifying weak passwords) and to provide feedback to a user about a password she has created. This latter promises to become more widespread as proactive feedback tools move from length-and-character-class heuristics [15] to data-driven feedback [10, 33]. Second, parameterized metrics aim to estimate security against real-world, rather than idealized, attacks. Researchers previously assumed automated techniques approximate real-world attackers [31, 69]; we are the first to test this assumption against attacks by professionals.

Parameterized metrics have been used to measure password strength in a number of previous studies [10, 14, 16, 20, 21, 31, 34, 40, 42, 53, 56, 65, 68, 69, 72]. While there are many different methods for cracking passwords, as we detail in Section 2.2, time and resource constraints lead many researchers to run only a single algorithm per study. However, it remains an open question whether this strategy accurately models real-world attackers, or whether choosing a different algorithm would change a study's results. We address this issue.

Throughout the paper, we refer to the *guess number* of a password, or how many guesses a particular parameterized algorithm took to arrive at that password. Because the algorithm must be run or simulated, there is necessarily a *guess cutoff*, or maximum guess after which remaining passwords are denoted "not guessed."

2.2 Types of Guessing Attacks

Researchers have long investigated how to guess passwords. A handful of studies [12, 16, 53] have compared the aggregate results of running different cracking approaches. Other studies have compared results of running different cracking approaches based on guess numbers [11, 18, 40]. We are the first to examine in detail the magnitude and causes of differences in these approaches' effectiveness at guessing specific passwords; we also compare approaches from academia and adversarial tools to a professional attacker. In this section, we highlight four major types of attacks.

Brute-force and mask attacks Brute-force attacks are conceptually the simplest. They are also inefficient and therefore used in practice only when targeting very short or randomly generated, system-assigned passwords.

Mask attacks are directed brute-force attacks in which password character-class structures, such as "seven lowercase letters followed by one digit" are exhausted in an attacker-defined order [58]. While this strategy may make many guesses without success, mask attacks can be effective for short passwords, as many users craft passwords matching popular structures [37, 63]. Real-world attackers also turn to mask attacks after more efficient methods exhaust their guesses. We evaluated mask attacks in our initial tests. Unsurprisingly, we found them significantly less efficient than other attacks we analyzed.

Probabilistic context-free grammar In 2009, Weir et al. proposed using a probabilistic context-free grammar (PCFG) with a large training set of passwords from major password breaches [67] to model passwords and generate guesses [70]. They use training data to create a context-free grammar in which non-terminals represent contiguous strings of a single character class. From the passwords observed in its training data, PCFG assigns probabilities to both the structure of a password (e.g., *monkey99* has the structure {*six letters*}{*two digits*}) and the component strings (e.g., "99" will be added to the list of two-digit strings it has seen). A number of research studies [11, 16, 19, 31, 40, 42, 56, 65, 69, 72] have used PCFG or a close variant to compute guessability.

Kelley et al. proposed other improvements to Weir et al.'s PCFG algorithm, like treating uppercase and lowercase letters separately and training with structures and component strings from separate sources [31]. Because they found these modifications improved guessing effectiveness, we incorporate their improvements in our tests. In addition, multiple groups of researchers have proposed using grammatical structures and semantic tokens as PCFG non-terminals [53, 68]. More recently, Komanduri proposed a series of PCFG improvements, including supporting hybrid structures and assigning probabilities to unseen terminals [32]. We incorporate his insights, which he found improves guessing efficiency.

Markov models Narayanan and Shmatikov first proposed using a Markov model of letters in natural language with finite automata representing password structures [45]. Castelluccia et al. used a similar algorithm for password meters [10]. John the Ripper and Hashcat offer simple Markov modes in their cracking toolkits as well.

Recently, Duermuth et al. [18] and Ma et al. [40] independently evaluated many variations of Markov models and types of smoothing in cracking passwords, using large sets of leaked passwords for training. Both groups compared their model with other probabilistic attacks, including Weir et al.'s original PCFG code, finding particular configurations of a Markov model to be more efficient at guessing passwords for some datasets. We use Ma et al.'s recommended model in our tests [40].

Mangled wordlist attacks Perhaps the most popular strategy in real-world password cracking is the dictionary attack. First proposed by Morris and Thompson in 1979 [43], modern-day dictionary attacks often combine *wordlists* with *mangling rules*, string transformations that modify wordlist entries to create additional guesses. Wordlists usually contain both natural language dictionaries and stolen password sets. Typical mangling rules perform transformations like appending digits and substituting characters [50, 59].

Many modern cracking tools, including John the Ripper [49], Hashcat [57], and PasswordsPro [30], support these attacks, which we term *mangled wordlist attacks*. The popularity of this category of attack is evident from these tools' wide use and success in password-cracking competitions [36,51]. Furthermore, a number of research papers have used John the Ripper, often with the default mangling rules [11,14,15,20,21,28,34,71] or additional mangling rules [16,19,72].

Expert password crackers, such as those offering forensic password-recovery services, frequently perform a variant of the mangled wordlist attack in which humans manually write, prioritize, and dynamically update rules [23]. We term these manual updates to mangling rules *freestyle rules*. As we discuss in Section 3, we evaluate guessability using off-the-shelf tools relying on publicly available wordlists and mangling rules. We also contract a password recovery industry leader to do the same using their proprietary wordlists and freestyle rules.

3 Methodology

We analyze four automated guessing algorithms and one manual cracking approach (together, our five *cracking approaches*). We first describe the password sets for which we calculated guessability, then explain the training data we used. Afterwards, we discuss our five cracking approaches. Finally, we discuss computational limitations of our analyses.

3.1 Datasets

We examine 13,345 passwords from four sets created under composition policies ranging from the typical to the currently less common to understand the success of password-guessing approaches against passwords of different characteristics. Since no major password leaks contain passwords created under strict composition policies, we leverage passwords that our group collected for prior studies of password-composition policies [31, 42, 56]. This choice of data also enables us to contract with a professional computer security firm to crack these unfamiliar passwords. Had we used any major password leak, their analysts would have already been familiar with most or all of the passwords contained in the leak, biasing results.

The passwords in these sets were collected using Amazon's Mechanical Turk crowdsourcing service. Two recent studies have demonstrated that passwords collected for research studies, while not perfect proxies for real data, are in many ways very representative of real passwords from high-value accounts [20, 42].

Despite these claims, we were also curious how real passwords would differ in our analyses from those collected on Mechanical Turk. Therefore, we repeated our analyses of Basic passwords (see below) with 15,000 plaintext passwords sampled from the RockYou gaming site leak [67] and another 15,000 sampled from a Yahoo! Voices leak [22]. As we detail in Appendix A.4, our Basic passwords and comparable passwords from these two real leaks yielded approximately the same results.

Next, we detail our datasets, summarized in Table 1. The **Basic** set comprises 3,062 passwords collected for a research study requiring a minimum length of 8 characters [31]. As we discuss in Section 4, the vast majority of 8-character passwords can be guessed using off-the-shelf, automated approaches. Hence, we give particular attention to longer and more complex passwords, which will likely represent best practices moving forward.

System administrators commonly require passwords to contain multiple character classes (lowercase letters, uppercase letters, digits, and symbols). The **Complex** set comprises passwords required to contain 8+ characters, include all 4 character classes, and not be in a cracking wordlist [46] after removing digits and symbols. They were also collected for research [42].

Recent increases in hashing speeds have made passwords of length 8 or less increasingly susceptible to offline guessing [24, 31]. We therefore examine 2,054 **LongBasic** passwords collected for research [31] that required a a minimum length of 16 characters. Finally, we

Table 1: Characteristics of passwords per set, including the percentage of characters that were lowercase (LC) or uppercase (UC) letters, digits, or symbols (Sym).

		Length	% of Characters			
Set	#	Mean (σ)	LC	UC	Digit	Sym
Basic	3,062	9.6 (2.2)	68	4	26	1
Complex	3,000	10.7 (3.2)	51	14	25	11
LongBasic	2,054	18.1 (3.1)	73	4	20	2
LongComplex	990	13.8 (2.6)	57	12	22	8

examine 990 **LongComplex** passwords, also collected for research [56], that needed to contain 12+ characters, including characters from 3 or more character classes.

3.2 Training Data

To compare cracking approaches as directly as possible, we used the same training data for each. That said, each algorithm uses training data differently, making perfectly equivalent comparisons impossible.

Our training data comprised leaked passwords and dictionaries. The passwords were from breaches of MySpace, RockYou, and Yahoo! (excluding the aforementioned 30,000 passwords analyzed in Appendix A.4). Using leaked passwords raises ethical concerns. We believe our use of such sets in this research is justifiable because the password sets are already available publicly and we exclude personally identifiable information, such as usernames. Furthermore, malicious agents use these sets in attacks [23]; failure to consider them in our analyses may give attackers an advantage over those who work in defensive security.

Prior research has found including natural-language dictionaries to work better than using just passwords [31, 69]. We used the dictionaries previously found most effective: all single words in the Google Web corpus [26], the UNIX dictionary [1], and a 250,000-word inflection dictionary [55]. The combined set of passwords and dictionaries contained 19.4 million unique entries. For cracking approaches that take only a wordlist, without frequency information, we ordered the wordlist by descending frequency and removed duplicates. We included frequency information for the other approaches.

3.3 Simulating Password Cracking

To investigate the degree to which research results can be biased by the choice of cracking algorithm, as well as how automated approaches compare to real attacks, we investigated two cracking tools and two probabilistic algorithms. We selected approaches based on their popularity in the academic literature or the password-cracking community, as well as their conceptual distinctness. We also contracted a computer security firm specializing in password cracking for the real-world attack.

Most cracking approaches do not natively provide guess numbers, and instrumenting them to calculate guessability was typically far from trivial. Because this instrumentation enabled the comparisons in this paper and can similarly support future research, we include many details in this section about this instrumentation. Furthermore, in Section 5, we introduce a Password Guessability Service so that other researchers can leverage our instrumentation and computational resources.

For each approach, we analyze as many guesses as computationally feasible, making 100 trillion (10^{14}) guesses for some approaches and ten billion (10^{10}) guesses for the most resource-intensive approach. With the exception of Hashcat, as explained below, we filter out guesses that do not comply with a password set's composition policy. For example, a LongComplex password's guess number excludes guesses with under 12 characters or fewer than 3 character classes.

We define **Min**$_{\text{auto}}$ as the minimum guess number (and therefore the most conservative security result) for a given password across our automated cracking approaches. This number approximates the best researchers can expect with well-configured automation.

In the following subsections, we detail the configuration (and terminology) of the five approaches we tested. We ran CPU-based approaches (JTR, PCFG, Markov) on a 64-core server. Each processor on this server was an AMD Opteron 6274 running at 1.4Ghz. The machine had 256 GB of RAM and 15 TB of disk. Its market value is over $10,000, yet we still faced steep resource limitations generating Markov guesses. We ran Hashcat (more precisely, oclHashcat) on a machine with six AMD R9 270 GPUs, 2 GB of RAM, and a dual-core processor.

Probabilistic context-free grammar Weir et al.'s probabilistic context-free grammar (termed **PCFG**) [70] has been widely discussed in recent years. We use Komanduri's implementation of PCFG [32], which improves upon the guessing efficiency of Weir et al.'s work [70] by assigning letter strings probabilities based on their frequency in the training data and assigning unseen strings a non-zero probability. This implementation is a newer version of Kelley et al.'s implementation of PCFG as a lookup table for quickly computing guess numbers, rather than enumerating guesses [31].

Based on our initial testing, discussed further in Section 4.1, we prepend our training data, ordered by frequency, before PCFG's first guess to improve performance. As a result, we do not use Komanduri's hybrid structures [32], which serve a similar purpose. We weight passwords 10× as heavily as dictionary entries.

We were able to simulate 10^{12} guesses for Complex passwords and 10^{14} guesses for the other three sets.

Markov model Second, we evaluated the **Markov**-model password guesser presented by Ma et al. [40], which implemented a number of variants differing by order and approaches to smoothing. We use the order-5 Markov-chain model, which they found most effective for English-language test sets. We tried using both our combined training data (dictionaries and paswords) using the same weighting as with PCFG, as well as only the passwords from our training data. The combined training data and passwords-only training data performed nearly identically. We report only on the combined training data, which was slightly more effective for Basic passwords and is most consistent with the other approaches.

We used Ma et al.'s code [40], which they shared with us, to enumerate a list of guesses in descending probability. We used a separate program to remove guesses that did not conform to the given password-composition policy. Because this approach is extremely resource-intensive, both conceptually (traversing a very large tree) and in its current implementation, we were not able to analyze as many guesses as for other approaches. As with PCFG, we found prepending the training data improved performance, albeit only marginally for Markov. Therefore, we used this tweak. We simulated over 10^{10} guesses for Basic passwords, similar to Ma et al. [40].

John the Ripper We also tested variants of a mangled wordlist attack implemented in two popular software tools. The first tool, John the Ripper (termed **JTR**), has been used in a number of prior studies as a security metric, as described in Section 2. In most cases, these prior studies used JTR with its stock mangling rules. However, pairing the stock rules with our 19.4-million-word wordlist produced only 10^8 guesses for Basic passwords. To generate more guesses, we augment the stock rules with 5,146 rules released for DEF CON's "Crack Me If You Can" (CMIYC) password-cracking contest in 2010 [35]. Specifically, we use Trustwave SpiderLabs' reordering of these rules for guessing efficiency [64]. Our JTR tests therefore use the stock mangling rules followed by the Spiderlabs rules. For completeness, Appendix A.2 presents these rules separately.

Instrumenting JTR to calculate precise guess numbers was an involved process. We used `john-1.7.9-jumbo` with the `--stdout` flag to output guesses to standard out. We piped these guesses into a program we wrote to perform a regular expression check filtering out guesses that do not conform to the given password policy. This program then does a fast hash table lookup with GNU `gperf` [27] to quickly evaluate whether a guess matches a password in our dataset. Using this method, we achieved a throughput speed of 3 million guesses per second and made more than 10^{13} guesses for Basic passwords.

Hashcat While Hashcat is conceptually similar to JTR, we chose to also include it in our tests for two reasons. First, we discovered in our testing that JTR and Hashcat iterate through guesses in a very different order, leading to significant differences in the efficacy of guessing specific passwords. JTR iterates through the entire wordlist using one mangling rule before proceeding to the subsequent mangling rule. Hashcat, in contrast, iterates over all mangling rules for the first wordlist entry before continuing to the subsequent wordlist entry.

Second, the GPU-based oclHashcat, which is often used in practice [23, 24, 36, 51], does not permit users to filter guesses that do not meet password-composition requirements except for computationally expensive hash functions. We accept this limitation both because it represents the actual behavior of a popular closed-source tool and because, for fast hashes like MD5 or NTLM, guessing without filtering cracks passwords faster in practice than applying filtering.

Unlike JTR, Hashcat does not have a default set of mangling rules, so we evaluated several. We generally report on only the most effective set, but detail our tests of four different rule sets in Appendix A.3. This most effective rule set, which we term **Hashcat** throughout the paper, resulted from our collaboration with a Hashcat user and password researcher from MWR InfoSecurity [25, 44], who shared his mangling rules for the purpose of this analysis. We believe such a configuration represents a typical expert configuration of Hashcat.

We used `oclHashcat-1.21`. While, like JTR, Hashcat provides a debugging feature that streams guesses to standard output, we found it extremely slow in practice relative to Hashcat's very efficient GPU implementation. In support of this study, Hashcat's developers generously added a feature to oclHashcat to count how many guesses it took to arrive at each password it cracked. This feature is activated using the flag `--outfile-format=11` in `oclHashcat-1.20` and above. We therefore hashed the passwords in our datasets using the NTLM hash function, which was the fastest for Hashcat to guess in our benchmarks. We then used Hashcat to actually crack these passwords while counting guesses, with throughput of roughly 10 billion guesses per second on our system. We made more than 10^{13} guesses for Basic passwords, along with nearly 10^{15} guesses for some alternate configurations reported in Appendix A.3.

Professional cracker An open question in measuring password guessability using off-the-shelf, automated tools is how these attacks compare to an experienced, real-world attacker. Such attackers manually customize and dynamically update their attacks based on a target set's characteristics and initial successful cracks.

To this end, we contracted an industry leader in professional password recovery services, KoreLogic (termed **Pros**), to attack the password sets we study. We believe KoreLogic is representative of expert password crackers because they have organized the DEF CON "Crack Me If You Can" password-cracking contest since 2010 [36] and perform password-recovery services for many Fortune-500 companies [38]. For this study, they instrumented their distributed cracking infrastructure to count guesses.

Like most experienced crackers, the KoreLogic analysts used tools including JTR and Hashcat with proprietary wordlists, mangling rules, mask lists, and Markov models optimized over 10 years of password auditing. Similarly, they dynamically update their mangling rules (termed *freestyle rules*) as additional passwords are cracked. To unpack which aspects of a professional attack (e.g., proprietary wordlists and mangling rules, freestyle rules, etc.) give experienced crackers an advantage, we first had KoreLogic attack a set of 4,239 Complex passwords (distinct from those reported in our other tests) in artificially limited configurations.

We then had the professionals attack the Complex, LongBasic, and LongComplex passwords with no artificial limitations. An experienced password analyst wrote freestyle rules for each set before cracking began, and again after 10^{13} guesses based on the passwords guessed to that point. They made more than 10^{14} guesses per set.

LongBasic and LongComplex approaches are rare in corporate environments and thus relatively unfamiliar to real-world attackers. To mitigate this unfamiliarity, we randomly split each set in two and designated half for training and half for testing. We provided analysts with the training half (in plaintext) to familiarize them with common patterns in these sets. Because we found that automated approaches can already crack most Basic passwords, rendering them insecure, we chose not to have the professionals attack Basic passwords.

3.4 Computational Limitations

As expected, the computational cost of generating guesses in each approach proved a crucial limiting factor in our tests. In three days, oclHashcat, the fastest of our approaches, produced 10^{15} guesses using a single AMD R9 290X GPU (roughly a $500 value). In contrast, the Markov approach (our slowest) required three days on a roughly $10,000 server (64 AMD Opteron 6274 CPU cores and 256 GB of RAM) to generate 10^{10} guesses without computing a single hash. In three days on the same machine as Markov, PCFG simulated 10^{13} guesses.

The inefficiency of Markov stems partially from our use of a research implementation. Even the most efficient implementation, however, would still face substantial conceptual barriers. Whereas Hashcat and JTR incur the same performance cost generating the quadrillionth guess as the first guess, Markov must maintain a tree of substring probabilities. As more guesses are desired, the tree must grow, increasing the cost of both storing and traversing it. While Markov produced a high rate of successful guesses per guess made (see Section 4.2), the cost of generating guesses makes it a poor choice for computing guessability beyond billions of guesses.

Further, our automated approaches differ significantly in how well they handle complex password-composition policies. For PCFG, non-terminal structures can be pruned before guessing starts, so only compliant passwords are ever generated. As a result, it takes about equal time for PCFG to generate Basic passwords as LongComplex passwords. In contrast, Markov must first generate all passwords in a probability range and then filter out non-compliant passwords, adding additional overhead per guess. JTR has a similar generate-then-filter mechanism, while Hashcat (as discussed above) does not allow this post-hoc filtering at all for fast hashes. This means that Markov and JTR take much longer to generate valid LongComplex guesses than Basic guesses, and Hashcat wastes guesses against the LongComplex set.

As a result of these factors, the largest guess is necessarily unequal among approaches we test, and even among test sets within each approach. To account for this, we only compare approaches directly at equivalent guess numbers. In addition, we argue that these computational limitations are important in practice, so our findings can help researchers understand these approaches and choose among them appropriately.

4 Results

We first show, in Section 4.1, that for each automated guessing approach we evaluated, different seemingly reasonable configurations produce very different cracking results, and that out-of-the-box configurations commonly used by researchers substantially underestimate password vulnerability.

Next, in Section 4.2, we examine the relative performance of the four automated approaches. We find they are similarly effective against Basic passwords. They have far less success against the other password sets, and their relative effectiveness also diverges.

For the three non-Basic sets, we also compare the automated approaches to the professional attack. Pros outperform the automated approaches, but only after a large number of guesses. As Pros crack more passwords, their manual adjustments prove quite effective; automated approaches lack this feedback mechanism. We also find that, at least through 10^{14} guesses, automated approaches can conservatively approximate human password-cracking experts, but only if a password is counted as guessed when *any* of the four automated approaches guesses it. A single approach is not enough.

In Section 4.3, we explore the degree to which different cracking approaches overlap in which particular passwords they guess. While multiple approaches successfully guess most Basic passwords, many passwords in the other classes are guessed only by a single approach. We also find that different cracking approaches provide systematically different results based on characteristics like the number of character classes in a password.

In Section 4.4, we revisit how the choice of guessing approach impacts research questions at a high level (e.g., how composition policies impact security) and lower level (e.g., if a particular password is hard to guess). While we find analyses on large, heterogeneous sets of passwords to be fairly robust, security estimates for a given password are very sensitive to the approach used.

4.1 The Importance of Configuration

We found that using any guessing approach naively performed far more poorly, sometimes by more than an order of magnitude, than more expert configurations.

Stock vs advanced configurations We experimented with several configurations each for Hashcat and JTR, including the default configurations they ship with, and observed stark differences in performance. We detail a few here; others are described in Appendices A.2 and A.3.

For example, Hashcat configured with the (default) Best64 mangling rules guessed only about 2% of the Complex passwords before running out of guesses. Using the mangling rules described in Section 3, it made far more guesses, eventually cracking 30% (Figure 1).

Similarly, JTR guessed less than 3% of Complex passwords before exhausting its stock rules. The larger set of rules described in Section 3 enabled it to guess 29% (see Appendix A.2 for details). We found similar configuration effects for LongComplex passwords, and analogous but milder effects for the Basic and LongBasic sets.

We also compared the PCFG implementation we use throughout the paper [32] with our approximation of the originally published algorithm [70], which differs in how probabilities are assigned (see Section 3). As we detail in Appendix A.1, the newer PCFG consistently outperforms the original algorithm; the details of the same conceptual approach greatly impact guessability analyses.

Choices of training data The performance of PCFG and Markov depends heavily on the quality of training data. Our group previously found that training with closely related passwords improves performance [31]. For our non-basic password sets, however, closely matched data is not available in publicly leaked sets.

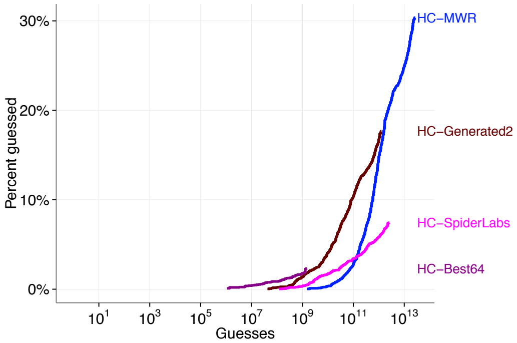

Figure 1: Results of Hashcat configured using the same wordlist, but different sets of mangling rules (described in Appendix A.3), to guess Complex passwords.

In tests reported in Appendix A.1, we thus incorporated closely matched data via cross-validation, in which we iteratively split the test set into training and testing portions. Using cross-validation improved guessing efficiency for three of the four password sets, most dramatically for LongBasic. This result demonstrates that an algorithm trained with generic training data will miss passwords that are vulnerable to an attacker who has training data that closely matches a target set. To minimize differences across approaches, however, PCFG results in the body of the paper use generic training data only.

Actionable takeaways Together, these results suggest that a researcher must carefully manage guessing configuration before calculating password guessability. In particular, tools like JTR and Hashcat will "out of the box" systematically underestimate password guessability. Unfortunately, many existing research studies rely on unoptimized configurations [11, 14, 15, 20, 21, 28, 34, 71].

While we report on the configurations we found most effective in extensive testing, we argue that the research community should establish configuration best practices, which may depend on the password sets targeted.

4.2 Comparison of Guessing Approaches

We first show that automated approaches differ in effectiveness based on the nature of the password sets being cracked and the number of guesses at which they are compared. We then compare these automated approaches to cracking by an expert attacker making dynamic updates, finding that the expert lags in initial guessing efficiency, yet becomes stronger over time. We find the minimum guess number across automated approaches can serve as a conservative proxy for guessability by an expert attacker.

4.2.1 Guessing by Automated Approaches

On some password sets and for specific numbers of guesses, the performance of all four approaches was similar (e.g., at 10^{12} guesses all but Markov had guessed 60-70% of Basic passwords). In contrast, on other sets, their performance was inconsistent at many points that would be relevant for real-world cracking (e.g., PCFG cracked 20% of Complex passwords by 10^{10} guesses, while Hashcat and JTR had cracked under 3%).

As shown in Figure 2, all four automated approaches were quite successful at guessing Basic passwords, the most widely used of the four classes. Whereas past work has found that, for password sets resembling our Basic passwords, PCFG often guesses more passwords than JTR [16] or that Markov performs significantly better than PCFG [40], good configurations of JTR, Markov, and PCFG performed somewhat similarly in our tests. Hashcat was less efficient at generating successful guesses in the millions and billions of guesses, yet it surpassed JTR by 10^{12} guesses and continued to generate successful guesses beyond 10^{13} guesses.

The four automated approaches had far less success guessing the other password sets. Figure 3 shows the guessability of the Complex passwords under each approach. Within the first ten million guesses, very few passwords were cracked by any approach. From that point until its guess cutoff, PCFG performed best, at points having guessed nearly ten times as many passwords as JTR. Although its initial guesses were often successful, the conceptual and implementation-specific performance issues we detailed in Section 3.4 prevented Markov from making over 100 million valid Complex guesses, orders of magnitude less than the other approaches we examined. A real attack using this algorithm would be similarly constrained.

Both Hashcat and JTR performed poorly compared to PCFG in early Complex guessing. By 10^9 guesses, each had each guessed under 3% of Complex passwords, compared to 20% for PCFG. Both Hashcat and JTR improve rapidly after 10^{10} guesses, however, eventually guessing around 30% of Complex passwords.

JTR required almost 10^{12} guesses and Hashcat required over 10^{13} guesses to crack 30% of Complex passwords. As we discuss in Section 4.3, there was less overlap in which passwords were guessed by multiple automated approaches for Complex passwords than for Basic passwords. As a result, the Min_{auto} curve in Figure 3, representing the smallest guess number per password across the automated approaches, shows that just under 10^{11} guesses are necessary for 30% of Complex passwords to have been guessed by at least one automated approach. Over 40% of Complex passwords were guessed by at least one automated approach in 10^{13} guesses.

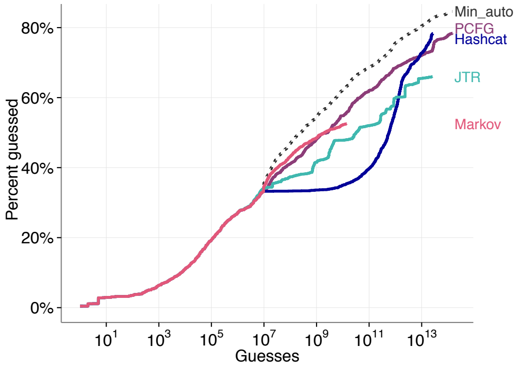

Figure 2: Automated approaches' success guessing Basic passwords. Min_{auto} represents the smallest guess number for a password by any automated approach.

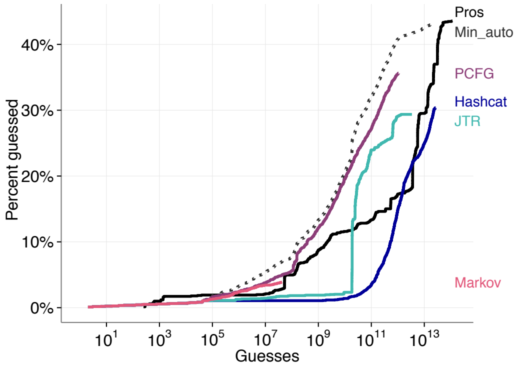

Figure 3: Success guessing Complex passwords. Pros are experts updating their guessing strategy dynamically.

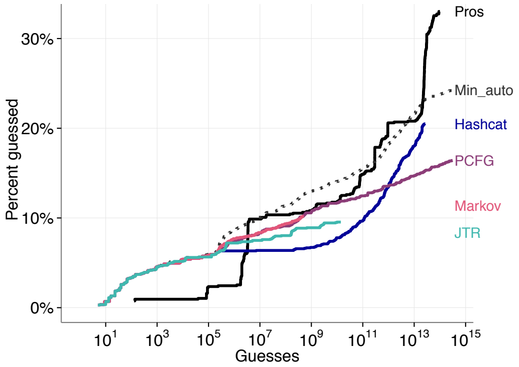

Figure 4: Success guessing LongBasic passwords.

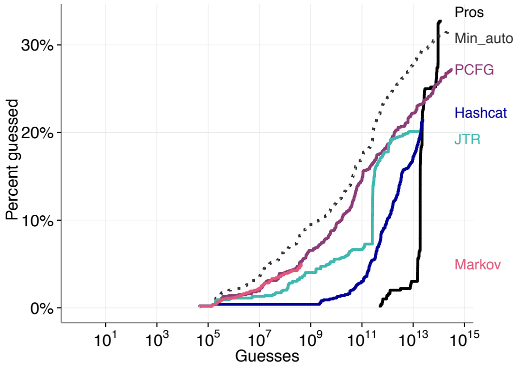

Figure 5: Success guessing LongComplex passwords.

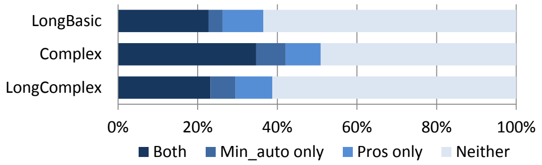

Figure 6: The proportion of passwords guessed by Min_{auto}, Pros, both, or neither within 10^{14} guesses.

LongBasic passwords were also challenging for all approaches to guess, though relative differences across approaches are not as stark as for Complex passwords. Markov was marginally more successful than other approaches at its cutoff just before 10^9 guesses. JTR and PCFG both continued to generate successful guesses through when JTR exhausted its guesses after guessing 10% of the passwords. Hashcat lagged slightly behind JTR at 10^9 guesses (7% cracked vs ∼9%), but was able to make more guesses than either, eventually guessing over 20% of the passwords, compared to 16% for PCFG and 10% for JTR at those approaches' guess cutoffs.

As with LongBasic passwords, all approaches had difficulty guessing LongComplex passwords. As shown in Figure 5, nearly 70% of LongComplex passwords were not guessed by any of the approaches we examined even after trillions of guesses. The relative performance of the four automated guessing approaches for LongComplex passwords again differed noticeably. Markov and PCFG again outperformed other approaches early. Markov guessed 5% of the passwords after 10^8 guesses, yet reached its guess cutoff soon thereafter. At 10^9 guesses PCFG and JTR had both also guessed at least 5% of the passwords, compared to almost no passwords guessed by Hashcat. PCFG's and JTR's performance diverged and then converged at higher guess numbers. Hashcat caught up at around 10^{13} guesses, cracking 20% of LongComplex passwords.

4.2.2 Guessing by Pros

As we expected, Pros guessed more passwords overall than any of the automated approaches. As we discussed in Section 3, we chose not to have Pros attack Basic passwords because those passwords could be guessed with automated approaches alone. As shown in Figures 3–5, within 10^{14} guesses Pros cracked 44% of Complex passwords, 33% of LongBasic passwords, and 33% of LongComplex passwords, improving on the guessing of the best automated approach.

Three aspects of guessing by Pros were particularly notable. First, even though Pros manually examined half of each password set and adjusted their mangling rules and wordlists before making the first guess against each set, automated approaches were often more successful at early guessing. For example, Markov surpassed Pros at guessing Complex passwords in the first 10^2 guesses and again from around 10^6 till Markov's guess cutoff at 5×10^7. Similarly, all four automated approaches guessed LongComplex passwords more successfully than Pros from the start of guessing until past 10^{13} guesses. All approaches guessed LongBasic passwords better than Pros for the first 10^6 guesses.

Second, while Pros lagged in early guessing, the freestyle rules an experienced analyst wrote at 10^{13} guesses proved rather effective and caused a large spike in successful guesses for all three password sets. Hashcat, the only automated approach that surpassed 10^{13} guesses for all sets, remained effective past 10^{13} guesses, yet did not experience nearly the same spike.

Third, while Pros were more successful across password sets once a sufficiently high number of guesses had been reached, the automated approaches we tested had guessing success that was, to a very rough approximation, surprisingly similar to Pros. As we discussed in Section 4.1 and discuss further in the appendix, this success required substantial configuration beyond each approach's performance out of the box.

We found that our Min_{auto} metric (the minimum guess number for each password across Hashcat, JTR, Markov, and PCFG) served as a conservative approximation of the success of Pros, at least through our automated guess cutoffs around 10^{13} guesses. As seen in Figures 3–6, Pros never substantially exceeded Min_{auto}, yet often performed worse than Min_{auto}.

Professional cracking with limitations To unpack why professional crackers have an advantage over novice attackers, we also had KoreLogic attack a different set of Complex passwords in artificially limited configurations. These limitations covered the wordlists they used, the mangling rules they used, and whether they were permitted to write freestyle rules. To avoid biasing subsequent tests, we provided them a comparable set of 4,239 Complex passwords [31] distinct from those examined in the rest of the paper. We call this alternate set $\textbf{Complex}_{pilot}$.

As shown in Table 2, we limited Pros in Trial 1 to use the same wordlist we used elsewhere in this paper and did not allow freestyle rules. In Trial 2, we did not limit the wordlist, but did limit mangling rules to those used in the 2010 Crack Me If You Can contest [35]. In Trial 3 and Trial 4, we did not limit the starting wordlist or mangling rules. In Trial 4, however, KoreLogic analysts dynamically adjusted their attacks through freestyle rules and wordlist tweaks after 10^{14} guesses.

We found that KoreLogic's set of proprietary mangling rules had a far greater impact on guessing efficiency than their proprietary wordlist (Figure 7). Furthermore, as evidenced by the difference between Trial 3

Table 2: The four trials of Pros guessing Complex$_{pilot}$. We artificially limited the first three trials to uncover why Pros have an advantage over more novice attackers.

Trial	Wordlist	Rules	Freestyle Rules
1	CMU wordlist	Anything	None
2	Anything	2010 CMIYC rules	None
3	Anything	Anything	None
4	Anything	Anything	Unlimited

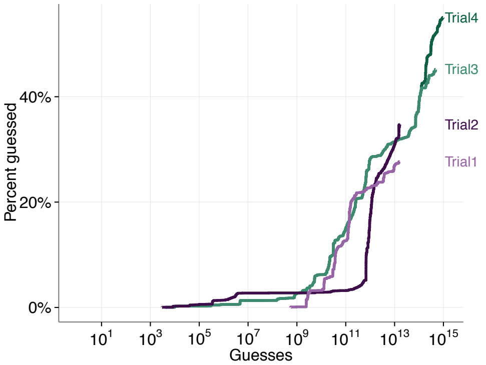

Figure 7: Complex$_{pilot}$ guessability by trial.

and Trial 4, freestyle rules also had a major impact at the point the analyst wrote them.

Actionable takeaways One conceptual advantage of parameterized metrics is that they model an attack using existing cracking approaches. However, it has long been unclear whether automated cracking approaches used by researchers effectively model the dynamically updated techniques used by expert real-world attackers. Our results demonstrate that only by considering multiple automated approaches in concert can researchers approximate professional password cracking.

One of our primary observations, both from comparing Pros to the automated approaches and from our trials artificially limiting Pros (Section 4.2.2), is that dynamically updated freestyle rules can be highly effective. This result raises the question of to what extent automated approaches can model dynamic updates. Although the adversarial cracking community has discussed techniques for automatically generating mangling rules from previous cracks [41], researchers have yet to leverage such techniques, highlighting an area ripe for future work.

Contrary to prior research (e.g., [16, 40]), we found that Hashcat, JTR, Markov, and PCFG all performed relatively effectively when configured and trained according to currently accepted best practices in the cracking and research communities. That said, our tests also highlighted a limitation of the guessability metric in not considering the performance cost of generating a guess. Despite its real-world popularity, Hashcat performed comparatively poorly until making trillions of guesses, yet generated guesses very quickly.

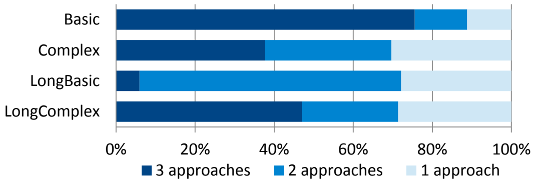

Figure 8: Number of automated approaches, excluding Markov, that cracked a particular password. We ignore passwords not guessed by any approach and use the same guess cutoff for all guessing approaches within a set.

If hashing a guess is the dominant time factor, as is the case for intentionally slow hash functions like bcrypt, PBKDF2, and scrypt, probabilistic approaches like Markov and PCFG are advantageous for an attacker. For fast hash functions like MD5 or NTLM, Hashcat's speed at generating and hashing guesses results in more passwords being guessed in the same wall-clock time. As discussed in Section 3.4, Markov proved comparatively very resource-intensive to run to a large guess number, especially for password sets with complex requirements. These practical considerations must play a role in how researchers select the best approaches for their needs.

4.3 Differences Across Approaches

Next, we focus on differences between approaches. We first examine if multiple approaches guess the same passwords. We then examine the guessability of passwords with particular characteristics, such as those containing multiple character classes or character substitutions. To examine differences across how approaches model passwords, for analyses in this section we do not prepend the training data to the guesses generated by the approach.

4.3.1 Overlap in Successful Guesses

While one would expect any two cracking approaches to guess slightly different subsets of passwords, we found larger-than-expected differences for three of the four password sets. Figure 8 shows the proportion of passwords in each class guessed by all four approaches, or only some subset of them. We exclude passwords guessed by none of the automated approaches. Within a password set, we examine all approaches only up to the minimum guess cutoff among Hashcat, JTR, and PCFG; we exclude Markov due to its low guess cutoffs.

The three approaches guessed many of the same Basic passwords: Three-fourths of Basic passwords guessed by any approach were guessed by all of them. Only 11% of Basic passwords were guessed only by a single ap-

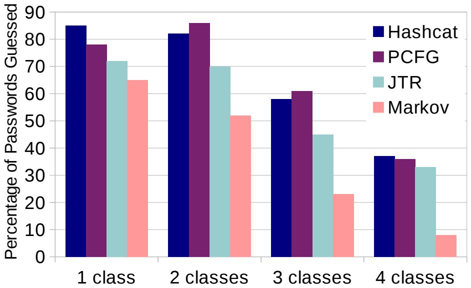

Figure 9: Percentage of Basic passwords each approach guessed, by character-class count.

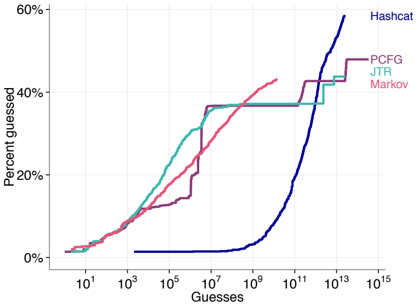

Figure 10: Approaches' effectiveness guessing passwords composed entirely of lowercase letters across sets.

proach. In contrast, only 6% of LongBasic passwords were guessed by all approaches, while 28% of Complex, LongBasic, and LongComplex passwords were guessed only by a single approach.

4.3.2 Guessing Success by Password Characteristics

While it is unsurprising that different approaches do better at guessing distinct types of passwords, we found differences that were large and difficult to predict.

Character classes and length We first considered how efficiently automated approaches guessed passwords relative to their length and character-class count. These two characteristics are of particular interest because they are frequently used in password-composition policies.

As shown in Figure 9, the impact of adding character classes is not as straightforward as one might expect. While the general trend is for passwords with more character classes to be stronger, the details vary. Markov experiences a large drop in effectiveness with each increase in character classes (63% to 52% to 23% to 8%). JTR, by contrast, finds only a minor difference between one and two classes (72% to 70%). PCFG actually increases in effectiveness between one and two classes (78% to 86%). Since changes in security and usability as a result of different policies are often incremental (e.g., [8]), the magnitude of these disagreements can easily affect research conclusions about the relative strength of passwords.

In contrast, we did not find surprising idiosyncrasies based on the length of the password. For all approaches, cracking efficiency decreased as length increased.

Character-level password characteristics As the research community seeks to understand the characteristics of good passwords, a researcher might investigate how easy it is to guess all-digit passwords, which are common [6], or examine the effect of character substitutions (e.g., *$Hplovecraft!$* → *$Hpl0v3cr@ft!$*) on guessability. Despite their sometimes similar effectiveness overall, approaches often diverged when guessing passwords that had these characteristics. As a result, researchers using different approaches could draw different conclusions about the guessability of these properties.

The guessability of the 1,490 passwords (across sets) composed entirely of lowercase letters varied starkly by guessing approach. This variation is particularly notable because such passwords made up 29% of Basic and LongBasic passwords, and were impermissible under the other two composition policies. As shown in Figure 10, Hashcat guessed few such passwords until well into the billions of guesses, whereas Markov successfully guessed passwords composed entirely of lowercase letters throughout its attack. In contrast, PCFG had a large spike in successful guesses between 1 million and 10 million guesses, but then plateaued. JTR had early success, but similarly plateaued from 10 million guesses until into the trillions of guesses.

Similarly, approaches differed in their efficiency guessing passwords containing character substitutions, which we identified using crowdsourcing on Amazon's Mechanical Turk. Passwords identified by crowdworkers as containing character substitutions included *4Everblessed*, *B1cycle_Race*, and *Ca$hmoneybr0*. PCFG performed poorly relative to JTR and Markov at guessing passwords with character substitutions. A researcher using only PCFG could mistakenly believe these passwords are much stronger than they actually are. We found similar differences with many other common characteristics, potentially skewing research conclusions.

Actionable takeaways Given the many passwords guessed by only a single cracking approach and the systematic differences in when passwords with certain characteristics are guessed, we argue that researchers must consider major cracking approaches in parallel.

Our results also show how comparative analyses uncover relative weaknesses of each approach. Upon close examination, many of these behaviors make sense. For example, PCFG abstracts passwords into structures of non-terminal characters based on character class, ignoring contextual information across these boundaries. As a result, *P@ssw0rd* would be split into "P," "@," "ssw," "0," and "rd," explaining PCFG's poor performance guessing passwords with character substitutions.

4.4 Robustness of Analyses to Approach

In this section, we examine whether differences among automated cracking approaches are likely to affect conclusions to two main types of research questions.

We first consider analyses of password sets, such as passwords created under particular password-composition policies. We find such analyses to be somewhat, but not completely, robust to the approach used.

In contrast, per-password analyses are very sensitive to the guessing approach. Currently, such analyses are mainly used in security audits [61] to detect weak passwords. In the future, however, per-password strength metrics may be used to provide detailed feedback to users during password creation, mirroring the recent trend of data-driven password meters [10, 33]. The ability to calculate a guess number per-password is a major advantage of parameterized metrics over statistical metrics, yet this advantage is lost if guess numbers change dramatically when a different approach is used. Unfortunately, we sometimes found huge differences across approaches.

4.4.1 Per Password Set

As an example of an analysis of large password sets, we consider the relative guessability of passwords created under different composition policies, as has been studied by Shay et al. [56] and Kelley et al. [31].

Figure 11 shows the relative guessability of the three password sets examined by the Pros. LongBasic passwords were most vulnerable, and LongComplex passwords least vulnerable, to early guessing (under 10^9 guesses). Between roughly 10^9 and 10^{12} guesses, LongBasic and Complex passwords followed similar curves, though Complex passwords were cracked with higher success past 10^{12} guesses. Very few LongComplex passwords were guessed before 10^{13} guesses, yet Pros quickly guessed about one-third of the LongComplex set between 10^{13} and 10^{14} guesses.

Performing the same analysis using Min_{auto} guess numbers instead (Figure 12) would lead to similar conclusions. LongBasic passwords were again more vulnerable than Complex or LongComplex under 10^8 guesses. After 10^{12} guesses, Complex passwords were easier to guess than LongBasic or LongComplex passwords. Basic passwords were easy to guess at all points. The main difference between Min_{auto} and Pros was that LongComplex passwords appear more vulnerable to the first 10^{12} guesses under Min_{auto} than Pros.

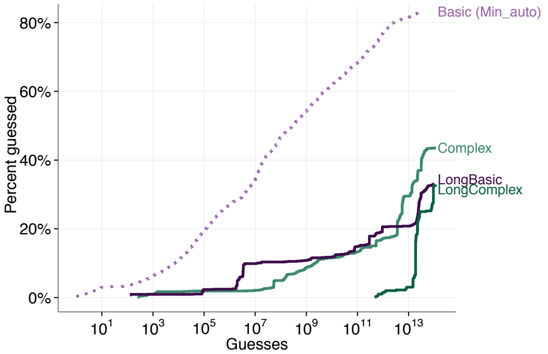

Figure 11: Pros' comparative success guessing each password. For reference, the dotted line represents the Min_{auto} guess across automated approaches for Basic passwords, which the Pros did not try to guess.

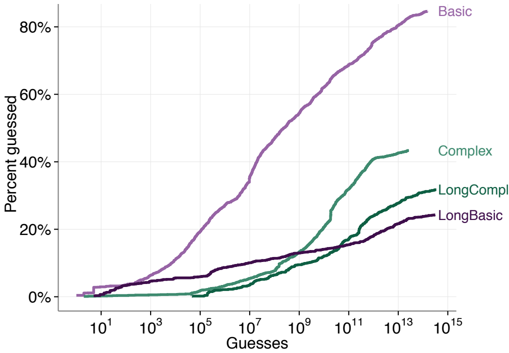

Figure 12: The guessability of all four password sets under Min_{auto}, representing the smallest guess number for each password across all four automated approaches.

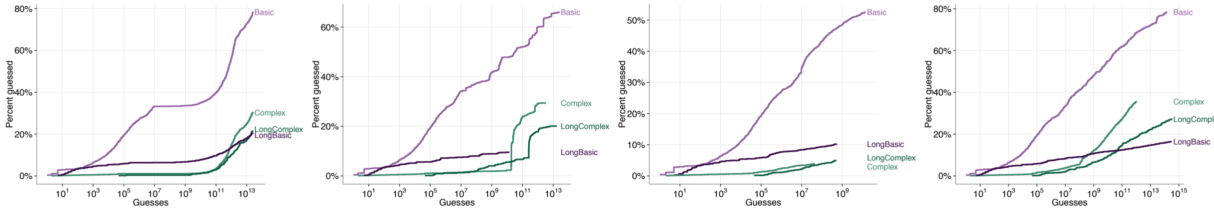
Based on this data, a researcher comparing composition policies would likely reach similar conclusions using either professionals or a combination of automated approaches. As shown in Figure 13, we repeated this analysis using each of the four automated approaches in isolation. Against every approach, Basic passwords are easily guessable, and LongBasic passwords are comparatively vulnerable during early guessing. After trillions of guesses, Hashcat, PCFG, and JTR find Long Complex passwords more secure than Complex passwords. In each case, a researcher would come to similar conclusions about the relative strength of these password sets.

4.4.2 Per Individual Password

Analyses of the strength of individual passwords, in contrast, proved very sensitive to the guessing approach. Although one would expect different approaches to guess passwords at somewhat different times, many passwords' guess numbers varied by orders of magnitude across approaches. This state of affairs could cause a very weak password to be misclassified as very strong.

We examined per-password differences pairwise among JTR, Markov, and PCFG, using the same guess



(a) Hashcat guessability. (b) JTR guessability. (c) Markov guessability. (d) PCFG guessability.

Figure 13: The relative guessability of the four different password sets under each of the four automated cracking approaches considered in isolation. The research conclusions would be fairly similar in each case.

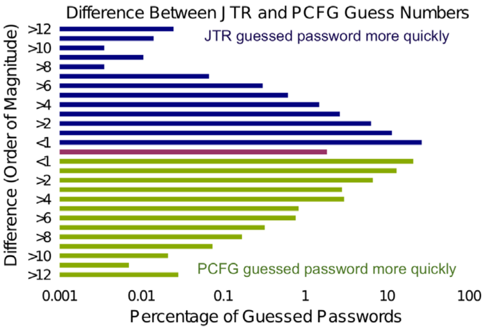


Figure 14: The % (log scale) of passwords guessed by JTR or PCFG whose guess numbers differed by a given order of magnitude. e.g., the blue > 6 bar represents passwords guessed by JTR more than 6, but no more than 7, orders of magnitude more quickly than by PCFG.

cutoff for each approach in a pair. Because Hashcat's early guesses were often unsuccessful, we exclude it from this analysis. Passwords not guessed by the guess cutoff were assigned a guess number one past the cutoff, lower-bounding differences between passwords guessed by one approach but not the other. For each password, we calculated the log_{10} of the ratio between guess numbers in the two approaches. For example, *iceman1232* was guess 595,300,840 for JTR and 61,554,045 for Markov, a 0.985 order of magnitude difference.

Among passwords guessed by JTR, PCFG, or both, 51% of passwords had guess numbers differing by more than an order of magnitude between approaches, indicating large variations in the resulting security conclusions. Alarmingly, some passwords had guess numbers differing by over 12 orders of magnitude (Figure 14). For example, *P@ssw0rd!* took JTR only 801 Complex guesses, yet PCFG never guessed it in our tests. Similarly, *1q2w3e4r5t6y7u8i* was the 29th LongBasic JTR guess, yet it was not among the 10^{14} such guesses PCFG made. In contrast, PCFG guessed *Abc@1993* after 48,670 guesses and *12345678password* after 130,555 guesses. JTR never guessed either password.

We found similar results in the two other pairwise comparisons. Among passwords guessed by Markov, PCFG, or both, 41% of guess numbers differed by at least one order of magnitude. In an extreme example, the passwords *1qaz!QAZ* and *1q2w3e4r5t6y7u8i* were among the first few hundred Markov guesses, yet not guessed by PCFG's guess cutoff. Conversely, *unitedstatesofamerica* was among PCFG's first few dozen LongBasic guesses, yet never guessed by Markov. For 37% of passwords, JTR and Markov guess numbers differed by at least one order of magnitude. Markov was particularly strong at guessing long passwords with predictable patterns. For instance, *password123456789*, *1234567890123456*, and *qwertyuiopasdfgh* were among Markov's first thirty guesses, yet JTR did not guess any of them by its cutoff.

Actionable takeaways As researchers and system administrators ask questions about password strength, they must consider whether their choice of cracking approach biases the results. When evaluating the strength of a large, heterogeneous password set, any of Hashcat, JTR, Markov, or PCFG—if configured effectively—provide fairly similar answers to research questions. Nonetheless, we recommend the more conservative strategy of calculating guessability using Min_{auto}.

In contrast, guessability results per-password can differ by many orders of magnitude between approaches even using the same training data. To mitigate these differences, we again recommend Min_{auto} for the increasingly important tasks of providing precise feedback on password strength to users and system administrators.

5 Conclusion

We report on the first broad, scientific investigation of the vulnerability of different types of passwords to guessing by an expert attacker and numerous configurations of off-the-shelf, automated approaches frequently used by researchers. We instrument these approaches, including both adversarial tools and academic research prototypes, to enable precise, guess-by-guess comparisons among automated approaches and between them and the expert.

We find that running a single guessing algorithm, particularly in its out-of-the-box configuration, often yields a very poor estimate of password strength. However, using several such algorithms, well-configured and in parallel, can be a good proxy for passwords' vulnerability to an expert attacker. We also find that while coarse-grained research results targeting heterogeneous sets of passwords are somewhat robust to the choice of (well-configured) guessing algorithm, many other analyses are not. For example, investigations of the effect on password strength of password characteristics, such as the number of character classes and the use of character substitutions, can reach different conclusions depending on the algorithm underlying the strength metric.

Finally, we hope our investigation of the effectiveness of many configurations of popular guessing approaches will help facilitate more accurate and easily reproducible research in the passwords research community. To that end, we have created a Password Guessability Service [9] that enables researchers to submit plaintext passwords and receive guessability analyses like those presented in this paper. We particularly encourage researchers investigating password-cracking algorithms to contribute to this service to improve the comparability of experiments.

A Appendix

We provide additional measurements of how guessing approaches perform in different configurations. To support the ecological validity of our study, we also repeat analyses from the body of the paper on password sets leaked from RockYou and Yahoo. We provide these details in hopes of encouraging greater accuracy and reproducibility across measurements of password guessability.

A.1 Alternate PCFG Configurations

We tested four different PCFG configurations. As in the body of the paper, **PCFG** represents Komanduri's implementation of PCFG [32], which assigns letter strings probabilities based on their frequency in the training data and assigns unseen strings a non-zero probability. For consistency across approaches, we prepend all policy-compliant elements of the training data in lieu of enabling Komanduri's similar hybrid structures [32].

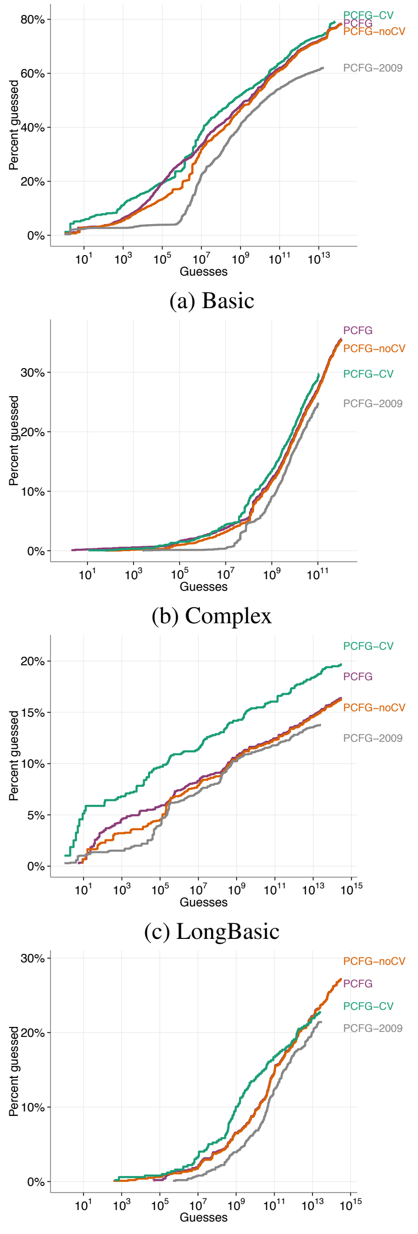
PCFG−noCV is the same as PCFG, but without the training data prepended. **PCFG−CV** is equivalent to PCFG−noCV except for using two-fold cross-validation. In each fold, we used half of the test passwords as additional training data, with a total weighting equal to the generic training data, as recommended by Kelley et al. [31]. **PCFG−2009** is our approximation of the original 2009 Weir et al. algorithm [70] in which alphabetic strings are assigned uniform probability and unseen terminals are a probability of zero.

As shown in Figure 15, prepending the training data and performing cross-validation both usually result in more efficient guessing, particularly for Long and LongBasic passwords. All three other configurations outperform the original PCFG−2009 implementation.

Figure 16 shows the guessability of the 350 passwords comprised only of digits across the Basic and LongBasic sets. Similar to the results for passwords of other common characteristics (Section 4.3.2), approaches differed. Of particular note is PCFG−2009, which plateaued at around 50% of such passwords guessed in fewer than 10 million guesses. Idiosyncratically, through 10^{14} guesses, it would never guess another password of this type because of the way it assigns probabilities.

A.2 Alternate JTR Configurations

We next separately analyze the sets of JTR mangling rules we combined in the body of the paper. **JTR_stock** represents the 23 default rules that come with JTR. **JTR_SpiderLabs** represents 5,146 rules published by KoreLogic during the 2010 DEF CON "Crack Me If You Can" password-cracking contest [35], later reordered for guessing efficiency by Trustwave Spiderlabs [64].



(a) Basic

(b) Complex

(c) LongBasic

(d) LongComplex

Figure 15: The guessing efficiency of the different PCFG configurations we tested.

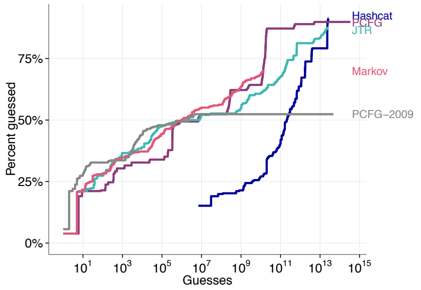


Figure 16: Guessing efficiency for the 350 Basic and LongBasic passwords composed entirely of digits.

As described in Section 3.3, our standard JTR configuration used JTR_stock followed by JTR_SpiderLabs. In isolation (Figure 17), JTR_stock rules were far more efficient on a guess-by-guess basis than JTR_SpiderLabs. Unfortunately, however, they quickly ran out of guesses. We exhausted JTR_stock in making fewer than 10^9 guesses for Basic passwords. More crucially, we made fewer than 10^5 guesses that were valid Complex passwords before exhausting these rules. Thus, any analysis of passwords that uses only the stock rules will vastly underestimate the guessability of passwords that contain (or are required to have) many different character classes.

The sharp jumps in the proportion of Complex and LongComplex passwords guessed by JTR_SpiderLabs result from one group of 13 rules. These rules capitalize the first letter, append digits, append special characters, and append both digits and special characters.

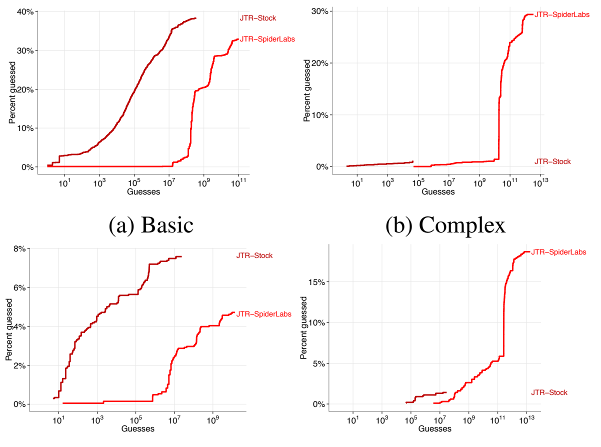
A.3 Alternate Hashcat Configurations

We tested eight Hashcat configurations and chose the one that best combined efficient early guessing with successfully continuing to guess passwords into the trillions of guesses. These configurations consist of four different sets of mangling rules, each with two different wordlists. The smaller wordlist was the same one we used in all other tests (Section 3.2). The larger wordlist augmented the same wordlist with all InsidePro wordlists[1] in descending frequency order and with duplicates removed.

Our four sets of mangling rules are the following:

Hashcat_best64: Although Hashcat does not have a default set of mangling rules, the Best64 mangling rules are often used analogously to JTR's stock rules.

Hashcat_generated2: Hashcat comes with a second set of mangling rules, "generated2." This set comprises 65,536 rules. Dustin Heywood of ATB Financial created them by randomly generating and then testing hundreds of millions of mangling rules over 6 months (2013-2014) on a 42-GPU cluster. The rules were optimized by Hashcat developers by removing semantic equivalents.



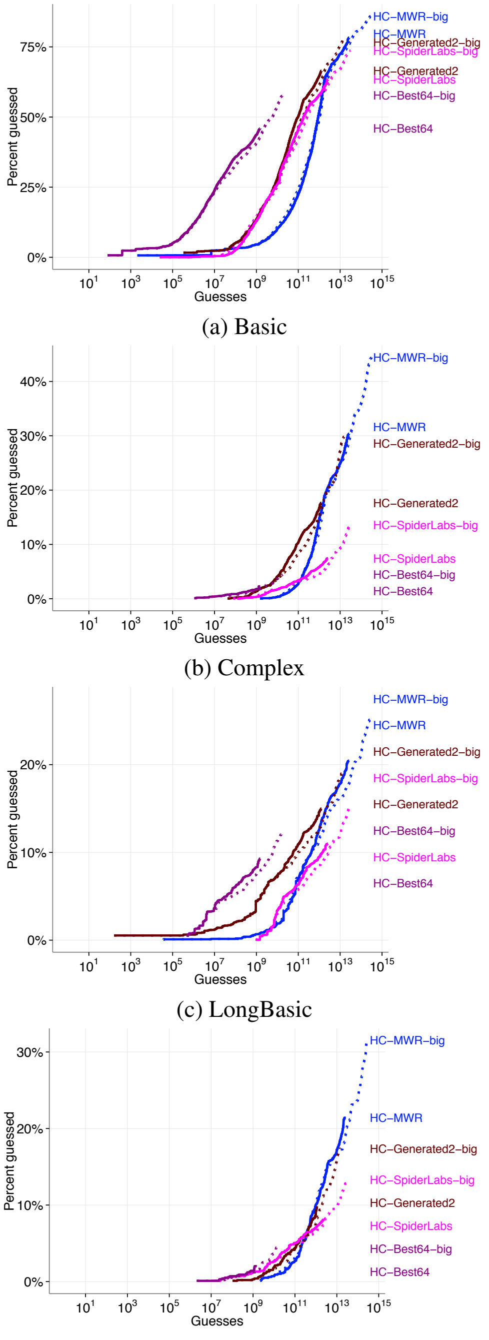
(a) Basic

(b) Complex

(c) LongBasic

(d) LongComplex

Figure 17: The guessing efficiency of JTR rules.



(a) Basic

(b) Complex

(c) LongBasic

(d) LongComplex

Figure 18: The guessing efficiency of Hashcat using four different sets of mangling rules. We tested each set with the wordlist used elsewhere in this paper, as well as a larger (**-big**) wordlist adding the InsidePro dictionaries.

[1] `http://www.insidepro.com/dictionaries.php`

Hashcat_SpiderLabs: We performed a manual translation to Hashcat of the SpiderLabs JTR rules (Section 3), which entailed removing clauses mandating minimum criteria; such rules are not permitted in oclHashcat.
Hashcat_MWR: We collaborated with with Matt Marx of MWR InfoSecurity to obtain the set of 1.4 million mangling rules he uses for password auditing [25, 44]. Following his suggestion, we augmented these rules with the aforementioned SpiderLabs rules.

Using the smaller wordlist, we exhausted all four sets of mangling rules. With the larger wordlist, we did not exhaust any set of rules. The curves in Figure 18 that use this larger dictionary have **-big** appended to the name and are graphed with dotted, rather than solid, lines.

We present the results of these eight configurations in Figure 18. True to their name, the Hashcat_best64 rules were the most efficient at guessing passwords. Unfortunately, they ran out of guesses using the smaller wordlist after only 10^9 guesses. For Complex and LongComplex passwords, Hashcat_best64 therefore guesses only a fraction of the number possible using the other sets of mangling rules, albeit in far fewer guesses. While not the most efficient guess-by-guess, the Hashcat_MWR rules eventually guessed the largest proportion of the different sets, most notably the Complex and LongComplex sets.

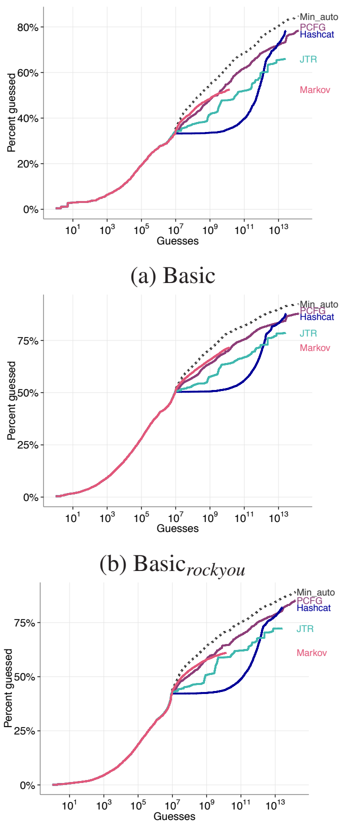
A.4 Ecological validity

To better understand how well our password sets, which we collected for research studies, compare to real plaintext passwords revealed in major password leaks, we compared the efficiency of the four automated cracking approaches in guessing Basic passwords, as well as the following two comparable sets of leaked passwords:
Basic$_{rockyou}$: 15,000 passwords randomly sampled from those containing 8+ characters in the RockYou gaming website leak of more than 32 million passwords [67]
Basic$_{yahoo}$: 15,000 passwords randomly sampled from those containing 8+ characters in the Yahoo! Voices leak of more than 450,000 passwords [22]

We found a high degree of similarity in the guessability of the Basic passwords collected for research and the leaked passwords. As shown in Figure 19, the four automated cracking approaches followed similar curves across the research passwords and the leaked passwords.

This similar guessability is notable because our analyses depend on using passwords collected by researchers for two reasons. First, no major password leak has contained passwords contained under strict composition requirements. Furthermore, in contracting experienced humans to attack the passwords, it was important to have them attack passwords they had not previously examined or tried to guess. Presumably, these experienced analysts would already have examined all major password leaks.

In the body of the paper, we reported how different approaches were impacted differently by the number of character classes contained in Basic passwords. When we repeated this analysis for Basic$_{rockyou}$ and Basic$_{yahoo}$ passwords, we found similar behavior (Figure 20). PCFG was more successful at guessing passwords containing two character classes, as opposed to only a single character class. PCFG only guesses strings that were found verbatim in its training data, which we hypothesize might be the cause of comparatively poor behavior for passwords of a single character class.



(a) Basic

(b) Basic$_{rockyou}$

(c) Basic$_{yahoo}$

Figure 19: The four automated cracking approaches targeting the Basic password set, 15,000 passwords sampled from the RockYou leak, and 15,000 passwords sampled from the Yahoo leak.

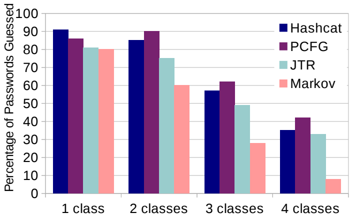


Figure 20: Combined percentage of Basic$_{rockyou}$ and Basic$_{yahoo}$ passwords each approach guessed by the number of character classes in the password.

Sound-Proof: Usable Two-Factor Authentication Based on Ambient Sound

Nikolaos Karapanos, Claudio Marforio, Claudio Soriente and Srdjan Čapkun
Institute of Information Security
ETH Zurich
{*firstname.lastname*}@*inf.ethz.ch*

Abstract

Two-factor authentication protects online accounts even if passwords are leaked. Most users, however, prefer password-only authentication. One reason why two-factor authentication is so unpopular is the extra steps that the user must complete in order to log in. Currently deployed two-factor authentication mechanisms require the user to interact with his phone to, for example, copy a verification code to the browser. Two-factor authentication schemes that eliminate user-phone interaction exist, but require additional software to be deployed.

In this paper we propose Sound-Proof, a usable and deployable two-factor authentication mechanism. Sound-Proof does not require interaction between the user and his phone. In Sound-Proof the second authentication factor is the proximity of the user's phone to the device being used to log in. The proximity of the two devices is verified by comparing the ambient noise recorded by their microphones. Audio recording and comparison are transparent to the user, so that the user experience is similar to the one of password-only authentication. Sound-Proof can be easily deployed as it works with current phones and major browsers without plugins. We build a prototype for both Android and iOS. We provide empirical evidence that ambient noise is a robust discriminant to determine the proximity of two devices both indoors and outdoors, and even if the phone is in a pocket or purse. We conduct a user study designed to compare the perceived usability of Sound-Proof with Google 2-Step Verification. Participants ranked Sound-Proof as more usable and the majority would be willing to use Sound-Proof even for scenarios in which two-factor authentication is optional.

1 Introduction

Software tokens on modern phones are replacing dedicated hardware tokens in two-factor authentication (2FA) mechanisms. Using a software token, in place of a hardware one, improves deployability and usability of 2FA. For service providers, 2FA based on software tokens results in a substantial reduction of manufacturing and shipping costs. From the user's perspective, there is no extra hardware to carry around and phones can accommodate software tokens from multiple service providers.

Despite the improvements introduced by software tokens, most users still prefer password-only authentication for services where 2FA is not mandatory [36, 12]. This is probably due to the extra burden that 2FA causes to the user [25, 51], since it typically requires the user to interact with his phone.

Recent work [14, 41] improves the usability of 2FA by eliminating the user-phone interaction. However, those proposals are not yet deployable as their requirements are not met by today's phones, computers or browsers.

In this paper, we focus on both the usability and deployability aspect of 2FA solutions. We propose Sound-Proof, a two-factor authentication mechanism that is transparent to the user and can be used with current phones and with major browsers without any plugin. In Sound-Proof the second authentication factor is the proximity of the user's phone to the computer being used to log in. When the user logs in, the two devices record the ambient noise via their microphones. The phone compares the two recordings, determines if the computer is located in the same environment, and ultimately decides whether the login attempt is legitimate or fraudulent.

Sound-Proof does not require the user to interact with his phone. The overall user experience is, therefore, close to password-only authentication. Sound-Proof works even if the phone is in the user's pocket or purse, and both indoors and outdoors. Sound-Proof can be easily deployed since it is compatible with current phones, computers and browsers. In particular, it works with any HTML5-compliant browser that implements the WebRTC API [24], which is currently being standardized by the W3C [15]. Chrome, Firefox and Opera already support WebRTC, Internet Explorer plans to support it [31], and we anticipate that other browsers will adopt it soon.

Similar to other approaches that do not require user-phone interaction nor a secure channel between the phone and the computer (e.g., [14]), Sound-Proof is not designed to protect against targeted attacks where the attacker is co-located with the victim and has the victim's login credentials. Our design choice favors usability and deployability over security and we argue that this can edge for larger user adoption.

We have implemented a prototype of Sound-Proof for both Android and iOS. Sound-Proof adds, on average, less than 5 seconds to a password-only login operation. This time is substantially shorter than the time overhead of 2FA mechanisms based on verification codes (roughly 25 seconds [50]). We also report on a user study we conducted which shows that users prefer Sound-Proof over Google 2-Step Verification [22].

In summary, we make the following contributions:

- We propose Sound-Proof, a novel 2FA mechanism that does not require user-phone interaction and is easily deployable. The second authentication factor is the proximity of the user's phone to the computer from which he is logging in. Proximity of the two devices is verified by comparing the ambient audio recorded via their microphones. Recording and comparison are transparent to the user.

- We implement a prototype of our solution for both Android and iOS. We use the prototype to evaluate the effectiveness of Sound-Proof in a number of different settings. We show that Sound-Proof works even if the phone is in the user's pocket or purse and that it fares well both indoors and outdoors.

- We conducted a user study to compare the perceived usability of Sound-Proof and Google 2-Step Verification. Participants ranked the usability of Sound-Proof higher than the one of Google 2-Step Verification, with a statistically significant difference. More importantly, we found that most participants would use Sound-Proof even if 2FA were optional.

The rest of the paper is organized as follows. Section 2 details our assumptions and goals while Section 3 reviews alternative approaches and discusses why they do not fulfill our objectives. Section 4 provides an overview on audio similarity techniques. We present Sound-Proof in Section 5 and its prototype implementation in Section 6. Section 7 evaluates Sound-Proof, while Section 8 reports on our user study. We discuss limitations and ways to further improve Sound-Proof in Section 9. Section 10 reviews related work and Section 11 concludes the paper.

2 Assumptions and Goals

System Model. We assume the general settings of browser-based web authentication. The user has a username and a password to authenticate to a web server. The server implements a 2FA mechanism that uses software tokens on phones.

The user points his browser to the server's webpage and enters his username and password. The server verifies the validity of the password and challenges the user to prove possession of the second authentication factor.

Threat Model. We assume a remote adversary who has obtained the victim's username and password via phishing, leakage of a password database, or via other means. His goal is to authenticate to the server on behalf of the user. In particular, the adversary visits the server's webpage and enters the username and password of the victim. The attack is successful if the adversary convinces the server that he also holds the second authentication factor of the victim.

We further assume that the adversary cannot compromise the victim's phone. If the adversary gains control of the platform where the software token runs, then the security of any 2FA scheme reduces to the security of password-only authentication. Also, the adversary cannot compromise the victim's computer. The compromise of the computer allows the adversary to mount a Man-In-The-Browser attack [34] and hijack the victim's session with the server, therefore defeating any 2FA mechanism.

We do not address targeted attacks where the adversary is co-located with the victim. 2FA mechanisms that do not require the user to interact with his phone cannot protect against targeted, co-located attacks. For example, if 2FA uses unauthenticated short-range communication [14], a co-located attacker can connect to the victim's phone and prove possession of the second authentication factor to the server. We argue that targeted, co-located attacks are less common than non-selective, remote attacks. Furthermore, any 2FA mechanism may not warrant protection against powerful attackers. For example, if 2FA uses verification codes, a determined attacker may gain physical access to the phone or read the code from a distance [6, 7, 37].

We do not consider Man-In-The-Middle adversaries. Client authentication is not sufficient to defeat MITM attacks in the context of web applications [29]. We also do not address active phishing attacks where the attacker lures the user into visiting a phishing website and relays the stolen credentials to the legitimate website in real-time. Such attacks can be thwarted by having the phone detect the phishing domain [14, 35]. This requires short-range communication between the phone and the browser. However, seamless short-range communication between the phone and the browser is currently not possible.

Design Goals.

- *Usability.* Users should authenticate using only their username and password as in password-only authentication. In particular, users should not be asked to interact with their phone — not even to pick up the phone or take it out of a pocket or purse.
- *Deployability.* The 2FA mechanism should work with common smartphones, computers and browsers. It should not require additional software on the computer or the installation of browser plugins. A plugin-based solution limits the usability of the system because (*i*) a different plugin may be required for each server, and (*ii*) the user must install the plugin every time he logs in from a computer for the first time. The mechanism should also work on a wide range of smartphones. We therefore discard the use of special hardware on the phone like NFC chips or biometric sensors.

3 Alternative Approaches

In this section we discuss traditional 2FA mechanisms, as well as 2FA proposals which minimize the user-phone interaction. For each solution we argue why it fails to meet our usability and deployability goals.

3.1 Traditional 2FA

Hardware Tokens. Hardware tokens range from the RSA SecurID [17] to recent dongles [53] that comply with the FIDO U2F [20] standard for universal 2FA. Such solutions require the user to carry and interact with the token and may be expensive to deploy because the service provider must ship one token per customer.

Software Tokens. Google 2-Step Verification [22] is an example of 2FA based on verification codes, that uses software tokens on phones. The verification code is retrieved either from an application running on the phone or via SMS. Such mechanisms require the user to copy the verification code from the phone to the browser.

Duo Push [16] and Encap Security [18] prompt the user with a push message on his phone with information on the current login attempt. Both solutions still require the user to interact with his phone to authorize the login.

3.2 Reduced-Interaction 2FA

Short-range Radio Communication. PhoneAuth [14] is a 2FA proposal that leverages unpaired Bluetooth communication between the browser and the phone, in order to eliminate user-phone interaction. The Bluetooth channel enables the server (through the browser) and the phone to engage in a challenge-response protocol which provides the second authentication factor. Similarly, [35] and [41] also leverage Bluetooth communication between the browser and the phone.

These schemes require the browser to expose a Bluetooth API that is currently not available on any browser. A specification to expose a Bluetooth API in browsers has been proposed by the Web Bluetooth Community Group [49]. It is unclear whether the proposed API will support the unauthenticated RFCOMM or similar functionality which is required to enable seamless connectivity between the browser and the phone. However, if the Bluetooth connection is unauthenticated, an adversary equipped with a powerful antenna may connect to the victim's phone from afar [52] and login on behalf of the user, despite 2FA.

Authy [5] is another approach that allows for seamless 2FA using Bluetooth communication between the computer and the phone. Authy, however, requires extra software on the computer.

As an alternative to Bluetooth, the browser and the phone can communicate over WiFi [41]. This approach only works when both devices are on the same network. Shirvanian et al., [41] use extra software on the computer to virtualize the wireless interface and create a software access point (AP) with which the phone needs to be associated. The user has to perform this setup procedure every time he uses a new computer to log in. Their solution also requires a phone application listening for incoming connections in the background, which is currently not possible on iOS.

Finally, the browser and the phone can communicate over NFC. NFC hardware is not commonly found in commodity computers, and current browsers do not expose APIs to access NFC. Furthermore, a solution based on NFC would not completely remove user-phone interaction because the user would still need to hold his phone close to the computer.

We acknowledge that 2FA mechanisms that employ direct communication between the browser and the phone may provide additional security against remote attackers. For example, the phone can detect if the user tries to login on a phishing website and block the attempt [14, 35]. The scheme in [41] further resists offline dictionary attacks against compromised hashed password databases. Nevertheless, none of such solutions can be deployed for the reasons we discussed above.

Near-ultrasound. SlickLogin [23] minimizes the user-phone interaction transferring the verification code from the computer to the phone using near-ultrasounds. The idea is to use spectrum frequencies that are non-audible for the majority of the population but that can be reproduced by the speakers of commodity computers ($>$ 18kHz). Using non-audible frequencies accommodates for scenarios where users may not want their devices to make audible noise. Due to their size, the speakers of commodity computers can only produce highly directional near-ultrasound frequencies [39]. Near-ultrasound signals also attenuate faster, when compared to sounds in the lower part of the spectrum (< 18kHz) [3, 28]. With SlickLogin, the user must ensure that the speaker volume is at a sufficient level during login. Also, login will fail if a headset is plugged into the laptop. Finally, this approach may not work in scenarios where there is in-band noise (e.g., when listening to music or in cafes) [28]. We also note that a solution based on near-ultrasounds may result unpleasant for young people and animals that are capable of hearing sounds above 18kHz [38].

Location Information. The server can check if the computer and the phone are co-located by comparing their GPS coordinates. GPS sensors are available on all modern phones but are rare on commodity computers. If the computer from which the user logs in has no GPS sensor, it can use the geolocation API exposed by some browsers [32]. Nevertheless, information retrieved via the geolocation API may not be accurate, for example when the device is behind a VPN or it is connected to a large managed network (such as enterprise or university networks). Furthermore, geolocation information can be easily guessed by an adversary. For example, assume the adversary knows the location of the victim's workplace and uses that location as the second authentication factor. This attack is likely to succeed during working hours since the victim is presumably at his workplace.

Other Sensors. A 2FA mechanism can combine the readings of multiple sensors that measure ambient characteristics, such as temperature, concentration of gases in the atmosphere, humidity, and altitude, as proposed in [42]. These combined sensor modalities can be used to verify the proximity between the computer through which the user is trying to login and his phone. However, today's computers and phones lack the hardware sensors that are required for such an approach to work.

4 Background on Sound Similarity

The problem of determining the similarity of two audio samples is close to the problem of audio fingerprinting and automatic media retrieval [13]. In media retrieval, a noisy recording is matched against a database of reference samples. This is done by extracting a set of relevant features from the noisy recording and comparing them against the features of the reference samples. The extracted features must be robust to, for example, background noise and attenuation. Bark Frequency Cepstrum Coefficients [26], wavelets [8] or peak frequencies [48] have been proposed as robust features for automatic media retrieval. Such techniques focus mostly on the frequency domain representation of the samples because they deal with time-misaligned samples. In our scenario, we compare two quasi-aligned samples (the offset is less than 150ms) and we therefore can also extract relevant information from their time domain representations.

In order to consider both time domain and frequency domain information of the recordings, we use one-third octave band filtering and cross-correlation.

One-third Octave Bands. Octave bands split the audible range of frequencies (roughly from 20Hz to 20kHz) in 11 non-overlapping bands where the ratio of the highest in-band frequency to the lowest in-band frequency is 2 to 1. Each octave is represented by its center frequency, where the center frequency of a particular octave is twice the center frequency of the previous octave. One-third octave bands split the first 10 octave bands in three and the last octave band in two, for a total of 32 bands. One-third octave bands are widely used in acoustics and their frequency ranges have been standardized [44]. The center frequency of the lowest band is 16Hz (covering from 14.1Hz to 17.8Hz) while the center frequency of the highest band is 20kHz (covering from 17780Hz to 22390Hz). In the following we denote with $B = [lb - hb]$ a set of contiguous one-third octave bands, from the band that has its central frequency at lbHz, to the band that has its central frequency at hbHz.

Splitting a signal in one-third octave bands provides high frequency resolution information of the original signal, while keeping its time-domain representation.

Cross-correlation. Cross-correlation is a standard measure of similarity between two time series. Let x, y denote two signals represented as n-points discrete time series,[1] the cross-correlation $c_{x,y}(l)$ measures their similarity as a function of the lag $l \in [0, n-1]$ applied to y:

$$c_{x,y}(l) = \sum_{i=0}^{n-1} x(i) \cdot y(i-l)$$

where $y(i) = 0$ if $i < 0$ or $i > n-1$.

To accommodate for different amplitudes of the two signals, the cross correlation can be normalized as:

$$c'_{x,y}(l) = \frac{c_{x,y}(l)}{\sqrt{c_{x,x}(0) \cdot c_{y,y}(0)}}$$

where $c_{x,x}(l)$ is known as auto-correlation.

The normalization maps $c'_{x,y}(l)$ in $[-1, 1]$. A value of $c'_{x,y}(l) = 1$ indicates that at lag l, the two signals have the same shape even if their amplitudes may be different; a value of $c'_{x,y}(l) = -1$ indicates that the two signals have the same shape but opposite signs. Finally, a value of $c'_{x,y}(l) = 0$ shows that the two signals are uncorrelated.

If the actual lag between the two signals is unknown, we can discard the sign information and use the absolute value of the maximum cross-correlation $\hat{c}_{x,y}(l) = \max_l(|c'_{x,y}(l)|)$ as a metric of similarity ($0 \leq \hat{c}_{x,y}(l) \leq 1$).

The computation overhead of $c_{x,y}(l)$ can be decreased by leveraging the cross-correlation theorem and computing $c_{x,y}(l) = F^{-1}(F(x)^* \cdot F(y))$, where $F()$ denotes the

[1] For simplicity we assume both series to have the same length.

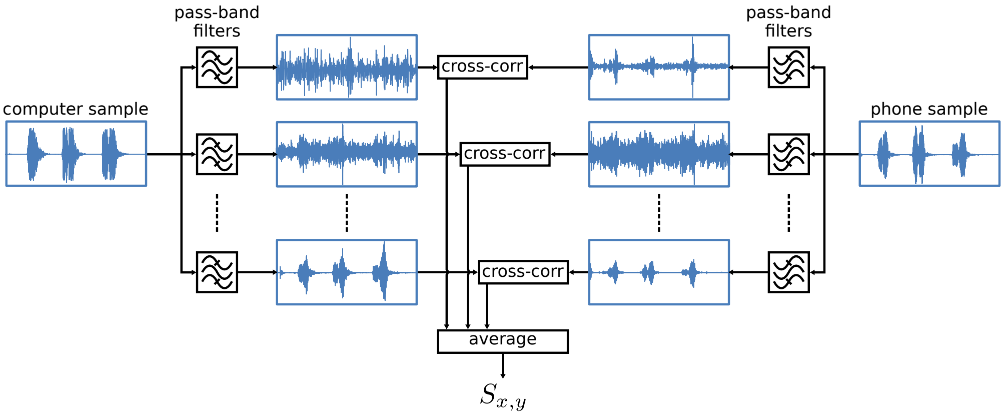

Figure 1: Block diagram of the function that computes the similarity score between two samples. The computation takes place on the phone. If $S_{x,y} > \tau_C$ and the average power of the samples is greater than τ_{dB}, the phone judges the login attempt as legitimate.

discrete Fourier transform and the asterisk denotes the complex conjugate.

5 Sound-Proof Architecture

The second authentication factor of Sound-Proof is the proximity of the user's phone to the computer being used to log in. The proximity of the two devices is determined by computing a similarity score between the ambient noise captured by their microphones. For privacy reasons we do not upload cleartext audio samples to the server. In our design, the computer encrypts its audio sample under the public key of the phone. The phone receives the encrypted sample, decrypts it, and computes the similarity score between the received sample and the one recorded locally. Finally, the phone tells the server whether the two devices are co-located or not. Note that the phone never uploads its recorded sample to the server. Communication between the computer and the phone goes through the server. We avoid short-range communication between the phone and the computer (e.g., via Bluetooth) because it requires changes to the browser or the installation of a plugin.

5.1 Similarity Score

Figure 1 shows a block diagram of the function that computes the similarity score. Each audio signal is input to a bank of pass-band filters to obtain n signal components, one per each of the one-third octave bands that we take into account. Let x_i be the signal component for the i-th one-third octave band of signal x. The similarity score is the average of the maximum cross-correlation over the pairs of signal components x_i, y_i:

$$S_{x,y} = \frac{1}{n} \sum_{i=1}^{i=n} \hat{c}_{x_i,y_i}(l)$$

where l is bounded between 0 and ℓ_{max}.

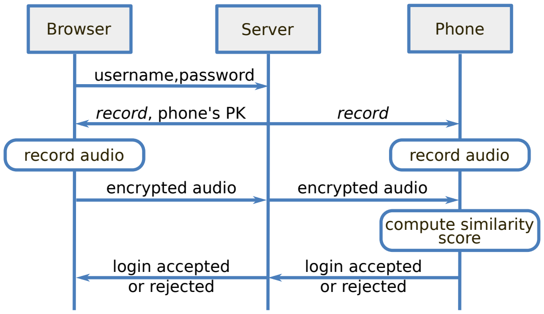

Figure 2: Sound-Proof authentication overview. At login, the phone and the computer record ambient noise with their microphones. The phone computes the similarity score between the two samples and returns the result to the server.

5.2 Enrollment and Login

Similar to other 2FA mechanisms based on software tokens, Sound-Proof requires the user to install an application on his phone and to bind the application to his account on the server. This one-time operation can be carried out using existing techniques to enroll software tokens, e.g., [22]. We assume that, at the end of the phone enrollment procedure, the server receives the unique public key of the application on the user's phone and binds that public key to the account of that user.

Figure 2 shows an overview of the login procedure. The user points the browser to the URL of the server and enters his username and password. The server retrieves the public key of the user's phone and sends it to the browser. Both the browser and the phone start recording through their local microphones for t seconds. During recording, the two devices synchronize their clocks with the server. When recording completes, each device adjusts the timestamp of its sample taking into account the clock difference with the server. The browser encrypts the audio sample under the phone's public key and sends it to the phone, using the server as a proxy. The phone decrypts the browser's sample and compares it against the one recorded locally. If the average power of both samples is above τ_{dB} and the similarity score is above τ_C, the phone concludes that it is co-located with the computer from which the user is logging in and informs the server that the login is legitimate.

The procedure is completely transparent to the user if the environment is sufficiently noisy. In case the environment is quiet, Sound-Proof requires the user to generate some noise, for example by clearing his throat.

5.3 Security Analysis

Remote Attacks. The security of Sound-Proof stems from the attacker's inability to guess the sound in the victim's environment at the time of the attack.

Let x be the sample recorded by the victim's phone and let y be the sample submitted by the attacker. A successful impersonation attack requires the average power of both signals to be above τ_{dB}, and each of the one-third octave band components of the two signals to be highly correlated. That is, the two samples must satisfy $Pwr(x) > \tau_{dB}$, $Pwr(y) > \tau_{dB}$ and $S_{x,y} > \tau_C$ with $l < \ell_{max}$.

We bound the lag l between 0 and ℓ_{max} to increase the security of the scheme against an adversary that successfully guesses the noise in the victim's environment at the time of the attack. Even if the adversary correctly guesses the noise in the victim's environment and can submit a similar audio sample, the two samples must be synchronized with an error smaller than ℓ_{max}. We also reject audio pairs where either sample has an average power below the threshold τ_{dB}. This is in order to prevent an impersonation attack when the victim's environment is quiet (e.g., while the victim is sleeping).

Quantifying the entropy of ambient noise, and hence the likelihood of the adversary guessing the signal recorded by the victim's phone, is a challenging task. Results are dependent on the environment, the language spoken by the victim, his gender or age to cite a few. In Section 7 we provide empirical evidence that Sound-Proof can discriminate between legitimate and fraudulent logins, even if the adversary correctly guesses the type of environment where the victim is located.

Co-located Attacks. Sound-Proof cannot withstand attackers who are co-located with the victim. A co-located attacker can capture the ambient sound in the victim's environment and thus successfully authenticate to the server, assuming that he also knows the victim's password. Sound-Proof shares this limitation with other 2FA mechanisms that do not require the user to interact with his phone and do not assume a secure channel between the phone and the computer (e.g., [14]). Resistance to co-located attackers requires either a secure phone-to-computer channel (as in [5, 41]) or user-phone interaction (as in [16, 22]). However, both techniques impose a significant usability burden.

6 Prototype Implementation

Our implementation works with Google Chrome (tested with version 38.0.2125.111), Mozilla Firefox (tested with version 33.0.2) and Opera (tested with version 25.0.1614.68). We anticipate the prototype to work with different versions of these browsers, as long as they implement the `navigator.getUserMedia()` API of WebRTC. We tested the phone application both on Android and on iOS. For Android, on a Samsung Galaxy S3, a Google Nexus 4 (both running Android version 4.4.4), a Sony Xperia Z3 Compact and a Motorola Nexus 6 (running Android version 5.0.2 and 5.1.1, respectively). We also tested different iPhone models (iPhone 4, 5 and 6) running iOS version 7.1.2 on the iPhone 4, and iOS version 8.1 on the newer models. The phone application should work on different phone models and with different OS versions without major modifications.

Web Server and Browser. The server component is implemented using the CherryPy [45] web framework and MySQL database. We use WebSocket [19] to push data from the server to the client. The client-side (browser) implementation is written entirely in HTML and JavaScript. Encryption of the audio recording uses AES256 with a fresh symmetric key; the symmetric key is encrypted under the public key of the phone using RSA2048. We use the HTML5 WebRTC API [15, 24]. In particular, we use the `navigator.getUserMedia()` API to access the local microphone from within the browser. Our prototype does not require browser code modifications or plugins.

Software Token. We implement the software token as an Android application as well as an iOS application. The mobile application stays idle in the background and is automatically activated when a push notification arrives. Push messages for Android and iOS use the Google GCM (Google Cloud Messaging) APIs [21] and Apple's APN (Apple Push Notifications) APIs [2] (in particular the silent push notification feature), respectively. Phone to server communication is protected with TLS.

Most of the Android code is written in Java (Android SDK), while the component that processes the audio samples is written in C (Android NDK). In particular, we use the ARM Ne10 library, based on the ARM NEON engine [4] to optimize vector operations and FFT computations. The iOS application is written in Objective-C and uses Apple's vDSP package of the Accelerate framework [1], in order to leverage the ARM NEON technology for vector operations and FFT computations. On both mobile platforms we parallelize the computation of the similarity score across the available processor cores.

Operations	Mean (ms)	Std.Dev.
Recording	3000	—
Similarity score computation	642	171
Cryptographic operations	118	15
Networking		
WiFi	978	135
Cellular	1243	209

Table 1: Overhead of the Sound-Proof prototype. On average it takes 4677ms (± 181ms) over WiFi and 4944ms (± 233ms) over Cellular to complete the 2FA verification.

Time Synchronization. Sound-Proof requires the recordings from the phone and the computer to be synchronized. For this reason, the two devices run a simple time-synchronization protocol (based on the Network Time Protocol [33]) with the server. The protocol is implemented over HTTP and allows each device to compute the difference between the local clock and the one of the server. Each device runs the time-synchronization protocol with the server while it is recording via its microphone. When recording completes, each device adjusts the timestamp of its sample taking into account the clock difference with the server.

Run-time Overhead. We compute the run-time overhead of Sound-Proof when the phone is connected either through WiFi or through the cellular network. We run 1000 login attempts with a Google Nexus 4 for each connection type, and we measure the time from the moment the user submits his username and password to the time the web server logs the user in. On average it takes 4677ms (± 181ms) over WiFi and 4944ms (± 233ms) over Cellular to complete the 2FA verification. Table 1 shows the average time and the standard deviation of each operation. The recording time is set to 3 seconds. The similarity score is computed over the set of one-third octave bands $B = [50\text{Hz} - 4\text{kHz}]$. (Section 7.1 discusses the selection of the band set.) After running the time-synchronization protocol, the resulting clock difference was, on average, 42.47ms (± 30.35ms).

7 Evaluation

Data Collection. We used our prototype to collect a large number of audio pairs. We set up a server that supported Sound-Proof. Two subjects logged in using Google Chrome[2] over 4 weeks. At each login, the phone and the computer recorded audio through their microphones for 3 seconds. We stored the two audio samples for post-processing.

Login attempts differed in the following settings. *Environment:* an office at our lab with either no ambient noise (labelled as Office) or with the computer playing music (Music); a living-room with the TV on (TV); a lecture hall while a faculty member was giving a lecture (Lecture); a train station (TrainStation); a cafe (Cafe). *User activity:* being silent, talking, coughing, or whistling. *Phone position:* on a table or a bench next to the user, in the trouser pocket, or in a purse. *Phone model:* Apple iPhone 5 or Google Nexus 4. *Computer model:* Mac Book Pro "Mid 2012" running OS X10.10 Yosemite or Dell E6510 running Windows 7.

At the end of the 4 weeks we had collected between 5 and 15 login attempts per each setting, totaling 2007 login attempts (4014 audio samples).

7.1 Analysis

We used the collected samples to find the configuration of system parameters (i.e., τ_{dB}, ℓ_{max}, B, and τ_C) that led to the best results in terms of False Rejection Rate (FRR) and the False Acceptance Rate (FAR). A false rejection occurs when a legitimate login is rejected. A false acceptance occurs when a fraudulent login is accepted. A fraudulent login is accepted if the sample submitted by the attacker and the sample recorded by the victim's phone have a similarity score greater than τ_C, and if both samples have an average power greater than τ_{dB}.

To compute the FAR, we used the following strategy. For each phone sample collected by one of the subjects (acting as the victim), we use all the computer samples collected by the other subject as the attacker's samples. We then switch the roles of the two subjects and repeat the procedure. The total number of victim–adversary sample pairs we considered was 2,045,680.

System Parameters. We set the average power threshold τ_{dB} to 40dB which, based on our measurements, is a good threshold to reject silence or very quiet recordings like the sound of a fridge buzzing or the sound of a clock ticking. Out of 2007 login attempts we found 5 attempts to have an average power of either sample below 40dB and we discard them for the rest of the evaluation.

We set ℓ_{max} to 150ms because this was the highest clock difference experienced while testing our time-synchronization protocol (see Section 6).

An important parameter of Sound-Proof is the set B of one-third octave bands to consider when computing the similarity score described in Section 5.1. The goal is to select a spectral region that (*i*) includes most common sounds and (*ii*) is robust to attenuation and directionality of audio signals. We discarded bands below 50Hz to remove very low-frequency noises. We also discarded bands above 8kHz, because these frequencies are attenuated by fabric and they are not suitable for scenarios where the phone is in a pocket or a purse. We tested all sets of one-third octave bands $B = [x - y]$ where x ranged from 50Hz to 100Hz and y ranged from 630Hz to 8kHz.

[2] We used Google Chrome since it is currently the most popular browser [43]. We have also tested Sound-Proof with other browsers and have experienced similar performance (see Section 9).

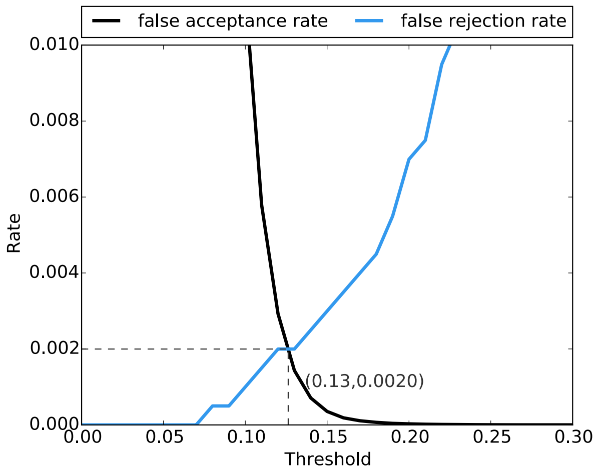

Figure 3: False Rejection Rate and False Acceptance Rate as a function of the threshold τ_C for $B = [50\text{Hz} - 4\text{kHz}]$. The Equal Error Rate is 0.0020 at $\tau_C = 0.13$.

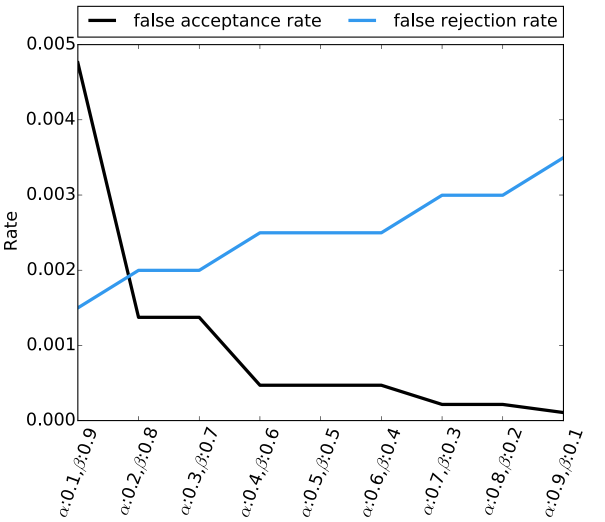
We found the smallest Equal Error Rate (ERR, defined as the crossing point of FRR and FAR) when using $B = [50\text{Hz} - 4\text{kHz}]$. Figure 3 shows the FRR and FAR using this set of bands where the ERR is 0.0020 at $\tau_C = 0.13$. We experienced worse results with one-third octave bands above 4kHz. This was likely due to the high directionality of the microphones found on commodity devices when recoding sounds at those frequencies [47].

We also computed the best set of one-third octave bands to use in case usability and security are weighted differently by the service provider.[3] In particular, we computed the sets of bands that minimized $f = \alpha \cdot FRR + \beta \cdot FAR$, for $\alpha \in [0.1, \ldots, 0.9]$ and $\beta = 1 - \alpha$. Figure 4(b) shows the set of bands that provided the best results for each configuration of α and β. As before, we experienced better results with bands below 4kHz. Figure 4(a) plots the FRR and FAR against the possible values of α and β. We stress that the set of bands may differ across two different points on the x-axis.

Experiments in the remaining of this section were run with the configuration of the parameters that minimized the ERR to 0.0020: $\tau_{dB} = 40\text{dB}$, $\ell_{max} = 150\text{ms}$, $B = [50\text{Hz} - 4\text{kHz}]$, and $\tau_C = 0.13$.



(a) False Rejection Rate and False Acceptance Rate when usability and security have different weights.

	B	τ_c
$\alpha = 0.1,\ \beta = 0.9$	$[80\text{Hz} - 2500\text{Hz}]$	0.12
$\alpha = 0.2,\ \beta = 0.8$	$[50\text{Hz} - 2500\text{Hz}]$	0.14
$\alpha = 0.3,\ \beta = 0.7$	$[50\text{Hz} - 2500\text{Hz}]$	0.14
$\alpha = 0.4,\ \beta = 0.6$	$[50\text{Hz} - 800\text{Hz}]$	0.19
$\alpha = 0.5,\ \beta = 0.5$	$[50\text{Hz} - 800\text{Hz}]$	0.19
$\alpha = 0.6,\ \beta = 0.4$	$[50\text{Hz} - 800\text{Hz}]$	0.19
$\alpha = 0.7,\ \beta = 0.3$	$[50\text{Hz} - 1000\text{Hz}]$	0.2
$\alpha = 0.8,\ \beta = 0.2$	$[50\text{Hz} - 1000\text{Hz}]$	0.2
$\alpha = 0.9,\ \beta = 0.1$	$[50\text{Hz} - 1250\text{Hz}]$	0.21

(b) One-third octave bands and similarity score threshold.

Figure 4: Minimizing $f = \alpha \cdot FRR + \beta \cdot FAR$, for $\alpha \in [0.1, \ldots, 0.9]$ and $\beta = 1 - \alpha$.

7.2 False Rejection Rate

In the following we evaluate the impact of each setting that we consider (environment, user activity, phone position, phone model, and computer model) on the FRR. Figures 5 and 6 show a box and whisker plot for each setting. The whiskers mark the 5th and the 95th percentiles of the similarity scores. The boxes show the 25th and 75th percentiles. The line and the solid square within each box mark the median and the average, respectively. A gray line marks the similarity score threshold ($\tau_C = 0.13$) and each red dot in the plots denotes a login attempt where the similarity score was below that threshold (i.e., a false rejection).

Environment. Figure 5 shows the similarity scores for each environment. Sound-Proof fares equally well indoors and outdoors. We did not experience rejections of legitimate logins for the Music (over 432 logins), the Lecture (over 122 logins), and the TV (over 430 logins) environments. The FRR was 0.003 (1 over 310 logins) for Office, 0.003 (1 over 370 logins) for TrainStation, and 0.006 (2 over 338 logins) for Cafe.

User Activity. Figure 6(a) shows the similarity scores for different user activities. In general, if the user makes any noise the similarity score improves. We only experienced a few rejections of legitimate logins when the

[3] For example, a social network provider may value usability higher than security.

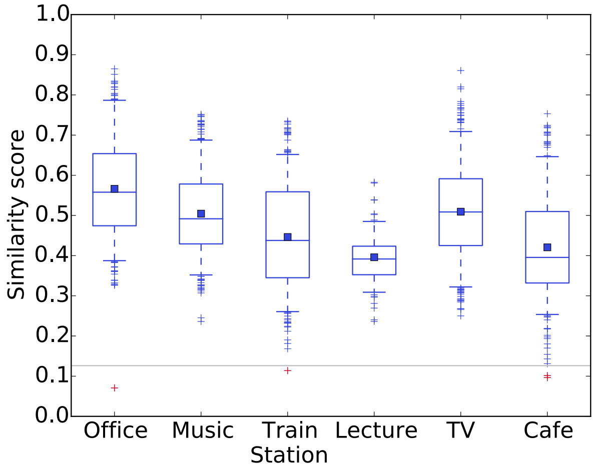


Figure 5: Impact of the environment on the False Rejection Rate.

	False Acceptance Rate		
	SC-SP	SC-DP	DC-DP
TV channel 1	1	0.1	0.1
TV channel 2	1	1	0
TV channel 3	1	0	-
TV channel 4	1	0	-
Web radio 1	1	0	0.4
Web radio 2	0.1	0.8	0.8
Web TV 1	0	0	0
Web TV 2	0	0	0

Table 2: False Acceptance Rate when the adversary and the victim devices record the same broadcast media. SC-SP stands for "same city and same Internet/cable provider", SC-DP stands for "same city but different Internet/cable providers", DC-DP stands for "different cities and different Internet/cable providers". A dash in the table means that the TV channel was not available at the victim's location.

user was silent (TrainStation and Cafe) or when he was coughing (Office). In the Lecture case the user could only be silent. We also avoided whistling in the cafe, because this may be awkward for some users. The FRR was 0.005 (3 over 579 logins) when the user was silent, 0.002 (1 over 529 logins) when the user was coughing, 0 (0 over 541 logins) when the user was speaking, and 0 (0 over 353 logins) when the user was whistling.

Phone Position. Figure 6(b) shows the similarity scores for different phone positions. Sound-Proof performs slightly better when the phone is on a table or on a bench. Worse performance when the phone is in a pocket or in a purse are likely due to the attenuation caused by the fabric around the microphone. The FRR was 0.001 (1 over 667 logins) with the phone on a table, 0.001 (1 over 675 logins) with the phone in a pocket, and 0.003 (2 over 660 logins) with the phone in a purse.

Phone Model. Figure 6(c) shows the similarity scores for the two phones. The Nexus 4 and the iPhone 5 performed equally good across all environments. The FRR was 0.002 (2 over 884 logins) with the iPhone 5 and 0.002 (2 over 1118 logins) with the Nexus 4.

Computer. Figure 6(d) shows the similarity scores for the two computers we used. We could not find significant differences between their performance. The FRR was 0.002 (3 over 1299 logins) with the MacBook Pro and 0.001 (1 over 703 logins) with the Dell.

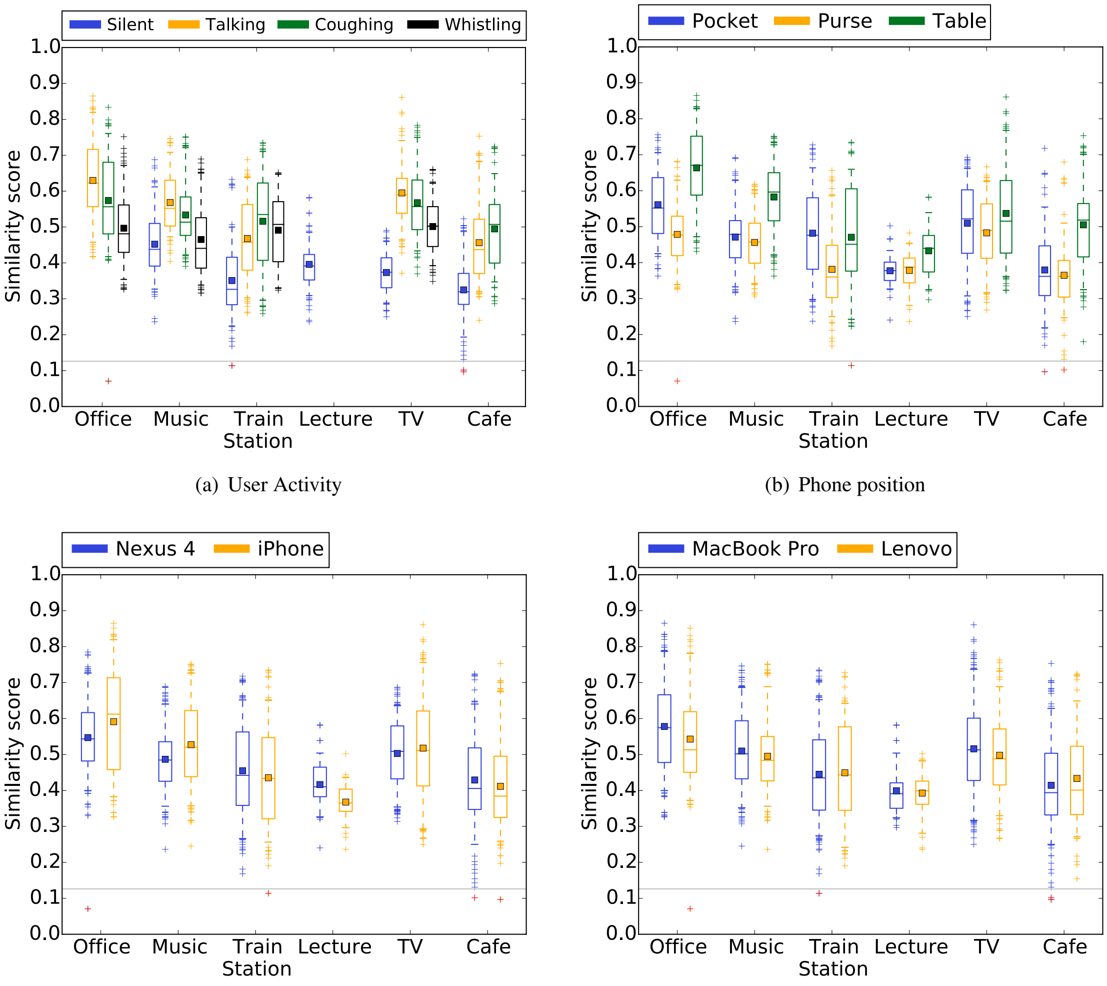
Distance Between Phone and Computer. In some settings (e.g., at home), the user's phone may be away from his computer. For instance, the user could leave the phone in his bedroom while watching TV or working in another room. We evaluated this scenario by placing the computer close to the TV in a living-room, and testing Sound-Proof while the phone was away from the computer. For this set of experiments we used the iPhone 5 and the MacBook Pro. The average noise level by the TV was measured at 50dB. We tested 3 different distances: 4, 8 and 12 meters (running 20 login attempts for each distance). All login attempts were successful (i.e., FRR=0). We also tried to log in while the phone was in another room behind a closed door, but logins were rejected.

Discussion. Based on the above results, we argue that the FRR of Sound-Proof is small enough to be practical for real-world usage. To put it in perspective, the FRR of Sound-Proof is likely to be smaller than the FRR due to mistyped passwords (0.04, as reported in [30]).

7.3 Advanced Attack Scenarios

A successful attack requires the adversary to submit a sample that is very similar to the one recoded by the victim's phone. For example, if the victim is in a cafe, the adversary should submit an audio sample that features typical sounds of that environment. In the following we assume a strong adversary that correctly guesses the victim's environment. We also evaluate the attack success rate in scenarios where the victim and the attacker access the same broadcast audio source from different locations.

Similar Environment Attack. In this experiment we assume that the victim and the adversary are located in similar environments. For each environment, we compute the FAR between each phone sample collected by one subject (the victim) and all the computer samples of the other subject (the adversary). We then switch the roles of the two subjects and repeat the procedure. The FAR for the Music and the TV environments were 0.012 (1063 over 91960 attempts) and 0.003 (311 over 90992 attempts), respectively. The FAR for the Lecture environment was 0.001 (8 over 7242 attempts). When both the victim and the attacker were located at a train station



(a) User Activity

(b) Phone position

(c) Phone model

(d) Computer

Figure 6: Impact of user activity, phone position, phone model, and computer model on the False Rejection Rate.

the FAR was 0.001 (44 over 67098 attempts). The FAR for the Office environment was 0.025 (1194 over 47250 attempts). When both the victim and the attacker were in a cafe the FAR was 0.001 (32 over 56994 attempts).

The above results show low FAR even when the attacker correctly guesses the victim's environment. This is due to the fact that ambient noise in a given environment is influenced by random events (e.g., background chatter, music, cups clinking, etc.) that cannot be controlled or predicted by the adversary.

Same Media Attack. In this experiment we assume that the victim and the adversary access the same audio source from different locations. This happens, for example, if the victim is watching TV and the adversary correctly guesses the channel to which the victim's TV is tuned. We place the victim's phone and the adversary's computer in different locations, but each of them next to a smart TV that was also capable of streaming web media. Since the devices have access to two identical audio sources, the adversary succeeds if the lag between the two audio signals is less than ℓ_{max}. We tested 4 cable TV channels, 2 web radios and 2 web TVs. For each scenario, we run the attack 100 times and report the FAR in Table 2. When the victim and the attacker were in the same city, we experienced differences based on the media provider. When the TVs reproduced content broadcasted by the same provider, the signals were closely synchronized and the similarity score was above the threshold τ_C. The FAR dropped in the case of web content. When the TVs reproduced content supplied by different providers, the lag between the signals caused the similarity score to drop below τ_C in most of the cases. The similarity score sensibly dropped when the victim and the attacker were located in different cities.

8 User Study

The goal of our user study was to evaluate the usability of Sound-Proof and to compare it with the usability of Google 2-Step Verification (2SV), since 2FA based on verification codes is arguably the most popular. (We only considered the version of Google 2SV that uses an application on the user's phone to generate verification codes.) We stress that the comparison focuses solely on the usability aspect of the two methods. In particular, we did not make the participants aware of the difference in the security guarantees, i.e., the fact that Google 2SV can better resist co-located attacks.

We ran repeated-measure experiments where each participant was asked to log in to a server using both mechanisms in random order. After using each 2FA mechanism, participants ranked its usability answering the System Usability Scale (SUS) [11]. The SUS is a widely-used scale to assess the usability of IT systems [9]. The SUS score ranges from 0 to 100, where higher scores indicate better usability.

8.1 Procedure

Recruitment. We recruited participants using a snowball sampling method. Most subjects were recruited outside our department and were not working in or studying computer science. The study was advertised as a user study to "evaluate the usability of two-factor authentication mechanisms". We informed participants that we would not collect any personal information and offered a compensation of CHF 20. Among all respondents to our email, we discarded the ones that were security experts and ended up with 32 participants.

Experiment. The experiment took place in our lab where we provided a laptop and a phone to complete the login procedures. Both devices were connected to the Internet through WiFi. We set up a Gmail account with Google 2SV enabled. We also created another website that supported Sound-Proof and mimicked the Gmail UI.

Participants saw a video where we explained the two mechanisms under evaluation. We told participants that they would need to log in using the account credentials and the hardware we provided. We also explained that we would record the keystrokes and the mouse movements (this allowed us to time the login attempts).

We then asked participants to fill in a pre-test questionnaire designed to collect demographic information. Participants logged in to our server using Sound-Proof and to Gmail using Google 2SV. We randomized the order in which each participant used the two mechanisms. After each login, participants rated the 2FA mechanism answering the SUS.

At the end of the experiment participants filled in a post-test questionnaire that covered aspects of the 2FA mechanisms under evaluation not covered by the SUS.

8.2 Results

Demographics. 58% of the participants were between 21 and 30 years old. 25% of the participants were between 31 and 40 years old. The remaining 17% of the participants were above 40 years old. 53% of the participants were female. 69% of the participants had a master or doctoral degree. 50% of the participants used 2FA for online banking and only 13% used Google 2SV to access their email accounts.

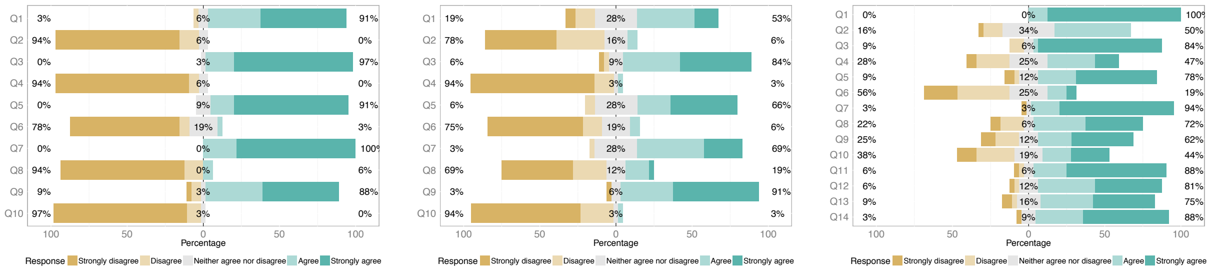
SUS Scores. The mean SUS score for Sound-Proof was 91.09 (±5.44). The mean SUS score for Google 2SV was 79.45 (±7.56). Figure 7(a) and Figure 7(b) show participant answers on 5-point Likert-scales for Sound-Proof and for Google 2SV, respectively. To analyze the statistical significance of these results, we used the following null hypothesis: "there will be no difference in perceived usability between Sound-Proof and Google 2SV". A one-way ANOVA test revealed that the difference of the SUS scores was statistically significant ($F(1,31) = 21.698,\ p < .001,\ \eta_p^2 = .412$), thus the null hypothesis can be rejected. We concluded that users perceive Sound-Proof to be more usable than Google 2SV. Appendix A reports the items of the SUS.

Login Time. We measured the login time from the moment when a participant clicked on the "login" button (right after entering the password), to the moment when that participant was logged in. We neglected the time spent entering username and password because we wanted to focus only on the time required by the 2FA mechanism. Login time for Sound-Proof was 4.7 seconds (±0.2 seconds); this time was required for the phone to receive the computer's sample and compare it with the one recorded locally. With Google 2SV, login time increased to 24.4 seconds (±7.1 seconds); this time was required for the participant to take the phone, start the application and copy the verification code from the phone to the browser.

Failure Rates. We did not witness any login failure for either of the two methods. We speculate that this may be due to the priming of the users right before the experiment, when we explained how the two methods work and that Sound-Proof may require users to make some noise in quiet environments.

Post-test Questionnaire. The post-test questionnaire was designed to collect information on the perceived quickness of the two mechanisms (Q1–Q2) and participants willingness to adopt any of the schemes (Q3–Q6). We also included items to inquire if participants would feel comfortable using the mechanisms in different environments (Q7–Q14). Figure 7(c) shows participants answers on 5-point Likert-scales. The full text of the items can be found in Appendix B.

All participants found Sound-Proof to be quick (Q1), while only 50% of the participants found Google 2SV to



(a) SUS answers for Sound-Proof

(b) SUS answers for Google 2SV

(c) Answers to the Post-test questionnaire

Figure 7: Distribution of the answers by the participants of the user study. System Usability Scale (SUS) of Sound-Proof (a) and Google 2-Step Verification (b), as well as the Post-test questionnaire (c). Percentages on the left side include participants that answered "Strongly disagree" or "Disagree". Percentages in the middle account for participants that answered "Neither agree, nor disagree". Percentages on the right side include participants that answered "Agree" or "Strongly agree".

be quick (Q2). If 2FA were mandatory, 84% of the participants would use Sound-Proof (Q3) and 47% would use Google 2SV (Q4). In case 2FA were optional the percentage of participants willing to use the two mechanisms dropped to 78% for Sound-Proof (Q5) and to 19% for Google 2SV (Q6). Similar to [36, 12], our results for Google 2SV suggest that users are likely not to use 2FA if it is optional. With Sound-Proof, the difference in user acceptance between a mandatory and an optional scenario is only 6%.

We asked participants if they would feel comfortable using either mechanism at home, at their workplace, in a cafe, and in a library. 95% of the participants would feel comfortable using Sound-Proof at home (Q7) and 77% of the participants would use it at the workplace (Q8). 68% would use it in a cafe (Q9) and 50% would use it in a library (Q10). Most participants (between 91% and 82%) would feel comfortable using Google 2SV in any of the scenario we considered (Q11–Q14).

The results of the post-test questionnaire suggest that users may be willing to adopt Sound-Proof because it is quicker and causes less burden, compared to Google 2SV. In some public places, however, users may feel more comfortable using Google 2SV. In Section 9 we discuss how to integrate the two approaches.

The post-test questionnaire allowed participants to comment on the 2FA mechanisms evaluated. Most participants found Sound-Proof to be user-friendly and appreciated the lack of interaction with the phone. Appendix C lists some of the users' comments.

9 Discussion

Software and Hardware Requirements. Similar to any other 2FA based on software tokens, Sound-Proof requires an application on the user's phone. Sound-Proof, however, does not require additional software on the computer and seamlessly works with any HTML5-compliant browser that implements the WebRTC API. Chrome, Firefox and Opera, already support WebRTC and a version of Internet Explorer supporting WebRTC will soon be released [31]. Sound-Proof needs the phone to have a data connection. Moreover, both the phone and the computer where the browser is running must be equipped with a microphone. Microphones are ubiquitous in phones, tablets and laptops. If a computer such as a desktop machine does not have an embedded microphone, Sound-Proof requires an external microphone, like the one of a webcam.

Other Browsers. Section 7 evaluates Sound-Proof using Google Chrome. We have also tested Sound-Proof with Mozilla Firefox and Opera. Each browser may use different algorithms to process the recorded audio (e.g., filtering for noise reduction), before delivering it to the web application. The WebRTC specification does not yet define how the recorded audio should be processed, leaving the specifics of the implementation to the browser vendor. When we ran our tests, Opera behaved like Chrome. Firefox audio processing was slightly different and it affected the performance our prototype. In particular, the Equal Error Rate computed over the samples collected while using Firefox was 0.012. We speculate that a better Equal Error Rate can be achieved with any browser if the software token performs the same audio processing of the browser being used to log in.

Privacy. The noise in the user's environment may leak private information to a prying server. In our design, the audio recorded by the phone is never uploaded to the server. A malicious server can also access the computer's microphone while the user is visiting the server's webpage. This is already the case for a number of websites that require access to the microphone. For example, websites for language learning, Gmail (for video-chats or phone calls), live chat-support services, or any site that uses speech-recognition require access to the microphone and may record the ambient noise any time the user visits the provider's webpage. All browsers we tested ask the user for permission before allowing a website to use `getUserMedia`. Moreover, browsers show an alert when a website triggers recording from the microphone. Providers are likely not to abuse the recording capability, since their reputation would be affected, if users detect unsolicited recording.

Quiet Environments. Sound-Proof rejects a login attempt if the power of either sample is below τ_{dB}. In case the environment is too quiet, the website can prompt the user to make any noise (by, e.g., clearing his throat, knocking on the table, etc.).

Fallback to Code-based 2FA. Sound-Proof can be combined with 2FA mechanisms based on verification codes, like Google 2SV. For example, the webpage can employ Sound-Proof as the default 2FA mechanism, but give to the user the option to log in entering a verification code. This may be useful in cases where the environment is quiet and the user feels uncomfortable making noise. Login based on verification codes is also convenient when the phone has no data connectivity (e.g., when roaming).

Failed Login Attempts and Throttling. Sound-Proof deems a login attempt as fraudulent if the similarity score between the two samples is below the threshold τ_C or if the power of either sample is below τ_{dB}. In this case, the server may request the two devices to repeat the recording and comparison phase. After a pre-defined number of failed trials, the server can fall-back to a 2FA mechanism based on verification codes. The server can also throttle login attempts in order to prevent "brute-force" attacks and to protect the user's phone battery from draining.

Login Evidence. Since audio recording and comparison is transparent to the user, he has no means to detect an ongoing attack. To mitigate this, at each login attempt the phone may vibrate, light up, or display a message to notify the user that a login attempt is taking place. The Sound-Proof application may also keep a log of the login attempts. Such techniques can help to make the user aware of fraudulent login attempts. Nevertheless, we stress that the user does not have to attend to the phone during legitimate login attempts.

Continuous Authentication. Sound-Proof can also be used as a form of continuous authentication. The server can periodically trigger Sound-Proof, while the user is logged in and interacts with the website. If the recordings of the two devices do not match, the server can forcibly log the user out. Nevertheless, such use can have a more significant impact on the user's privacy, as well as affect the battery life of the user's phone.

Alternative Devices. Our 2FA mechanism uses the phone as a software token. Another option is to use a smartwatch and we plan to develop a Sound-Proof application for smartwatches based on Android Wear and Apple Watch. We speculate that smartwatches can further lower the false rejection rate because of the proximity of the computer and the smartwatch during logins.

Logins from the Phone. If a user tries to log in from the same device where the Sound-Proof application is running, the browser and the application will capture audio through the same microphone and, therefore, the login attempt will be accepted. This requires the mobile OS to allow access to the microphone by the browser and, at the same time, by the Sound-Proof application. If the mobile OS does not allow concurrent access to the microphone, Sound-Proof can fall back to code-based 2FA.

Comparative Analysis. We use the framework of Bonneau et al. [10] to compare Sound-Proof with Google 2-Step Verification (Google 2SV), with PhoneAuth [14], and with the 2FA protocol of [41] that uses WiFi to create a channel between the phone and the computer (referred to as FBD-WF-WF in [41]). The framework of Bonneau et al. considers 25 "benefits" that an authentication scheme should provide, categorized in terms of usability, deployability, and security. Table 3 shows the overall comparison. The evaluation of Google 2SV in Table 3 matches the one reported by [10], besides the fact that we consider Google 2SV to be non-proprietary. *Usability:* No scheme is scalable nor it is effortless for the user because they all require a password as the first authentication factor. They are all "Quasi-Nothing-to-Carry" because they leverage the user's phone. Sound-Proof and PhoneAuth are more efficient to use than Google 2SV because they do not require the user to interact with his phone. They are also more efficient to use than FBD-WF-WF, because the latter requires a non-negligible setup time every time the user logs in from a new computer. All mechanisms incur some errors if the user enters the wrong password (Infrequent-Errors). All mechanisms also require similar recovery procedures if the user loses his phone. *Deployability:* Sound-Proof, PhoneAuth, and FBD-WF-WF score better than Google 2SV in the category "Accessible" because the user is asked nothing but his password. The three schemes are also better than Google 2SV in terms of cost per user, assuming users already have a phone. None of the mechanisms is server-compatible. Sound-Proof and Google 2SV are the only browser-compatible mechanisms as they require no changes to current browsers or computers. Google 2SV is more mature, and all of them are non-proprietary. *Security:* The security provided by Sound-Proof, PhoneAuth, and FBD-WF-WF is similar to the one provided by Google 2SV. However, we rate Sound-Proof and PhoneAuth as not resilient to targeted impersonation, since a targeted, co-located attacker can launch the attack from the victim's environment. FBD-WF-WF uses a paired connection between the user's computer and phone, and can better resist such attacks.

	Usability								Deployability						Security										
Scheme	Memorywise-Effortless	Scalable-for-Users	Nothing-to-Carry	Physically Effortless	Easy-to-Learn	Efficient-to-Use	Infrequent-Errors	Easy-Recovery-from-Loss	Accessible	Negligible-Cost-per-User	Server-Compatible	Browser-Compatible	Mature	Non-Proprietary	Resilient-to-Physical-Observation	Resilient-to-Targeted-Impersonation	Resilient-to-Throttled-Guessing	Resilient-to-Unthrottled-Guessing	Resilient-to-Internal-Observation	Resilient-to-Leaks-from-Other-Verifiers	Resilient-to-Phishing	Resilient-to-Theft	No-Trusted-Third-Party	Requiring-Explicit-Consent	Unlinkable
Sound-Proof			S		Y	Y	S	S	Y	Y		Y		Y	S		Y	Y		Y	Y	Y	Y	Y	
Google 2SV			S		Y	S	S	S	S	S		Y	Y	Y	S	S	Y	Y		Y	Y	Y	Y	Y	
PhoneAuth			S		Y	Y	S	S	Y	Y				Y	S		Y	Y		Y	Y	Y	Y	Y	
FBD-WF-WF			S		Y	S	S	S	Y	Y				Y	S	S	Y	Y		Y	Y	Y	Y	Y	

Table 3: Comparison of Sound-Proof against Google 2-Step Verification (Google 2SV), PhoneAuth [14], and FBD-WF-WF [41], using the framework of Bonneau et al. [10]. We use 'Y' to denote that the benefit is provided and 'S' to denote that the benefit is somewhat provided.

10 Related Work

Section 3 discusses alternative approaches to 2FA. In the following we review related work that leverages audio to verify the proximity of two devices.

Halevi et al., [27] use ambient audio to detect the proximity of two devices to thwart relay attacks in NFC payment systems. They compute the cross-correlation between the audio recorded by the two devices and employ machine-learning techniques to tell whether the two samples were recorded at the same location or not. The authors claim perfect results (0 false acceptance and false rejection rate). They, however, assume the two devices to have the same hardware (the experiment campaign used two Nokia N97 phones). Furthermore, their setup allows a maximum distance of 30 centimeters between the two devices. Our application scenario (web authentication) requires a solution that works (*i*) with heterogeneous devices, (*ii*) indoors and outdoors, and (*iii*) irrespective of the phone's position (e.g., in the user's pocket or purse). As such, we propose a different function to compute the similarity of the two samples, which we empirically found to be more robust, than what proposed in [27], in our settings.

Truong et al., [46] investigate relay attacks in zero-interaction authentication systems and use techniques similar to the ones of [27]. They propose a framework that detects co-location of two devices comparing features from multiple sensors, including GPS, Bluetooth, WiFi and audio. The authors conclude that an audio-only solution is not robust to detect co-location (20% of false rejections) and advocate for the combination of multiple sensors. Furthermore, their technique requires the two devices to sense the environment for 10 seconds. This time budget may not be available for web authentication.

The authors of [40] use ambient audio to derive a pairwise cryptographic key between two co-located devices. They use an audio fingerprinting scheme similar to the one of [26] and leverage fuzzy commitment schemes to accommodate for the difference of the two recordings. Their scheme may, in principle, be used to verify proximity of two devices in a 2FA mechanism. However, the experiments of [40] reveal that the key derivation is hardly feasible in outdoor scenarios. Our scheme takes advantage of noisy environments and, therefore, can be used in outdoor scenarios like train stations.

11 Conclusion

We proposed Sound-Proof, a two-factor authentication mechanism that does not require the user to interact with his phone and that can already be used with major browsers. We have shown that Sound-Proof works even if the phone is in the user's pocket or purse, and that it fares well both indoors and outdoors. Participants of a user study rated Sound-Proof to be more usable than Google 2-Step Verification. More importantly, most participants would use Sound-Proof for online services in which 2FA is optional. Sound-Proof improves the usability and deployability of 2FA and, as such, can foster large-scale adoption.

Acknowledgments

We thank Kurt Heutschi for the valuable discussions and insights on audio processing. We also thank our shepherd Joseph Bonneau, as well as the anonymous reviewers who helped to improve this paper with their useful feedback and comments.

Appendix

A System Usability Scale

We report the items of the System Usability Scale [11]. All items were answered with a 5-point Likert-scale from *Strongly Disagree* to *Strongly Agree.*

Q1 I think that I would like to use this system frequently.
Q2 I found the system unnecessarily complex.
Q3 I thought the system was easy to use.
Q4 I think that I would need the support of a technical person to be able to use this system.
Q5 I found the various functions in this system were well integrated.
Q6 I thought there was too much inconsistency in this system.
Q7 I would imagine that most people would learn to use this system very quickly.
Q8 I found the system very cumbersome to use.
Q9 I felt very confident using the system.
Q10 I needed to learn a lot of things before I could get going with this system.

B Post-test Questionnaire

We report the items of the post-test questionnaire. All items were answered with a 5-point Likert-scale from *Strongly Disagree* to *Strongly Agree.*

Q1 I thought the audio-based method was quick.
Q2 I thought the code-based method was quick.
Q3 If Second-Factor Authentication were mandatory, I would use the audio-based method to log in.
Q4 If Second-Factor Authentication were mandatory, I would use the code-based method to log in.
Q5 If Second-Factor Authentication were optional, I would use the audio-based method to log in.
Q6 If Second-Factor Authentication were optional, I would use the code-based method to log in.
Q7 I would feel comfortable using the audio-based method at home.
Q8 I would feel comfortable using the audio-based method at my workplace.
Q9 I would feel comfortable using the audio-based method in a cafe.
Q10 I would feel comfortable using the audio-based method in a library.
Q11 I would feel comfortable using the code-based method at home.
Q12 I would feel comfortable using the code-based method at my workplace.
Q13 I would feel comfortable using the code-based method in a cafe.
Q14 I would feel comfortable using the code-based method in a library.

C User Comments

This section lists some of the comments that participants added to their post-test questionnaire.

> "Sound-Proof is faster and automatic. Increased security without having to do more things"

> "I would use Sound-Proof, because it is less complicated and faster. I do not need to unlock the phone and open the application. In a public place it would feel a bit awkward unless it becomes widespread. Anyway, I am already logged in most websites that I use."

> "I like the audio idea, because what I hate the most about second-factor authentication is to have to take my phone out or find it around."

> "Sound-Proof is much easier. I am security-conscious and already use 2FA. I would be willing to switch to the audio-based method."

> "I already use Google 2SV and prefer it because I think it's more secure. However, Sound-Proof is seamless."

Android Permissions Remystified: A Field Study on Contextual Integrity

Abstract

We instrumented the Android platform to collect data regarding how often and under what circumstances smartphone applications access protected resources regulated by permissions. We performed a 36-person field study to explore the notion of "contextual integrity," i.e., how often applications access protected resources when users are not expecting it. Based on our collection of 27M data points and exit interviews with participants, we examine the situations in which users would like the ability to deny applications access to protected resources. At least 80% of our participants would have preferred to prevent at least one permission request, and overall, they stated a desire to block over a third of all requests. Our findings pave the way for future systems to automatically determine the situations in which users would want to be confronted with security decisions.

1 Introduction

Mobile platform permission models regulate how applications access certain resources, such as users' personal information or sensor data (e.g., camera, GPS, etc.). For instance, previous versions of Android prompt the user during application installation with a list of all the permissions that the application may use in the future; if the user is uncomfortable granting any of these requests, her only option is to discontinue installation [3]. On iOS and Android M, the user is prompted at runtime the first time an application requests any of a handful of data types, such as location, address book contacts, or photos [34].

Research has shown that few people read the Android install-time permission requests and even fewer comprehend them [16]. Another problem is habituation: on average, Android applications present the user with four permission requests during the installation process [13]. While iOS users are likely to see fewer permission requests than Android users, because there are fewer possible permissions and they are only displayed the first time the data is actually requested, it is not clear whether or not users are being prompted about access to data that they actually find concerning, or whether they would approve of subsequent requests [15].

Nissenbaum posited that the reason why most privacy models fail to predict violations is that they fail to consider contextual integrity [32]. That is, privacy violations occur when personal information is used in ways that defy users' expectations. We believe that this notion of "privacy as contextual integrity" can be applied to smartphone permission systems to yield more effective permissions by only prompting users when an application's access to sensitive data is likely to defy expectations. As a first step down this path, we examined how applications are currently accessing this data and then examined whether or not it complied with users' expectations.

We modified Android to log whenever an application accessed a permission-protected resource and then gave these modified smartphones to 36 participants who used them as their primary phones for one week. The purpose of this was to perform dynamic analysis to determine how often various applications are actually accessing protected resources under realistic circumstances. Afterwards, subjects returned the phones to our laboratory and completed exit surveys. We showed them various instances over the past week where applications had accessed certain types of data and asked whether those instances were expected, and whether they would have wanted to deny access. Participants wanted to block a third of the requests. Their decisions were governed primarily by two factors: whether they had privacy concerns surrounding the specific data type and whether they understood why the application needed it.

We contribute the following:

- To our knowledge, we performed the first field study to quantify the permission usage by third-party applications under realistic circumstances.

- We show that our participants wanted to block access to protected resources a third of the time. This suggests that some requests should be granted by runtime consent dialogs, rather than Android's previous all-or-nothing install-time approval approach.
- We show that the visibility of the requesting application and the frequency at which requests occur are two important factors which need to be taken into account in designing a runtime consent platform.

2 Related Work

While users are required to approve Android application permission requests during installation, most do not pay attention and fewer comprehend these requests [16, 26]. In fact, even developers are not fully knowledgeable about permissions [40], and are given a lot of freedom when posting an application to the Google Play Store [7]. Applications often do not follow the principle of least privilege, intentionally or unintentionally [44]. Other work has suggested improving the Android permission model with better definitions and hierarchical breakdowns [8]. Some researchers have experimented with adding fine-grained access control to the Android model [11]. Providing users with more privacy information and personal examples has been shown to help users in choosing applications with fewer permissions [21,27].

Previous work has examined the overuse of permissions by applications [13, 20], and attempted to identify malicious applications through their permission requests [36] or through natural language processing of application descriptions [35]. Researchers have also developed static analysis tools to analyze Android permission specifications [6, 9, 13]. Our work complements this static analysis by applying dynamic analysis to permission usage. Other researchers have applied dynamic analysis to native (non-Java) APIs among third-party mobile markets [39]; we apply it to the Java APIs available to developers in the Google Play Store.

Researchers examined user privacy expectations surrounding application permissions, and found that users were often surprised by the abilities of background applications to collect data [25, 42]. Their level of concern varied from annoyance to seeking retribution when presented with possible risks associated with permissions [15]. Some studies employed crowdsourcing to create a privacy model based on user expectations [30].

Researchers have designed systems to track or reduce privacy violations by recommending applications based on users' security concerns [2, 12, 19, 24, 28, 46–48]. Other tools dynamically block runtime permission requests [37]. Enck et al. found that a considerable number of applications transmitted location or other user data to third parties without requiring user consent [12]. Hornyack et al.'s AppFence system gave users the ability to deny data to applications or substitute fake data [24]. However, this broke application functionality for one-third of the applications tested.

Reducing the number of security decisions a user must make is likely to decrease habituation, and therefore, it is critical to identify *which* security decisions users should be asked to make. Based on this theory, Felt et al. created a decision tree to aid platform designers in determining the most appropriate permission-granting mechanism for a given resource (e.g., access to benign resources should be granted automatically, whereas access to dangerous resources should require approval) [14]. They concluded that the majority of Android permissions can be automatically granted, but 16% (corresponding to the 12 permissions in Table 1) should be granted via runtime dialogs.

Nissenbaum's theory of contextual integrity can help us to analyze "the appropriateness of a flow" in the context of permissions granted to Android applications [32]. There is ambiguity in defining when an application actually needs access to user data to run properly. It is quite easy to see why a location-sharing application would need access to GPS data, whereas that same request coming from a game like Angry Birds is less obvious. "Contextual integrity is preserved if information flows according to contextual norms" [32], however, the lack of thorough documentation on the Android permission model makes it easier for programmers to neglect these norms, whether intentionally or accidentally [38]. Deciding on whether an application is violating users' privacy can be quite complicated since "the scope of privacy is wide-ranging" [32]. To that end, we performed dynamic analysis to measure how often (and under what circumstances) applications were accessing protected resources, whether this complied with users' expectations, as well as how often they might be prompted if we adopt Felt et al.'s proposal to require runtime user confirmation before accessing a subset of these resources [14]. Finally, we show how it is possible to develop a classifier to automatically determine whether or not to prompt the user based on varying contextual factors.

3 Methodology

Our long-term research goal is to minimize habituation by only confronting users with *necessary* security decisions and avoiding showing them permission requests that are either expected, reversible, or unconcerning. Selecting which permissions to ask about requires understanding how often users would be confronted with each type of request (to assess the risk of habituation) and user reactions to these requests (to assess the benefit to users). In this study, we explored the problem space in two parts:

we instrumented Android so that we could collect actual usage data to understand how often access to various protected resources is requested by applications in practice, and then we surveyed our participants to understand the requests that they would not have granted, if given the option. This field study involved 36 participants over the course of one week of normal smartphone usage. In this section, we describe the log data that we collected, our recruitment procedure, and then our exit survey.

3.1 Tracking Access to Sensitive Data

In Android, when applications attempt to access protected resources (e.g., personal information, sensor data, etc.) at runtime, the operating system checks to see whether or not the requesting application was previously granted access during installation. We modified the Android platform to add a logging framework so that we could determine every time one of these resources was accessed by an application at runtime. Because our target device was a Samsung Nexus S smartphone, we modified Android 4.1.1 (Jellybean), which was the newest version of Android supported by our hardware.

3.1.1 Data Collection Architecture

Our goal was to collect as much data as possible about each applications' access to protected resources, while minimizing our impact on system performance. Our data collection framework consisted of two main components: a series of "producers" that hooked various Android API calls and a "consumer" embedded in the main Android framework service that wrote the data to a log file and uploaded it to our collection server.

We logged three kinds of permission requests. First, we logged function calls checked by `checkPermission()` in the Android `Context` implementation. Instrumenting the `Context` implementation, instead of the `ActivityManagerService` or `PackageManager`, allowed us to also log the function name invoked by the user-space application. Next, we logged access to the `ContentProvider` class, which verifies the read and write permissions of an application prior to it accessing structured data (e.g., contacts or calendars) [5]. Finally, we tracked permission checks during `Intent` transmission by instrumenting the `ActivityManagerService` and `BroadcastQueue`. `Intents` allow an application to pass messages to another application when an activity is to be performed in that other application (e.g., opening a URL in the web browser) [4].

We created a component called `Producer` that fetches the data from the above instrumented points and sends it back to the `Consumer`, which is responsible for logging everything reported. `Producers` are scattered across the Android Platform, since permission checks occur in multiple places. The `Producer` that logged the most data was in `system_server` and recorded direct function calls to Android's Java API. For a majority of privileged function calls, when a user application invokes the function, it sends the request to `system_server` via `Binder`. `Binder` is the most prominent IPC mechanism implemented to communicate with the Android Platform (whereas `Intents` communicate between applications). For requests that do not make IPC calls to the `system_server`, a `Producer` is placed in the user application context (e.g., in the case of `ContentProviders`).

The `Consumer` class is responsible for logging data produced by each `Producer`. Additionally, the `Consumer` also stores contextual information, which we describe in Section 3.1.2. The `Consumer` syncs data with the filesystem periodically to minimize impact on system performance. All log data is written to the internal storage of the device because the Android kernel is not allowed to write to external storage for security reasons. Although this protects our data from curious or careless users, it also limits our storage capacity. Thus, we compressed the log files once every two hours and upload them to our collection servers whenever the phone had an active Internet connection (the average uploaded and zipped log file was around 108KB and contained 9,000 events).

Due to the high volume of permission checks we encountered and our goal of keeping system performance at acceptable levels, we added rate-limiting logic to the `Consumer`. Specifically, if it has logged permission checks for a particular application/permission combination more than 10,000 times, it examines whether it did so while exceeding an average rate of 1 permission check every 2 seconds. If so, the `Consumer` will only record 10% of all future requests for this application/permission combination. When this rate-limiting is enabled, the `Consumer` tracks these application/permission combinations and updates all the `Producers` so that they start dropping these log entries. Finally, the `Consumer` makes a note of whenever this occurs so that we can extrapolate the true number of permission checks that occurred.

3.1.2 Data Collection

We hooked the permission-checking APIs so that every time the system checked whether an application had been granted a particular permission, we logged the name of the permission, the name of the application, and the API method that resulted in the check. In addition to timestamps, we collected the following contextual data:

- **Visibility**—We categorized whether the requesting application was visible to the user, using four categories: running (a) as a service with no user interaction; (b) as a service, but with user interaction via notifications or sounds; (c) as a foreground process, but in the background due to multitasking; or (d) as a foreground process with direct user interaction.

- **Screen Status**—Whether the screen was on/off.
- **Connectivity**—The phone's WiFi connection state.
- **Location**—The user's last known coordinates. In order to preserve battery life, we collected cached location data, rather than directly querying the GPS.
- **View**—The UI elements in the requesting application that were exposed to the user at the time that a protected resource was accessed. Specifically, since the UI is built from an XML file, we recorded the name of the screen as defined in the DOM.
- **History**—A list of applications with which the user interacted prior to the requesting application.
- **Path**—When access to a `ContentProvider` object was requested, the path to the specific content.

Felt et al. proposed granting most Android permissions without *a priori* user approval and granting 12 permissions (Table 1) at runtime so that users have contextual information to infer why the data might be needed [14]. The idea is that, if the user is asked to grant a permission while using an application, she may have some understanding of why the application needs that permission based on what she was doing. We initially wanted to perform experience sampling by probabilistically questioning participants whenever any of these 12 permissions were checked [29]. Our goal was to survey participants about whether access to these resources was expected and whether it should proceed, but we were concerned that this would prime them to the security focus of our experiment, biasing their subsequent behaviors. Instead, we instrumented the phones to probabilistically take screenshots of what participants were doing when these 12 permissions were checked so that we could ask them about it during the exit survey. We used reservoir sampling to minimize storage and performance impacts, while also ensuring that the screenshots covered a broad set of applications and permissions [43].

Figure 1 shows a screenshot captured during the study along with its corresponding log entry. The user was playing the Solitaire game while Spotify requested a WiFi scan. Since this permission was of interest (Table 1), our instrumentation took a screenshot. Since Spotify was not the application the participant was interacting with, its visibility was set to *false*. The history shows that prior to Spotify calling `getScanResults()`, the user had viewed Solitaire, the call screen, the launcher, and the list of MMS conversations.

Permission Type	**Activity**
WRITE_SYNC_SETTINGS	Change application sync settings when the user is roaming
ACCESS_WIFI_STATE	View nearby SSIDs
INTERNET	Access Internet when roaming
NFC	Communicate via NFC
READ_HISTORY_BOOKMARKS	Read users' browser history
ACCESS_FINE_LOCATION	Read GPS location
ACCESS_COARSE_LOCATION	Read network-inferred location (i.e., cell tower and/or WiFi)
LOCATION_HARDWARE	Directly access GPS data
READ_CALL_LOG	Read call history
ADD_VOICEMAIL	Read call history
READ_SMS	Read sent/received/draft SMS
SEND_SMS	Send SMS

Table 1: The 12 permissions that Felt et al. recommend be granted via runtime dialogs [14]. We randomly took screenshots when these permissions were requested by applications, and we asked about them in our exit survey.

3.2 Recruitment

We placed an online recruitment advertisement on Craigslist in October of 2014, under the "et cetera jobs" section.[1] The title of the advertisement was "Research Study on Android Smartphones," and it stated that the study was about how people interact with their smartphones. We made no mention of security or privacy. Those interested in participating were directed to an online consent form. Upon agreeing to the consent form, potential participants were directed to a screening application in the Google Play store. The screening application asked for information about each potential participant's age, gender, smartphone make and model. It also collected data on their phones' internal memory size and the installed applications. We screened out applicants who were under 18 years of age or used providers other than T-Mobile, since our experimental phones could not attain 3G speeds on other providers. We collected data on participants' installed applications so that we could preinstall free applications prior to them visiting our laboratory. (We copied paid applications from their phones, since we could not download those ahead of time.)

We contacted participants who met our screening requirements to schedule a time to do the initial setup. Overall, 48 people showed up to our laboratory, and of those, 40 qualified (8 were rejected because our screening application did not distinguish some Metro PCS users

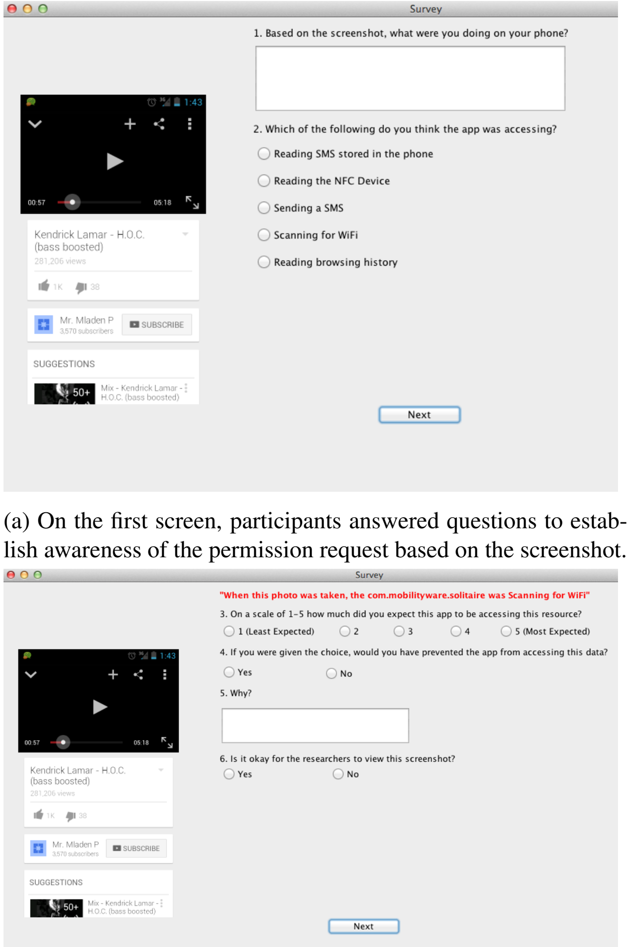
from T-Mobile users). In the email, we noted that due to the space constraints of our experimental phones, we might not be able to install all the applications on their existing phones, and therefore they needed to make a note of the ones that they planned to use that week. The initial setup took roughly 30 minutes and involved transferring their SIM cards, helping them set up their Google and other accounts, and making sure they had all the applications they needed. We compensated each participant with a $35 gift card for showing up at the setup session. Out of 40 people who were given phones, 2 did not return them, and 2 did not regularly use them during the study period. Of our 36 remaining participants who used the phones regularly, 19 were male and 17 were female; ages ranged from 20 to 63 years old (μ = 32, σ= 11).

After the initial setup session, participants used the experimental phones for one week in lieu of their normal phones. They were allowed to install and uninstall applications, and we instructed them to use these phones as they would their normal phones. Our logging framework kept track of every protected resource accessed by a user-level application along with the previously-mentioned contextual data. Due to storage constraints on the devices, our software uploaded log files to our server every two hours. However, to preserve participants' privacy, screenshots remained on the phones during the course of the week. At the end of the week, each participant returned to our laboratory, completed an exit survey, returned the phone, and then received an additional $100 gift card (i.e., slightly more than the value of the phone).

3.3 Exit Survey

When participants returned to our laboratory, they completed an exit survey. The exit survey software ran on a laptop in a private room so that it could ask questions about what they were doing on their phones during the course of the week without raising privacy concerns. We did not view their screenshots until participants gave us permission. The survey had three components:

- **Screenshots**—Our software displayed a screenshot taken after one of the 12 resources in Table 1 was accessed. Next to the screenshot (Figure 2a), we asked participants what they were doing on the phone when the screenshot was taken (open-ended). We also asked them to indicate which of several actions they believed the application was performing, chosen from a multiple-choice list of permissions presented in plain language (e.g., "reading browser history," "sending a SMS," etc.). After answering these questions, they proceeded to a second page of questions (Figure 2b). We informed participants at the top of this page of the resource that the application had accessed when the screenshot was taken, and asked them to indicate how much they expected this (5-point Likert scale). Next, we asked, "if you were given the choice, would you have prevented the app from accessing this data," and to explain why or why not. Finally, we asked for permission to view the screenshot. This phase of the exit survey was repeated for 10-15 different screenshots per participant, based on the number of screenshots saved by our reservoir sampling algorithm.
- **Locked Screens**—The second part of our survey involved questions about the same protected resources, though accessed while device screens were off (i.e., participants were not using their phones). Because there were no contextual cues (i.e., screenshots), we outright told participants which applications were accessing which resources and asked them multiple choice questions about whether they wanted to prevent this and the degree to which these



1. Based on the screenshot, what were you doing on your phone?

2. Which of the following do you think the app was accessing?

○ Reading SMS stored in the phone
○ Reading the NFC Device
○ Sending a SMS
○ Scanning for WiFi
○ Reading browsing history

(a) On the first screen, participants answered questions to establish awareness of the permission request based on the screenshot.

"When this photo was taken, the com.mobilityware.solitaire was Scanning for WiFi"

3. On a scale of 1-5 how much did you expect this app to be accessing this resource?

○ 1 (Least Expected) ○ 2 ○ 3 ○ 4 ○ 5 (Most Expected)

4. If you were given the choice, would you have prevented the app from accessing this data?

○ Yes ○ No

5. Why?

6. Is it okay for the researchers to view this screenshot?

○ Yes ○ No

(b) On the second screen, they saw the resource accessed, stated whether it was expected, and whether it should have been blocked.

Figure 2: Exit Survey Interface

behaviors were expected. They answered these questions for up to 10 requests, similarly chosen by our reservoir sampling algorithm to yield a breadth of application/permission combinations.

- **Personal Privacy Preferences**—Finally, in order to correlate survey responses with privacy preferences, participants completed two privacy scales. Because of the numerous reliability problems with the Westin index [45], we computed the average of both Buchanan et al.'s Privacy Concerns Scale (PCS) [10] and Malhotra et al.'s Internet Users' Information Privacy Concerns (IUIPC) scale [31].

After participants completed the exit survey, we re-entered the room, answered any remaining questions, and then assisted them in transferring their SIM cards back into their personal phones. Finally, we compensated each participant with a $100 gift card.

Three researchers independently coded 423 responses to the open-ended question in the screenshot portion of the survey. The number of responses per participant varied, as they were randomly selected based on the number of screenshots taken: participants who used their phones more heavily had more screenshots, and thus answered more questions. Prior to meeting to achieve consensus, the three coders disagreed on 42 responses, which resulted in an inter-rater agreement of 90%. Taking into account the 9 possible codings for each response, Fleiss' kappa yielded 0.61, indicating substantial agreement.

4 Application Behaviors

Over the week-long period, we logged 27M application requests to protected resources governed by Android permissions. This translates to over 100,000 requests per user/day. In this section, we quantify the circumstances under which these resources were accessed. We focus on the rate at which resources were accessed when participants were not actively using those applications (i.e., situations likely to defy users' expectations), access to certain resources with particularly high frequency, and the impact of replacing certain requests with runtime confirmation dialogs (as per Felt et al.'s suggestion [14]).

4.1 Invisible Permission Requests

In many cases, it is entirely expected that an application might make frequent requests to resources protected by permissions. For instance, the INTERNET permission is used every time an application needs to open a socket, ACCESS_FINE_LOCATION is used every time the user's location is checked by a mapping application, and so on. However, in these cases, one expects users to have certain contextual cues to help them understand that these applications are running and making these requests. Based on our log data, most requests occurred while participants were not actually interacting with those applications, nor did they have any cues to indicate that the applications were even running. When resources are accessed, applications can be in five different states, with regard to their visibility to users:

1. **Visible foreground application (12.04%)**: the user is using the application requesting the resource.
2. **Invisible background application (0.70%)**: due to multitasking, the application is in the background.
3. **Visible background service (12.86%)**: the application is a background service, but the user may be aware of its presence due to other cues (e.g., it is playing music or is present in the notification bar).
4. **Invisible background service (14.40%)**: the application is a background service without visibility.
5. **Screen off (60.00%)**: the application is running, but the phone screen is off because it is not in use.

Permission	Requests
ACCESS_NETWORK_STATE	31,206
WAKE_LOCK	23,816
ACCESS_FINE_LOCATION	5,652
GET_ACCOUNTS	3,411
ACCESS_WIFI_STATE	1,826
UPDATE_DEVICE_STATS	1,426
ACCESS_COARSE_LOCATION	1,277
AUTHENTICATE_ACCOUNTS	644
READ_SYNC_SETTINGS	426
INTERNET	416

Table 2: The most frequently requested permissions by applications with zero visibility to the user.

Application	Requests
Facebook	36,346
Google Location Reporting	31,747
Facebook Messenger	22,008
Taptu DJ	10,662
Google Maps	5,483
Google Gapps	4,472
Foursquare	3,527
Yahoo Weather	2,659
Devexpert Weather	2,567
Tile Game(Umoni)	2,239

Table 3: The applications making the most permission requests while running invisibly to the user.

Combining the 3.3M (12.04% of 27M) requests that were granted when the user was actively using the application (Category 1) with the 3.5M (12.86% of 27M) requests that were granted when the user had other contextual cues to indicate that the application was running (Category 3), we can see that fewer than one quarter of all permission requests (24.90% of 27M) occurred when the user had clear indications that those applications were running. This suggests that during the vast majority of the time, access to protected resources occurs opaquely to users. We focus on these 20.3M "invisible" requests (75.10% of 27M) in the remainder of this subsection.

Harbach et al. found that users' phone screens are off 94% of the time on average [22]. We observed that 60% of permission requests occurred while participants' phone screens were off, which suggests that permission requests occurred less frequently than when participants were using their phones. At the same time, certain applications made more requests when participants were not using their phones: "Brave Frontier Service," "Microsoft Sky Drive," and "Tile game by UMoni." Our study collected data on over 300 applications, and therefore it is possible that with a larger sample size, we would observe other applications engaging in this behavior. All of the aforementioned applications primarily requested ACCESS_WIFI_STATE and INTERNET. While a definitive explanation for this behavior requires examining source code or the call stacks of these applications, we hypothesize that they were continuously updating local data from remote servers. For instance, Sky Drive may have been updating documents, whereas the other two applications may have been checking the status of multiplayer games.

Table 2 shows the most frequently requested permissions from applications running invisibly to the user (i.e., Categories 2, 4, and 5); Table 3 shows the applications responsible for these requests (Appendix A lists the permissions requested by these applications). We normalized the numbers to show requests per user/day. ACCESS_NETWORK_STATE was most frequently requested, averaging 31,206 times per user/day—roughly once every 3 seconds. This is due to applications constantly checking for Internet connectivity. However, the 5,562 requests/day to ACCESS_FINE_LOCATION and 1,277 requests/day to ACCESS_COARSE_LOCATION are more concerning, as this could enable detailed tracking of the user's movement throughout the day. Similarly, a user's location can be inferred by using ACCESS_WIFI_STATE to get data on nearby WiFi SSIDs.

Contextual integrity means ensuring that information flows are appropriate, as determined by the user. Thus, users need the ability to see information flows. Current mobile platforms have done some work to let the user know about location tracking. For instance, recent versions of Android allow users to see which applications have used location data recently. While attribution is a positive step towards contextual integrity, attribution is most beneficial for actions that are reversible, whereas the disclosure of location information is not something that can be undone [14]. We observed that fewer than 1% of location requests were made when the applications were visible to the user or resulted in the displaying of a GPS notification icon. Given that Thompson et al. showed that most users do not understand that applications running in the background may have the same abilities as applications running in the foreground [42], it is likely that in the vast majority of cases, users do not know when their locations are being disclosed.

This low visibility rate is because Android only shows a notification icon when the GPS sensor is accessed, while offering alternative ways of inferring location. In 66.1% of applications' location requests, they directly queried the `TelephonyManager`, which can be used to determine location via cellular tower information. In 33.3% of the cases, applications requested the SSIDs of nearby WiFi networks. In the remaining 0.6% of cases, applications accessed location information using one of three built-in location providers: GPS, network, or passive. Applications accessed the GPS location provider only 6% of the time (which displayed a GPS notification). In the other 94% of the time, 13% queried the network provider (i.e., approximate location based on nearby cellular towers and WiFi SSIDs) and 81% queried the passive location provider. The passive location provider caches prior requests made to either the GPS or network providers. Thus, across all requests for location data, the GPS notification icon appeared 0.04% of the time.

While the alternatives to querying the GPS are less accurate, users are still surprised by their accuracy [17]. This suggests a serious violation of contextual integrity, since users likely have no idea their locations are being requested in the vast majority of cases. Thus, runtime notifications for location tracking need to be improved [18].

Apart from these invisible location requests, we also observed applications reading stored SMS messages (125 times per user/day), reading browser history (5 times per user/day), and accessing the camera (once per user/day). Though the use of these permissions does not necessarily lead to privacy violations, users have no contextual cues to understand that these requests are occurring.

4.2 High Frequency Requests

Some permission requests occurred so frequently that a few applications (i.e., Facebook, Facebook Messenger, Google Location Reporting, Google Maps, Farm Heroes Saga) had to be rate limited in our log files (see Section 3.1.1), so that the logs would not fill up users' remaining storage or incur performance overhead. Table 4 shows the complete list of application/permission combinations that exceeded the threshold. For instance, the most frequent requests came from Facebook requesting ACCESS_NETWORK_STATE with an average interval of 213.88 ms (i.e., almost 5 times per second).

With the exception of Google's applications, all rate-limited applications made excessive requests for the connectivity state. We hypothesize that once these applications lose connectivity, they continuously poll the system until it is regained. Their use of the `getActiveNetworkInfo()` method results in permission checks and returns `NetworkInfo` objects, which allow them to determine connection state (e.g., connected, disconnected, etc.) and type (e.g., WiFi, Bluetooth, cellular, etc.). Thus, these requests do not appear to be leaking sensitive information *per se*, but their frequency may have adverse effects on performance and battery life. It is possible that using the `ConnectivityManager`'s `NetworkCallback` method may be able to fulfill this need with far fewer permission checks.

Application / Permission	**Peak (ms)**	**Avg. (ms)**

4.3 Frequency of Data Exposure

Felt et al. posited that while most permissions can be granted automatically in order to not habituate users to relatively benign risks, certain requests should require runtime consent [14]. They advocated using runtime dialogs before the following actions should proceed:

1. Reading location information (e.g., using conventional location APIs, scanning WiFi SSIDs, etc.).
2. Reading the user's web browser history.
3. Reading saved SMS messages.
4. Sending SMS messages that incur charges, or inappropriately spamming the user's contact list.

These four actions are governed by the 12 Android permissions listed in Table 1. Of the 300 applications that we observed during the experiment, 91 (30.3%) performed one of these actions. On average, these permissions were requested 213 times per hour/user—roughly every 20 seconds. However, permission checks occur under a variety of circumstances, only a subset of which expose sensitive resources. As a result, platform develop-

Resource	**Visible**		**Invisible**		**Total**	
	Data Exposed	**Requests**	**Data Exposed**	**Requests**	**Data Exposed**	**Requests**
Location	758	2,205	3,881	8,755	4,639	10,960
Read SMS data	378	486	72	125	450	611
Sending SMS	7	7	1	1	8	8
Browser History	12	14	2	5	14	19
Total	1,155	2,712	3,956	8,886	5,111	11,598

Table 5: The sensitive permission requests (per user/day) when requesting applications were visible/invisible to users. "Data exposed" reflects the subset of permission-protected requests that resulted in sensitive data being accessed.

ers may decide to only show runtime warnings to users when protected data is read or modified. Thus, we attempted to quantify the frequency with which permission checks actually result in access to sensitive resources for each of these four categories. Table 5 shows the number of requests seen per user/day under each of these four categories, separating the instances in which sensitive data was exposed from the total permission requests observed. Unlike Section 4.1, we include "visible" permission requests (i.e., those occurring while the user was actively using the application or had other contextual information to indicate it was running). We didn't observe any uses of NFC, READ_CALL_LOG, ADD_VOICEMAIL, accessing WRITE_SYNC_SETTINGS or INTERNET while roaming in our dataset.

Of the location permission checks, a majority were due to requests for location provider information (e.g., `getBestProvider()` returns the best location provider based on application requirements), or checking WiFi state (e.g., `getWifiState()` only reveals whether WiFi is enabled). Only a portion of the requests actually exposed participants' locations (e.g., `getLastKnownLocation()` or `getScanResults()` exposed SSIDs of nearby WiFi networks).

Although a majority of requests for the READ_SMS permission exposed content in the SMS store (e.g., `Query()` reads the contents of the SMS store), a considerable portion simply read information about the SMS store (e.g., `renewMmsConnectivity()` resets an applications' connection to the MMS store). An exception to this is the use of SEND_SMS, which resulted in the transmission of an SMS message every time the permission was requested.

Regarding browser history, both accessing visited URLs (`getAllVisitedUrls()`) and reorganizing bookmark folders (`addFolderToCurrent()`) result in the same permission being checked. However, the latter does not expose specific URLs to the invoking application.

Our analysis of the API calls indicated that on average, only half of all permission checks granted applications access to sensitive data. For instance, across both visible and invisible requests, 5,111 of the 11,598 (44.3%) permission checks involving the 12 permissions in Table 1 resulted in the exposure of sensitive data (Table 5).

While limiting runtime permission requests to only the cases in which protected resources are exposed will greatly decrease the number of user interruptions, the frequency with which these requests occur is still too great. Prompting the user on the first request is also not appropriate (e.g., à la iOS and Android M), because our data show that in the vast majority of cases, the user has no contextual cues to understand when protected resources are being accessed. Thus, a user may grant a request the first time an application asks, because it is appropriate in that instance, but then she may be surprised to find that the application continues to access that resource in other contexts (e.g., when the application is not actively used). As a result, a more intelligent method is needed to determine when a given permission request is likely to be deemed appropriate by the user.

5 User Expectations and Reactions

To identify when users might want to be prompted about permission requests, our exit survey focused on participants' reactions to the 12 permissions in Table 1, limiting the number of requests shown to each participant based on our reservoir sampling algorithm, which was designed to ask participants about a diverse set of permission/application combinations. We collected participants' reactions to 673 permission requests ($\approx$19/participant). Of these, 423 included screenshots because participants were actively using their phones when the requests were made, whereas 250 permission requests were performed while device screens were off.[2] Of the former, 243 screenshots were taken while the requesting application was visible (Category 1 and 3 from Section 4.1), whereas 180 were taken while the application was invisible (Category 2 and 4 from Section 4.1). In this section, we describe the situations in which requests

[2] Our first 11 participants did not answer questions about permission requests occurring while not using their devices, and therefore the data only corresponds to our last 25 participants.

defied users' expectations. We present explanations for why participants wanted to block certain requests, the factors influencing those decisions, and how expectations changed when devices were not in use.

5.1 Reasons for Blocking

When viewing screenshots of what they were doing when an application requested a permission, 30 participants (80% of 36) stated that they would have preferred to block at least one request, whereas 6 stated a willingness to allow all requests, regardless of resource type or application. Across the entire study, participants wanted to block 35% of these 423 permission requests. When we asked participants to explain their rationales for these decisions, two main themes emerged: the request did not—in their minds—pertain to application functionality or it involved information they were uncomfortable sharing.

5.1.1 Relevance to Application Functionality

When prompted for the reason behind blocking a permission request, 19 (53% of 36) participants did not believe it was necessary for the application to perform its task. Of the 149 (35% of 423) requests that participants would have preferred to block, 79 (53%) were perceived as being irrelevant to the functionality of the application:

- *"It wasn't doing anything that needed my current location."* (P1)
- *"I don't understand why this app would do anything with SMS."* (P10)

Accordingly, functionality was the most common reason for wanting a permission request to proceed. Out of the 274 permissible requests, 195 (71% of 274) were perceived as necessary for the core functionality of the application, as noted by thirty-one (86% of 36) participants:

- *"Because it's a weather app and it needs to know where you are to give you weather information."*(P13)
- *"I think it needs to read the SMS to keep track of the chat conversation."*(P12)

Beyond being necessary for core functionality, participants wanted 10% (27 of 274) of requests to proceed because they offered convenience; 90% of these requests were for location data, and the majority of those applications were published under the Weather, Social, and Travel & Local categories in the Google Play store:

- *"It selects the closest stop to me so I don't have to scroll through the whole list."* (P0)
- *"This app should read my current location. I'd like for it to, so I won't have to manually enter in my zip code / area."* (P4)

Thus, requests were allowed when they were expected: when participants rated the extent to which each request was expected on a 5-point Likert scale, allowable requests averaged 3.2, whereas blocked requests averaged 2.3 (lower is less expected).

5.1.2 Privacy Concerns

Participants also wanted to deny permission requests that involved data that they considered sensitive, regardless of whether they believed the application actually needed the data to function. Nineteen (53% of 36) participants noted privacy as a concern while blocking a request, and of the 149 requests that participants wanted to block, 49 (32% of 149) requests were blocked for this reason:

- *"SMS messages are quite personal."* (P14)
- *"It is part of a personal conversation."* (P11)
- *"Pictures could be very private and I wouldn't like for anybody to have access."* (P16)

Conversely, 24 participants (66% of 36) wanted requests to proceed simply because they did not believe that the data involved was particularly sensitive; this reasoning accounted for 21% of the 274 allowable requests:

- *"I'm ok with my location being recorded, no concerns."* (P3)
- *"No personal info being shared."* (P29)

5.2 Influential Factors

Based on participants' responses to the 423 permission requests involving screenshots (i.e., requests occurring while they were actively using their phones), we quantitatively examined how various factors influenced their desire to block some of these requests.

Effects of Identifying Permissions on Blocking: In the exit survey, we asked participants to guess the permission an application was requesting, based on the screenshot of what they were doing at the time. The real answer was among four other incorrect answers. Of the 149 cases where participants wanted to block permission requests, they were only able to correctly state what permission was being requested 24% of the time; whereas when wanting a request to proceed, they correctly identified the requested permission 44% (120 of 274) of the time. However, Pearson's product-moment test on the average number of blocked requests per user and the average number of correct answers per user[3] did not yield a statistically significant correlation ($r = -0.171$, $p < 0.317$).

Effects of Visibility on Expectations: We were particularly interested in exploring if permission requests originating from foreground applications (i.e., visible to the

[3] Both measures were normally distributed.

user) were more expected than ones from background applications. Of the 243 visible permission requests that we asked about in our exit survey, participants correctly identified the requested permission 44% of the time, and their average rating on our expectation scale was 3.4. On the other hand, participants correctly identified the resources accessed by background applications only 29% of the time (52 of 180), and their average rating on our expectation scale was 3.0. A Wilcoxon Signed-Rank test with continuity correction revealed a statistically significant difference in participants' expectations between these two groups (V=441.5, p<0.001).

Effects of Visibility on Blocking: Participants wanted to block 71 (29% of 243) permission requests originating from applications running in the foreground, whereas this increased by almost 50% when the applications were in the background invisible to them (43% of 180). We calculated the percentage of denials for each participant, for both visible and invisible requests. A Wilcoxon Signed-Rank test with continuity correction revealed a statistically significant difference (V=58, p<0.001).

Effects of Privacy Preferences on Blocking: Participants completed the Privacy Concerns Scale (PCS) [10] and the Internet Users' Information Privacy Concerns (IUIPC) scale [31]. A Spearman's rank test yielded no statistically significant correlation between their privacy preferences and their desire to block permission requests ($\rho = 0.156$, p<0.364).

Effects of Expectations on Blocking: We examined whether participants' expectations surrounding requests correlated with their desire to block them. For each participant, we calculated their average Likert scores for their expectations and the percentage of requests that they wanted to block. Pearson's product-moment test showed a statistically significant correlation (r=-0.39, p<0.018). The negative correlation shows that participants were more likely to deny unexpected requests.

5.3 User Inactivity and Resource Access

In the second part of the exit survey, participants answered questions about 10 resource requests that occurred when the screen was off (not in use). Overall, they were more likely to expect resource requests to occur when using their devices ($\mu = 3.26$ versus $\mu = 2.66$). They also stated a willingness to block almost half of the permission requests (49.6% of 250) when not in use, compared to a third of the requests that occurred when using their phones (35.2% of 423). However, neither of these differences was statistically significant.

6 Feasibility of Runtime Requests

Felt et al. posited that certain sensitive permissions (Table 1) should require runtime consent [14], but in Section 4.3 we showed that the frequencies with which applications are requesting these permissions make it impractical to prompt the user each time a request occurs. Instead, the major mobile platforms have shifted towards a model of prompting the user the first time an application requests access to certain resources: iOS does this for a selected set of resources, such as location and contacts, and Android M does this for "dangerous" permissions.

How many prompts would users see, if we added runtime prompts for the first use of these 12 permissions? We analyzed a scheme where a runtime prompt is displayed at most once for each unique triplet of (application, permission, application visibility), assuming the screen is on. With a naïve scheme, our study data indicates our participants would have seen an average of 34 runtime prompts (ranging from 13 to 77, σ=11). As a refinement, we propose that the user should be prompted only if sensitive data will be exposed (Section 4.3), reducing the average number of prompts to 29.

Of these 29 prompts, 21 (72%) are related to location. Apple iOS already prompts users when an application accesses location for the first time, with no evidence of user habituation or annoyance. Focusing on the remaining prompts, we see that our policy would introduce an average of 8 new prompts per user: about 5 for reading SMS, 1 for sending SMS, and 2 for reading browser history. Our data covers only the first week of use, but as we only prompt on first use of a permission, we expect that the number of prompts would decline greatly in subsequent weeks, suggesting that this policy would likely not introduce significant risk of habituation or annoyance. Thus, our results suggest adding runtime prompts for reading SMS, sending SMS, and reading browser history would be useful given their sensitivity and low frequency.

Our data suggests that taking visibility into account is important. If we ignore visibility and prompted only once for each pair of (application, permission), users would have no way to select a different policy for when the application is visible or not visible. In contrast, "ask-on-first-use" for the triple (application, permission, visibility) gives users the option to vary their decision based on the visibility of the requesting application. We evaluated these two policies by analyzing the exit survey data (limited to situations where the screen was on) for cases where the same user was asked twice in the survey about situations with the same (application, permission) pair or the same (application, permission, visibility) triplet, to see whether the user's first decision to block or not matched their subsequent decisions. For the former policy, we saw only 51.3% agreement; for the latter, agreement increased to 83.5%. This suggests that the (application, permission, visibility) triplet captures many of the contextual factors that users care about, and thus it is reasonable to prompt only once per unique triplet.

A complicating factor is that applications can also run even when the user is not actively using the phone. In addition to the 29 prompts mentioned above, our data indicates applications would have triggered an average of 7 more prompts while the user was not actively using the phone: 6 for location and one for reading SMS. It is not clear how to handle prompts when the user is not available to respond to the prompt: attribution might be helpful, but further research is needed.

6.1 Modeling Users' Decisions

We constructed several statistical models to examine whether users' desire to block certain permission requests could be predicted using the contextual data that we collected. If such a relationship exists, a classifier could determine when to deny potentially unexpected permission requests without user intervention. Conversely, the classifier could be used to only prompt the user about questionable data requests. Thus, the response variable in our models is the user's choice of whether to block the given permission request. Our predictive variables consisted of the information that might be available at runtime: permission type (with the restriction that the invoked function exposes data), requesting application, and visibility of that application. We constructed several mixed effects binary logistic regression models to account for both inter-subject and intra-subject effects.

6.1.1 Model Selection

In our mixed effects models, permission types and the visibility of the requesting application were fixed effects, because all possible values for each variable existed in our data set. Visibility had two values: visible (the user is interacting with the application or has other contextual cues to know that it is running) and invisible. Permission types were categorized based on Table 5. The application name and the participant ID were included as random effects, because our survey data did not have an exhaustive list of all possible applications a user could run, and the participant has a non-systematic effect on the data.

Table 6 shows two goodness-of-fit metrics: the Akaike Information Criterion (AIC) and Bayesian Information Criterion (BIC). Lower values for AIC and BIC represent better fit. Table 6 shows the different parameters included in each model. We found no evidence of interaction effects and therefore did not include them. Visual inspection of residual plots of each model did not reveal obvious deviations from homoscedasticity or normality.

Predictors	**AIC**	**BIC**	**Screen State**
UserCode	490.60	498.69	Screen On
Application	545.98	554.07	Screen On
Application UserCode	491.86	503.99	Screen On
Permission Application UserCode	494.69	527.05	Screen On
Visibility **Application** **UserCode**	**481.65**	**497.83**	**Screen On**
Permission Visibility Application UserCode	484.23	520.64	Screen On
UserCode	245.13	252.25	Screen Off
Application	349.38	356.50	Screen Off
Application UserCode	238.84	249.52	Screen Off
Permission **Application** **UserCode**	**235.48**	**263.97**	**Screen Off**

Table 6: Goodness-of-fit metrics for various mixed effects logistic regression models on the exit survey data.

We initially included the phone's screen state as another variable. However, we found that creating two separate models based on the screen state resulted in better fit than using a single model that accounted for screen state as a fixed effect. When the screen was on, the best fit was a model including application visibility and application name, while controlling for subject effects. Here, fit improved once permission type was removed from the model, which shows that the decision to block a permission request was based on contextual factors: users do not categorically deny permission requests based solely on the type of resource being accessed (i.e., they also account for their trust in the application, as well as whether they happened to be actively using it). When the screen was off, however, the effect of permission type was relatively stronger. The strong subject effect in both models indicates that these decisions vary from one user to the next. As a result, any classifier developed to automatically decide whether to block a permission at runtime (or prompt the user) will need to be tailored to that particular user's needs.

6.1.2 Predicting User Reactions

Using these two models, we built two classifiers to make decisions about whether to block any of the sensitive permission requests listed in Table 5. We used our exit survey data as ground truth, and used 5-fold cross-validation to evaluate model accuracy.

We calculated the receiver operating characteristic (ROC) to capture the tradeoff between true-positive and false-positive rate. The quality of the classifier can be quantified with a single value by calculating the area under its ROC curve (AUC) [23]. The closer the AUC gets to 1.0, the better the classifier is. When screens were on, the AUC was 0.7, which is 40% better than the random baseline (0.5). When screens were off, the AUC was 0.8, which is 60% better than a random baseline.

7 Discussion

During the study, 80% of our participants deemed at least one permission request as inappropriate. This violates Nissenbaum's notion of "privacy as contextual integrity" because applications were performing actions that defied users' expectations [33]. Felt et al. posited that users may be able to better understand why permission requests are needed if some of these requests are granted via runtime consent dialogs, rather than Android's previous install-time notification approach [14]. By granting permissions at runtime, users will have additional contextual information; based on what they were doing at the time that resources are requested, they may have a better idea of why those resources are being requested.

We make two primary contributions that system designers can use to make more usable permissions systems. We show that the visibility of the requesting application and the frequency at which requests occur are two important factors in designing a runtime consent platform. Also, we show that "prompt-on-first-use" per triplet could be implemented for some sensitive permissions without risking user habituation or annoyance.

Based on the frequency with which runtime permissions are requested (Section 4), it is infeasible to prompt users every time. Doing so would overwhelm them and lead to habituation. At the same time, drawing user attention to the situations in which users are likely to be concerned will lead to greater control and awareness. Thus, the challenge is in acquiring their preferences by confronting them minimally and then automatically inferring *when* users are likely to find a permission request unexpected, and only prompting them in these cases. Our data suggests that participants' desires to block particular permissions were heavily influenced by two main factors: their understanding of the relevance of a permission request to the functionality of the requesting application and their individual privacy concerns.

Our models in Section 6.1 showed that individual characteristics greatly explain the variance between what different users deem appropriate, in terms of access to protected resources. While responses to privacy scales failed to explain these differences, this was not a surprise, as the disconnect between stated privacy preferences and behaviors is well-documented (e.g., [1]). This means that in order to accurately model user preferences, the system will need to learn what a specific user deems inappropriate over time. Thus, a feedback loop is likely needed: when devices are "new," users will be required to provide more input surrounding permission requests, and then based on their responses, they will see fewer requests in the future. Our data suggests that prompting once for each unique (application, permission, application visibility) triplet can serve as a practical mechanism in acquiring users' privacy preferences.

Beyond individual subject characteristics (i.e., personal preferences), participants based their decisions to block certain permission requests on the specific applications making the requests and whether they had contextual cues to indicate that the applications were running (and therefore needed the data to function). Future systems could take these factors into account when deciding whether or not to draw user attention to a particular request. For example, when an application that a user is not actively using requests access to a protected resource, she should be shown a runtime prompt. Our data indicates that, if the user decides to grant a request in this situation, then with probability 0.84 the same decision will hold in future situations where she is actively using that same application, and therefore a subsequent prompt may not be needed. At a minimum, platforms need to treat permission requests from background applications differently than those originating from foreground applications. Similarly, applications running in the background should use passive indicators to communicate when they are accessing particular resources. Platforms can also be designed to make decisions about whether or not access to resources should be granted based on whether contextual cues are present, or at its most basic, whether the device screen is even on.

Finally, we built our models and analyzed our data within the framework of what resources our participants *believed* were necessary for applications to correctly function. Obviously, their perceptions may have been incorrect: if they better understood why a particular resource was necessary, they may have been more permissive. Thus, it is incumbent on developers to adequately communicate why particular resources are needed, as this impacts user notions of contextual integrity. Yet, no mechanisms in Android exist for developers to do this as part of the permission-granting process. For example, one could imagine requiring metadata to be provided that explains how each requested resource will be used, and then automatically integrating this information into permission requests. Tan et al. examined a similar feature on iOS that allows developers to include free-form text in runtime permission dialogs and observed that users were more likely to grant requests that included this text [41]. Thus, we believe that including succinct explanations in these requests would help preserve contextual integrity by promoting greater transparency.

In conclusion, we believe this study was instructive in showing the circumstances in which Android permission requests are made under real-world usage. While prior work has already identified some limitations of deployed mobile permissions systems, we believe our study can benefit system designers by demonstrating several ways in which contextual integrity can be improved, thereby empowering users to make better security decisions.

A Invisible requests

Following list shows the set of applications that have requested the most number of permissions while executing invisibly to the user and the most requested permission types by each respective application.

- *Facebook App*— ACCESS NETWORK STATE, ACCESS FINE LOCATION, ACCESS WIFI STATE ,WAKE LOCK,
- *Google Location*—WAKE LOCK, ACCESS FINE LOCATION, GET ACCOUNTS, ACCESS COARSE LOCATION,
- *Facebook Messenger*—ACCESS NETWORK STATE, ACCESS WIFI STATE, WAKE LOCK, READ PHONE STATE,
- *Taptu DJ*—ACCESS NETWORK STATE, INTERNET, NFC
- *Google Maps*—ACCESS NETWORK STATE, GET ACCOUNTS, WAKE LOCK, ACCESS FINE LOCATION,
- *Google (Gapps)*—WAKE LOCK, ACCESS FINE LOCATION, AUTHENTICATE ACCOUNTS, ACCESS NETWORK STATE,
- *Fouraquare*—ACCESS WIFI STATE, WAKE LOCK, ACCESS FINE LOCATION, INTERNET,
- *Yahoo Weather*—ACCESS FINE LOCATION, ACCESS NETWORK STATE, INTERNET, ACCESS WIFI STATE,

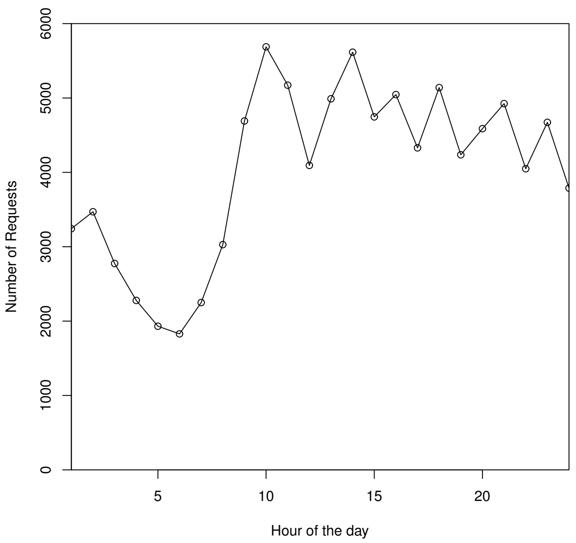
- *Devexpert Weather*—ACCESS NETWORK STATE, INTERNET, ACCESS FINE LOCATION,
- *Tile Game(Umoni)*—ACCESS NETWORK STATE, WAKE LOCK, INTERNET, ACCESS WIFI STATE,

Following is the most frequently requested permission type by applications while running invisibly to the user and the applications who requested the respective permission type most.

- *ACCESS_NETWORK_STATE*— Facebook App, Google Maps, Facebook Messenger, Google (Gapps), Taptu - DJ
- *WAKE_LOCK*—Google (Location), Google (Gapps), Google (GMS), Facebook App, GTalk.
- *ACCESS_FINE_LOCATION*—Google (Location), Google (Gapps), Facebook App, Yahoo Weather, Rhapsody (Music)
- *GET_ACCOUNTS*—Google (Location), Google (Gapps), Google (Login), Google (GM), Google (Vending)
- *ACCESS_WIFI_STATE*—Google (Location), Google (Gapps), Facebook App, Foursqaure, Facebook Messenger
- *UPDATE_DEVICE_STATS*—Google (SystemUI), Google (Location), Google (Gapps)
- *ACCESS_COARSE_LOCATION*—Google (Location), Google (Gapps), Google (News), Facebook App, Google Maps
- *AUTHENTICATE_ACCOUNTS*—Google (Gapps), Google (Login), Twitter, Yahoo Mail, Google (GMS)
- *READ_SYNC_SETTINGS*—Google (GM), Google (GMS), android.process.acore, Google (Email), Google (Gapps)
- *INTERNET*—Google (Vending), Google (Gapps), Google (GM), Facebook App, Google (Location)

B Distribution of Requests

The following graph shows the distribution of requests throughout a given day averaged across the data set.



C Permission Type Breakdown

This table lists the most frequently used permissions during the study period. (per user / per day)

Permission Type	Requests
ACCESS_NETWORK_STATE	41077
WAKE_LOCK	27030
ACCESS_FINE_LOCATION	7400
GET_ACCOUNTS	4387
UPDATE_DEVICE_STATS	2873
ACCESS_WIFI_STATE	2092
ACCESS_COARSE_LOCATION	1468
AUTHENTICATE_ACCOUNTS	1335
READ_SYNC_SETTINGS	836
VIBRATE	740
INTERNET	739
READ_SMS	611
READ_PHONE_STATE	345
STATUS_BAR	290
WRITE_SYNC_SETTINGS	206
CHANGE_COMPONENT_ENABLED_STATE	197
CHANGE_WIFI_STATE	168
READ_CALENDAR	166
ACCOUNT_MANAGER	134
ACCESS_ALL_DOWNLOADS	127
READ_EXTERNAL_STORAGE	126
USE_CREDENTIALS	101
READ_LOGS	94

D User Application Breakdown

This table shows the applications that most frequently requested access to protected resources during the study period. (per user / per day)

Application Name	Requests
facebook.katana	40041
google.process.location	32426
facebook.orca	24702
taptu.streams	15188
google.android.apps.maps	6501
google.process.gapps	5340
yahoo.mobile.client.android.weather	5505
tumblr	4251
king.farmheroessaga	3862
joelapenna.foursquared	3729
telenav.app.android.scout_us	3335

Abstract

Private Set Intersection (PSI) allows two parties to compute the intersection of private sets while revealing nothing more than the intersection itself. PSI needs to be applied to large data sets in scenarios such as measurement of ad conversion rates, data sharing, or contact discovery. Existing PSI protocols do not scale up well, and therefore some applications use insecure solutions instead.

We describe a new approach for designing PSI protocols based on permutation-based hashing, which enables to reduce the length of items mapped to bins while ensuring that no collisions occur. We denote this approach as Phasing, for Permutation-based Hashing Set Intersection. Phasing can dramatically improve the performance of PSI protocols whose overhead depends on the length of the representations of input items.

We apply Phasing to design a new approach for circuit-based PSI protocols. The resulting protocol is up to 5 times faster than the previously best Sort-Compare-Shuffle circuit of Huang et al. (NDSS 2012). We also apply Phasing to the OT-based PSI protocol of Pinkas et al. (USENIX Security 2014), which is the fastest PSI protocol to date. Together with additional improvements that reduce the computation complexity by a logarithmic factor, the resulting protocol improves run-time by a factor of up to 20 and can also have similar communication overhead as the previously best PSI protocol in that respect. The new protocol is only moderately less efficient than an *insecure* PSI protocol that is currently used by real-world applications, and is therefore the first secure PSI protocol that is scalable to the demands and the constraints of current real-world settings.

1 Introduction

Private set intersection (PSI) allows two parties P_1 and P_2 with respective input sets X and Y to compute the intersection $X \cap Y$ of their sets without revealing any information but the intersection itself. Although PSI has been widely studied in the literature, many real-world applications today use an insecure hash-based protocol instead of a secure PSI protocol, mainly because of the insufficient efficiency of current PSI protocols.

In this work we present *Phasing*, Permutation-based Hashing Set Intersection, which is a new approach for constructing PSI protocols based on a hashing technique that ensures that hashed elements can be represented by short strings without any collisions. The overhead of recent PSI protocols depends on the length of these representations, and this new structure of construction, together with other improvements, results in very efficient performance that is only moderately larger than that of the *insecure* protocol that is in current real-world usage.

1.1 Motivating Scenarios

The motivation for this work comes from scenarios where PSI must be applied quite frequently to large sets of data, and therefore performance becomes critical. Moreover, the communication overhead might be even more important than the computation overhead, since in large data centers it is often easier to add computing power than to improve the outgoing communication infrastructure. We describe here three scenarios which require large-scale PSI implementations.

Measuring ad conversion rates Online advertising, which is a huge business, typically measures the success of ad campaigns by measuring the success of converting viewers into customers. A popular way of measuring this value is by computing the conversion rate, which is the percentage of ad viewers who later visit the advertised site or perform a transaction there. For banner ads or services like Google Adwords it is easy to approximate this value by measuring ad click-throughs. However, measuring click-throughs is insufficient in other online advertising settings. One such setting is *mobile advertising*, which is becoming a dominating part of online advertising. Even though mobile ads have a great effect, click-throughs are an insufficient measure of their utility, since it is unlikely, due to small displays and the casual nature of mobile browsing, that a user will click on an ad and, say, purchase a car using his mobile device. Another setting where click rate measurement is unsatisfactory is advertising of offline goods, like groceries, where the purchase itself is done offline.[1]

An alternative method of measuring ad performance is to compare the list of people who have seen an ad with those who have completed a transaction. These lists are held by the advertiser (say, Google or Facebook), and by merchants, respectively. It is often possible to identify users on both ends, using identifiers such as credit card numbers, email addresses, etc. A simple solution, which ignores privacy, is for one side to disclose its list of customers to the other side, which then computes the necessary statistics. Another option is to run a PSI protocol between the two parties. (The protocol should probably be a variant of PSI, e.g. compute total revenues from customers who have seen an ad. Such protocols can be derived from basic PSI protocols.) In fact, Facebook is running a service of this type with Datalogix, Epsilon and Acxiom, companies which have transaction records for a large part of loyalty card holders in the US. According to reports[2], the computation is done using a variant of the *insecure* naive hashing PSI protocol that we describe in §3.1. Our results show that it can be computed using secure protocols even for large data sets.

Security incident information sharing Security incident handlers can benefit from information sharing since it provides them with a global view during incidents. However, incident data is often sensitive and potentially embarrassing. The shared information might reveal information about the business of the company that provided it, or of its customers. Therefore, information is typically shared rather sparsely and protected using legal agreements. Automated large scale sharing will improve security, and there is in fact work to that end, such as the IETF Managed Incident Lightweight Exchange (MILE) effort. Many computations that are applied to the shared data compute the intersection and its variants. Applying PSI to perform these computations can simplify the legal issues of information sharing. Efficient PSI protocols will enable it to be run often and in large scale.

Private contact discovery When a new user registers to a service it is often essential to identify current registered users who are also contacts of the new user. This operation can be done by simply revealing the user's contact list to the service, but can also be done in a privacy preserving manner by running a PSI protocol between the user's contact list and the registered users of the service. This latter approach is used by the TextSecure and Secret applications, but for performance reasons they use the insecure naive hashing PSI protocol described in §3.1.[3]

In these cases each user has a small number of records n_2, e.g., $n_2 = 256$, whereas the service has millions of registered users (in our experiments we use $n_1 = 2^{24}$). It therefore holds that $n_2 \ll n_1$. In our best PSI protocol, the client needs only $\mathsf{O}(n_2 \log n_1)$ memory, $\mathsf{O}(n_2)$ symmetric cryptographic operations and $\mathsf{O}(n_1)$ cheap hash table lookups, and the communication is $\mathsf{O}(n_1 \log n_1)$. (The communication overhead is indeed high as it depends on n_1, but this seems inevitable if brute force searches are to be prevented.)

1.2 Our Contributions

Our goal in this work is to enable PSI computations for large scale sets that were previously beyond the capabilities of state-of-the-art protocols. The constructions that we design in this work improve performance by more than an order of magnitude. We obtain these improvements by generalizing the hashing approach of [22] and applying it to generic secure computation-based PSI protocols. We replace the hash function in [22] by a permutation which enables us to reduce the bit-length of internal representations. Moreover, we suggest several improvements to the OT-based PSI protocol of [22]. We explain our contributions in more detail next:

Phasing: Using permutation-based hashing to reduce the bit-length of representations. The overhead of the best current PSI protocol [22] is linear in the length of the representations of items in the sets (i.e., the ids of items in the sets). The protocol maps items into bins, and since each bin has very few items in it, it is tempting to hash the ids to shorter values and trust the birthday paradox to ensure that no two items in the same bin are hashed to the same representation. However, a closer examination shows that to ensure that the collision probability is smaller than $2^{-\lambda}$, the length of the representation must be at least λ bits, which is too long.

In this work we utilize the permutation-based hashing techniques of [1] to reduce the bit-length of the ids of items that are mapped to bins. These ideas were suggested in an algorithmic setting to reduce memory us-

[3] See `https://whispersystems.org/blog/contact-discovery/` and `https://medium.com/@davidbyttow/demystifying-secret-12ab82fda29f` , respectively.

age, and as far as we know this is the first time that they are used in a cryptographic or security setting to improve performance. Essentially, when using β bins the first $\log\beta$ bits in an item's hashed representation define the bin to which the item is mapped, and the other bits are used in a way which provably prevents collisions. This approach reduces the bit-length of the values used in the PSI protocol by $\log\beta$ bits, and this yields reduced overhead by up to 60%-75% for the settings we examined.

Circuit-Phasing: Improved circuit-based PSI. As we discuss in §3.4 there is a great advantage in using generic secure computation for computing PSI, since this enables to easily compute variants of the basic PSI functionality. Generic secure computation protocols evaluate Boolean circuits computing the desired functionality. The best known circuit for computing PSI was based on the Sort-Compare-Shuffle circuit of [12]. We describe Circuit-Phasing, a new generic protocol that uses hashing (specifically, Cuckoo hashing and simple hashing) and secure circuit evaluation. In comparison with the previous approach, our circuits have a smaller number of AND gates, a lower depth of the circuit (which affects the number of communication rounds in some protocols), and a much smaller memory footprint. These factors lead to a significantly better performance.

OT-Phasing: Improved OT-based PSI. We introduce the OT-Phasing protocol which improves the OT-based PSI protocol of [22] as follows:

- **Improved computation and memory.** We reduce the length of the strings that are processed in the OT from $\mathsf{O}(\log^2 n)$ to $\mathsf{O}(\log n)$, which results in a reduction of computation and memory complexity for the client from $\mathsf{O}(n\log^2 n)$ to $\mathsf{O}(n\log n)$.
- **3-way Cuckoo hashing.** We use 3 instead of 2 hash functions to generate a more densely populated Cuckoo table and thus decrease the overall number of bins and hence OTs.

OT-Phasing improves over state-of-the-art PSI both in terms of run-time and communication. Compared to the previously fastest PSI protocol of [22], our protocol improves run-time by up to factor 10 in the WAN setting and by up to factor 20 in the LAN setting. Furthermore, our OT-Phasing protocol in some cases achieves similar communication as [18], which was shown to achieve the lowest communication of all PSI protocols [22].

1.3 Outline

We give preliminary information in §2 and summarize related work in §3. In §4 we describe Phasing, our optimization for permutation-based hashing that reduces the bit-length of elements in PSI. Afterwards, we apply Phasing to generic secure computation protocols, and present Circuit-Phasing, our new approach for circuit-based PSI §5. Thereafter, we apply Phasing to the previously fastest OT-based PSI protocol of [22] and present several optimizations in §6. In §7 we analyze the hashing failure probability of Circuit- and OT-Phasing. Finally, we provide an evaluation of our PSI protocols in §8.

2 Preliminaries

2.1 Notation

We denote the parties as P_1 and P_2. For all protocols we assume that P_2 obtains the output. The respective input sets are denoted as X and Y, with sizes $n_1 = |X|$ and $n_2 = |Y|$. Often $n_1 = n_2$ and we use the notation $n = n_1 = n_2$. We assume that elements are of bit-length σ.

We call the symmetric security parameter κ, the bit-length of the elliptic curves φ, and the statistical security parameter λ. Throughout the paper we assume 128-bit security, i.e., $\kappa = 128$, $\varphi = 283$ (using Koblitz-curves), and $\lambda = 40$. For symmetric encryption we use AES-128.

We refer to the concatenation of bit-strings by $||$, to the exclusive-OR (XOR) operation by $\oplus$, and to the i-th element in a sequence S by $S[i]$. In many protocols, we shorten the size of hash values that are sent to $\ell = \lambda + \log_2(n_1) + \log_2(n_2)$ instead of 2κ. This yields collision probability $2^{-\lambda}$, which is suited for most applications.

2.2 Security

Two types of adversaries are typically discussed in the secure computation literature: A *semi-honest* adversary is trusted to follow the protocol, but attempts to learn as much information as possible from the messages it receives. This adversary model is appropriate for scenarios where execution of the correct software is enforced by software attestation or where an attacker might obtain the transcript of the protocol *after* its execution, either by stealing it or by legally enforcing its disclosure. In contrast, a *malicious* adversary can behave arbitrarily. Most work on PSI was in the semi-honest setting. Protocols that are secure against malicious adversaries, e.g., [9, 10, 14], are considerably less efficient. We focus on optimal performance and therefore design protocols secure against semi-honest adversaries only. Furthermore, the security of the protocols is proven in the random oracle model, as is justified in the full version [21].

2.3 Hashing to Bins

Our protocols hash the input items to bins and then operate on each bin separately. In general, our hashing schemes use a table T consisting of β bins. An element e is mapped to the table by computing an address $a = H(e)$ using a hash function H that is modeled as a random function. A value related to e is then stored in bin $T[a]$.

There is a rich literature on hashing schemes, which differ in the methods for coping with collisions, the complexity for insertion/deletion/look-up, and the utilization of storage space. In [9, 10, 22], hashing to bins was used to improve the number of comparisons that are performed in PSI protocols. In the following, we detail the two most promising hashing schemes for use in PSI, according to [22]: *simple hashing* and *Cuckoo hashing*. For the OT-based PSI protocol of [22] it was shown that a combination of simple hashing (for P_1) and Cuckoo hashing (for P_2) results in the best performance.

2.3.1 Simple Hashing

Simple hashing builds the table T by mapping each element e to bin $T[H(e)]$ and appending e to the bin. Each bin must, of course, be able to store more than one element. The size of the most populated bin was analyzed in [23], and depends on the relation between the number of bins and the total number of elements. Most importantly for our application, when hashing n elements into $\beta = n$ bins, it was shown that the maximum number of elements in a bin is $\frac{\ln n}{\ln \ln n}(1+o(1))$. In §7.1 we give a theoretical and an empirical analysis of the maximum number of elements in a bin.

2.3.2 Cuckoo Hashing

Cuckoo hashing [19] uses h hash functions $H_1, ..., H_h$ to map an element e to a bin using either one of the h hash functions. (Typically, h is set to be $h = 2$; we also use $h = 3$.) In contrast to simple hashing, it allows at most one element to be stored in a bin. If a collision occurs, Cuckoo hashing evicts the element in the bin and performs the insertion again for the evicted element. This process is repeated until an empty bin is found for the evicted element. If the resulting sequence of insertion attempts fails a certain number of times, the current evicted element is placed in a special bin called stash. In [16] it was shown that for $h = 2$ hash functions, $\beta = 2(1+\varepsilon)n$ bins, and a stash of size $s \leq \ln n$, the insertion of elements fails with small probability of $O(n^{-s})$, which is smaller than $n^{-(s-1)}$ for sufficiently large values of n (cf. §7.2).

2.4 Oblivious Transfer

1-ouf-of-2 oblivious transfer (OT) [8] is a protocol where the receiver with choice bit c, chooses one of two strings (x_0, x_1) held by the sender. The receiver receives x_c but gains no information about x_{1-c}, while the sender gains no information about c.

OT extension protocols [2, 17] precompute a small number (say, $\kappa = 128$) of "real" public-key-based OTs, and then compute any polynomial number of OTs using symmetric-key cryptography alone. The most efficient OT variant that we use computes *random OT*. In that protocol the sender has no input but obtains random (x_0, x_1) as output, while the receiver with input c obtains x_c [2]. The advantage of this protocol is that the sender does not need to send messages based on its inputs, as it does not have any inputs, and instead computes them on-the-fly during the OT extension protocol. As a result, the communication overhead of the protocol is greatly reduced.

An additional improvement that we use, described in [17], efficiently computes 1-out-of-N OT for short strings. The communication for a random 1-out-of-N OT (for $3 \leq N \leq 256$) is only 2κ-bits, whereas the communication for a random 1-out-of-2 OT is κ-bits. The computation for a random 1-out-of-N OT amounts to four pseudo-random generator (PRG) and one correlation-robust function (CRF) evaluations for the receiver and two PRG and N CRF evaluations for the sender. In addition, if the sender only requires $i \leq N$ outputs of the OT, it only needs to perform i CRF evaluations.

We use 1-out-of-N OT since we have to perform OTs for every bit of an element. By using 1-out-of-N OT for $N = 2^\mu$, we process μ bits in parallel with communication equal to that of processing two bits. We denote m 1-out-of-N OTs on ℓ-bit strings by $\binom{N}{1}$-OT$_\ell^m$.

2.5 Generic Secure Computation

Generic secure two-party computation protocols allow two parties to securely evaluate any function that can be expressed as a Boolean circuit. The communication overhead and the number of cryptographic operations that are computed are linear in the number of non-linear (AND) gates in the circuit, since linear (XOR) gates can be evaluated "for free" in current protocols. Furthermore, some protocols require a number of interaction rounds that are linear in the AND depth of the circuit. The two main approaches for generic secure two-party computation on Boolean circuits are *Yao's garbled circuits* [25] and the protocol by *Goldreich-Micali-Wigderson* [11]. We give a summary of these protocols in the full version [21].

3 Related Work

We reflect on existing PSI protocols by following the classification of PSI protocols in [22]: the *naive hashing* protocol (§3.1), *server-aided* PSI protocols (§3.2), *public-key cryptography-based* PSI protocols (§3.3), *generic secure computation-based* PSI protocols (§3.4), and *OT-based* PSI protocols (§3.5). For each category, we review existing work and outline the best performing protocol, according to [22].

3.1 (Insecure) Naive Hashing

In the naive hashing protocol, detailed in the full version [21], P_1 permutes and hashes its elements, and sends the results to P_2 which compares these values to the hashes of its elements. This approach is very efficient and is currently employed in practice, but it allows P_2 to brute-force the elements of P_1 if they do not have high entropy. Furthermore, even if inputs elements have high entropy, forward-secrecy is not provided since P_2 can check at any later time whether an element was in X.

3.2 Server-Aided PSI

To increase the efficiency of PSI, protocols that use a semi-trusted third party were proposed [15]. These protocols are secure as long as the third party does not collude with any of the participants. We mention this set of protocols here for completeness, as they require different trust assumptions as protocols involving no third party.

The protocol of [15] has only a slightly higher overhead than the naive hashing PSI solution described in §3.1. In that protocol, P_1 samples a random κ-bit key k and sends it to P_2. Both parties compute $h_i = F_k(x_i)$ (resp. $h'_j = F_k(y_j)$), where F_k is a pseudo-random permutation that is parametrized by k. Both parties then send the hashes to the third party (in randomly permuted order) who then computes $I = h_i \cap h'_j$, for all $1 \le i \le n_1$ and $1 \le j \le n_2$ and sends I to P_2. P_2 obtains the intersection by computing $F_k^{-1}(e)$ for each $e \in I$.

3.3 Public-Key Cryptography based PSI

The first protocols for PSI were outlined in [13, 18] and were based on the Diffie-Hellmann (DH) key exchange. The overhead of these protocols is $\mathsf{O}(n)$ exponentiations. In [9, 10], a PSI protocol based on El-Gamal encryption was introduced that uses oblivious polynomial evaluation and requires $\mathsf{O}(n \log\log(n))$ public-key encryptions (the advantage of that protocol was that its security was not based on the random oracle model). A PSI protocol that uses blind-RSA was introduced in [3].

We implement the DH-based protocol of [13, 18] based on elliptic-curve-cryptography, which was shown to achieve lowest communication in [22]. We describe the protocol in the full version [21].

3.4 PSI based on Generic Protocols

Generic secure computation can be used to perform PSI by encoding the intersection functionality as a Boolean circuit. The most straightforward method for this encoding is to perform a pairwise-comparison which compares each element of one party to all elements of the other party. However, this circuit uses $\mathsf{O}(n^2)$ comparisons and hence scales very poorly for larger set sizes [12]. The *Sort-Compare-Shuffle (SCS)* circuit of [12] is much more efficient. As indicated by its name, the circuit first *sorts* the union of the elements of both parties, then *compares* adjacent elements for equality, and finally *shuffles* the result to avoid information leakage. The sort and shuffle operations are implemented using a sorting network of only $\mathsf{O}(n \log n)$ comparisons, and the comparison step requires only $\mathsf{O}(n)$ comparisons.

The work of [12] describes a size-optimized version of this circuit for use in Yao's garbled circuits; [22] describes a depth-optimized version for use in the GMW protocol. The size-optimized SCS circuit has $\sigma(3n\log_2 n + 4n)$ AND gates[4] and AND depth $(\sigma + 2)\log_2(2n) + \log_2(\sigma) + 1$ while the depth-optimized SCS circuit has about the same number of gates and AND depth of $(\log_2(\sigma) + 4)\log_2(2n)$, for $n = (n_1 + n_2)/2$.

PSI protocols based on generic secure computation have higher run-time and communication complexity than most special-purpose PSI protocols [4, 22]. Yet, these protocols are of great importance since they enable to easily compute any functionality that is based on basic PSI. Consider, for example, an application that needs to find if the size of the intersection is greater than some threshold, or compute the sum of revenues from items in the intersection. Computing these functionalities using specialized PSI protocols requires to change the protocols, whereas a PSI protocol based on generic computation can be adapted to compute these functionalities by using a slightly modified circuit. In other words, changing specialized protocols to have a new functionality requires to employ a cryptographer to design a new protocol variant, whereas changing the functionality of a generic protocol only requires to design a new circuit computing the new functionality. The latter task is of course much simpler. An approximate PSI protocol that uses generic secure computation protocols in combination with Bloom filters was given in [24].

3.5 OT-based PSI

OT-based PSI protocols are the most recent category of PSI protocols. Their research has been motivated by recent efficiency improvements in OT extension. The garbled Bloom filter protocol of [7] was the first OT-based PSI protocol and was improved in [22]. A novel OT-based PSI protocol, which we denote *OT-PSI* protocol,

[4] The original description of the SCS circuit in [12] embedded input keys into AND gates in the sort circuit to reduce communication. We did not use this optimization in our implementation.

was introduced in [22], combining OT and hashing to achieve the best run-time among all analyzed PSI protocols. We next summarize the OT-PSI protocol of [22] and give a detailed description in the full version [21].

The abstract idea of the OT-PSI protocol is to have both parties hash their elements into bins using the same hash function (Step 1, cf. §3.5.1) and compare the elements mapped to the same bin. The comparison is done using OTs that generate random masks from the elements (Step 2, cf. §3.5.2), such that the intersection of the random masks corresponds to the intersection of the original inputs (Step 3, cf. §3.5.3). Finally, the intersection of the elements in the stash is computed (§3.5.4). We give the overhead of the protocol in §3.5.5.

3.5.1 PSI via Hashing to Bins

In the first step of the protocol, the parties map their elements into their respective hash tables T_1 and T_2, consisting of $\beta = h(1+\varepsilon)n_2$ bins (cf. §7). P_2 uses Cuckoo hashing with h hash functions (with $h = 2$), and obtains a one-dimensional hash table T_2. P_1 hashes each item h times (once for each hash function) using *simple hashing* and obtains a two-dimensional hash table T_1 (where the first dimension addresses the bin and the second dimension the elements in the bin). Each party then pads all bins in its table to the maximum size using respective dummy elements: P_1 pads each bin to max_β elements using a dummy element d_1 (where max_β is computed using β and n_1 as detailed in §7 to set the probability of mapping more items to a bin to be negligible), while P_2 fills each empty bin with dummy element d_2 (different than d_1). The padding is performed to hide the number of elements that were mapped to a specific bin, which would leak information about the input.

3.5.2 Masking via OT

After the hashing, the parties use OT to generate an ℓ-bit random mask for each element in their hash table.

Naively, for each bin, and for each item that P_2 mapped to the bin, the parties run a 1-out-of-2 OT for each bit of this item. P_2 is the receiver and its input to the OT is the value of the corresponding bit in the single item that it mapped to the bin. P_1's input is two random ℓ-bit strings. After running these OTs for all σ bits of the item, P_1 sends to P_2 the XOR of the strings corresponding to the bits of P_1's item. Note that if P_1's item is equal to that of P_2 then the sent value is equal to the XOR of the output strings that P_2 received in the OTs. Otherwise the values are different with high probability, which depends on the length ℓ of the output strings.

This basic protocol was improved upon in [22] in several ways:

- Recall that OT extension is more efficient when applied to 1-out-of-N OT [17]. Therefore, the protocol uses μ-bit characters instead of a binary representation. It splits the elements into t μ-bit characters, and uses t invocations of 1-out-of-N OT where $N = 2^\mu$, instead of $t\mu$ invocations of 1-out-of-2 OT.
- In each bin the parties run OTs for all max_β items that P_1 mapped to the bin, and to all characters in these items. P_2's inputs are the same for all max_β OTs corresponding to the same character. Thus, the parties could replace them with a single OT, where the output string of the OT has max_β longer size.
- Recall that random OT, where the protocol randomly defines the inputs of P_1, is more efficient than an OT where P_1 chooses these inputs by itself. For the purpose of PSI the protocol can use random OT. It is also important to note that if P_1 mapped $m < max_\beta$ elements to a bin, it only needs to evaluate inputs for m random OTs in this bin and not for all max_β random OTs that are taking place. This improves the overhead of the protocol.

3.5.3 Intersection

The parties compute the intersection of their elements using the random masks (XOR values) generated during Step 2: P_1 generates a set V as the masks for all of its non-dummy elements. P_1 then randomly permutes the set V to hide information about the number of elements in each bin, and sends V to P_2. P_2 computes the intersection $X \cap Y$ by computing the plaintext intersection between V and the set of XOR values that it computed.

3.5.4 Including a Stash

The OT-based PSI protocol of [22] uses Cuckoo hashing with a stash of size s. The intersection of P_2's elements with P_1's elements is done by running the masking procedure of Step 2 for all s items in the stash, comparing them with all n_1 items in P_1's input. Finally, P_1 sends the masks it computed to P_2 (in randomly permuted order) which can then check the intersection as in Step 3.

3.5.5 Overhead

The overhead of this protocol is linear in the bit-length of the input elements. Therefore, any reduction in the bit-length of the inputs directly results in a similar improvement in the overhead.

For readers interested in the exact overhead of the protocol, we describe here the details of the overhead. In total, the parties have to evaluate random $\binom{N}{1}$-$\mathrm{OT}^{\beta t}_{max_\beta \ell}$ +$\binom{N}{1}$-$\mathrm{OT}^{st}_{n_1 \ell}$ and send $(h+s)n_1$ masks of ℓ-bit length, where $\beta = h(n_2+\varepsilon)$, $N = 2^\mu$, $t = \lceil \sigma/\mu \rceil$, $\ell = \lambda +$

$\log_2(n_1) + \log_2(n_2)$, and s is the size of the stash. To be exact, the server has to perform $2t(\beta + s)$ pseudo-random generator evaluations during OT extension, $(h+s)n_1t$ correlation-robust function evaluations to generate the random masks, and send $(2+s)n_1\ell$ bits. The client has to perform $4t(\beta+s)$ pseudo-random generator evaluations during OT extension, $n_2tmax_\beta\ell/o + sn_1t\ell/o$ correlation-robust function evaluations to generate the random masks, and send $2(\beta+s)t\kappa$ bits during OT extension, where o is the output length of the correlation-robust function. Note especially that the client has to evaluate the correlation-robust function $\mathsf{O}(n\log^2 n)$ times to generate the random bits which represent the masks of the server's elements. This cost can become prohibitive for larger sets, as we will show in our evaluation in §8.

4 Permutation-based Hashing

The overhead of the OT-based PSI protocol of [22] and of the circuit-based PSI protocols we describe in §5 depends on the bit-lengths of the items that the parties map to bins. The bit-length of the stored items can be reduced based on a permutation-based hashing technique that was suggested in [1] for reducing the memory usage of Cuckoo hashing. That construction was presented in an algorithmic setting to improve memory usage. As far as we know this is the first time that it is used in secure computation or in a cryptographic context.

The construction uses a Feistel-like structure. Let $x = x_L|x_R$ be the bit representation of an input item, where $|x_L| = \log\beta$, i.e. is equal to the bit-length of an index of an entry in the hash table. (We assume here that the number of bins β in the hash table is a power of 2. It was shown in [1] how to handle the general case.) Let $f()$ be a random function whose range is $[0, \beta-1]$. Then item x is mapped to bin $x_L \oplus f(x_R)$. The value that is stored in the bin is x_R, which has a length that is shorter by $\log\beta$ bits than the length of the original item. This is a great improvement, since the length of the stored data is significantly reduced, especially if $|x|$ is not much greater than $\log\beta$. As for the security, it can be shown based on the results in [1] that if the function f is k-wise independent, where $k = \text{polylog}\, n$, then the maximum load of a bin is $\log n$ with high probability.

The structure of the mapping function ensures that if two items x, x' store the same value in the same bin then it must hold that $x = x'$: if the two items are mapped to the same bin, then $x_L \oplus f(x_R) = x'_L \oplus f(x'_R)$. Since the stored values satisfy $x_R = x'_R$ it must also hold that $x_L = x'_L$, and therefore $x = x'$.

As a concrete example, assume that $|x| = 32$ and that the table has $\beta = 2^{20}$ bins. Then the values that are stored in each bin are only 12 bits long, instead of 32 bits in the original scheme. Note also that the computation of the bin location requires a single instantiation of f, which can be implemented with a medium-size lookup table.

A comment about an alternative approach An alternative, and more straightforward approach for reducing the bit-length could map x using a random *permutation* $p()$ to a random $|x|$-bit string $p(x)$. The first $\log\beta$ bits of $p(x)$ are used to define the bin to which x is mapped, and the value stored in that bin holds the remaining $|x| - \log\beta$ bits of $p(x)$. This construction, too, has a shorter length for the values that are stored in the bins, but it suffers from two drawbacks: From a performance perspective, this construction requires the usage of a random *permutation* on $|x|$ bits, which is harder to compute than a random *function*. From a theoretical perspective, it is impossible to have efficient constructions of k-wise independent permutations, and therefore we only know how to prove the $\log n$ maximum load of the bins under the stronger assumption that the permutation is random.

5 Circuit-Phasing

PSI protocols that are based on generic secure computation are of great importance due to their flexibility (cf. §3.4 for details). The best known construction of a circuit computing the intersection (of σ-bit elements) is the SCS circuit of [12] with about $3n\sigma\log_2 n$ AND gates and an AND depth of $\Theta(\log_2\sigma \cdot \log_2 n)$. We describe a new construction of circuits with the same order of AND gates (but with smaller constants), and a much smaller depth. Our experiments, detailed in §8.1, demonstrate that the new circuits result in much better performance.

The new protocol, which we denote as Circuit-Phasing, is based on the two parties mapping their inputs to hash tables before applying the circuit. The idea is similar to the OT-based PSI protocol of [22] described in §3.5, but instead of using OTs for the comparisons, the protocol evaluates a pairwise-comparison circuit between each bin of P_1 and P_2 in parallel:

- Both parties use a table of size $\beta = \mathsf{O}(n)$ to store their elements. Our analysis (§7) shows that setting $\beta = 2.4n$ reduces the error probability to be negligible for reasonable input sizes ($2^8 \leq n \leq 2^{24}$) when setting the stash size according to Tab. 4.
- P_2 maps its input elements to β bins using Cuckoo hashing with two hash functions and a stash; empty bins are padded with a dummy element d_2.
- P_1 maps its input elements into β bins using simple hashing. The size of the bins is set to be max_β, a parameter that is set to ensure that no bin overflows (see §7.1). The remaining slots in each bin are padded with a dummy element $d_1 \neq d_2$. The analy-

sis described in §7.1 shows how max_β is computed and is set to a value smaller than $\log_2 n$.

- The parties securely evaluate a circuit that compares the element that was mapped to a bin by P_2 to each of the max_β elements mapped to it by P_1.
- Finally, each element in P_2's stash is checked for equality with all n_1 input elements of P_1 by securely evaluating a circuit computing this functionality.
- To reduce the bit-length of the elements in the bins, and respectively the circuit size, the protocol uses permutation-based hashing as described in §4. (Note that using this technique is impossible with SCS circuits of [12].)

A detailed analysis of the circuit size and depth Let m be the size of P_1's input to the circuit with $m = \beta max_\beta + sn_1$, i.e., for each of the β bins, P_1 inputs max_β items as well as n_1 items for each of the s positions in the stash. The circuit computes a total of m comparisons between the elements of the two parties. Each element is of length σ' bits, which is the reduced length of the elements after being mapped to bins using permutation-based hashing, i.e. $\sigma' = \sigma - \log_2 \beta$.

A comparison of two σ'-bit elements is done by computing the bitwise XOR of the elements and then a tree of $\sigma' - 1$ OR gates, with depth $\lceil \log_2 \sigma' \rceil$. The topmost gate of this tree is a NOR gate. Afterwards, the circuit computes the XOR of the results of all comparisons involving each item of P_2. (Note that at most one of the comparisons results in a match, therefore the circuit can compute the XOR, rather than the OR, of the results of the comparisons.) Overall, the circuit consists of about $m \cdot (\sigma' - 1) \approx n_1 \cdot (max_\beta + s) \cdot (\sigma' - 1)$ non-linear gates and has an AND depth of $\lceil \log_2 \sigma \rceil$.

Advantages Circuit-Phasing has several advantages over the SCS circuit:

- Compared to the number of AND gates in the SCS circuit, which is $3n\sigma \log n$, and recalling that $\sigma' < \sigma$, and that max_β was shown in our experiments to be no greater than $\log n$, the number of non-linear gates in Circuit-Phasing is smaller by a factor greater than 3 compared to the number of non-linear gates in the SCS circuit (even though both circuits have the same big "O" asymptotic sizes).
- The main advantage of Circuit-Phasing is the low AND depth of $\log_2(\sigma)$, which is also independent of the number of elements n. This affects the overhead of the GMW protocol that requires a round of interaction for every level in the circuit.
- Another advantage of Circuit-Phasing is its simple structure: the same small comparison circuit is evaluated for each bin. This property allows for a SIMD (Single Instruction Multiple Data) evaluation with a very low memory footprint and easy parallelization.

Hashing failures: The correct performance of the protocol depends on the successful completion of the hashing operations: The Cuckoo hashing must succeed, and the simple hashing must not place more than max_β elements in each bin. Tables of size $2(1+\varepsilon)n$ and $max_\beta = \mathsf{O}(\log n)$ guarantee these properties with high probability. We analyze the exactly required table sizes in §7 and set them to be negligible in the statistical security parameter λ.

6 OT-Phasing

We improve the OT-PSI protocol of [22] by applying the following changes to the protocol:

- Reducing the bit-length of the items using the permutation-based hashing technique described in §4. This improvement reduces the length of the items from $|x|$ bits to $|x| - \beta$ bits, where β is the size of the tables, and consequently reduces the number of OTs by a factor of $\beta/|x|$.
- Using OTs on a single mask instead of on $\mathsf{O}(\log n)$ masks before. This improvement is detailed in §6.1.
- Improving the utilization of bins by using 3-way Cuckoo hashing (§6.2).

We call the resulting PSI protocol that combines all these optimizations OT-Phasing. In the full version [21], we evaluate the performance gain of each optimization individually and micro-benchmark the resulting protocol.

6.1 A Single Mask per Bin

In order to hide information about the number of items that were mapped to a bin, the original OT-PSI protocol of [22] (cf. §3.5) padded all bins to a maximum size of $max_\beta = \mathsf{O}(\log n)$. The protocol then ran OTs on max_β masks of ℓ-bit length where the parties had to generate and process all of the max_β masks. We describe here a new construction that enables the parties to compute only a constant number of masks per element, regardless of the number of elements that were mapped to the bin by P_1. While this change seems only small, it greatly increases the performance and scalability of the protocol (cf. iterative performance improvements in the full version [21]). In particular, this change results in two improvements to the protocol:

- The number of symmetric cryptographic operations to generate the masks is reduced from $\mathsf{O}(\log^2 n)$ to $\mathsf{O}(\log n)$. Furthermore, note that P_2 had to compute the plaintext intersection between his $n_2 max_\beta$ generated masks and the $2n_1$ masks sent by P_1. This also greatly improves the memory footprint and plaintext intersection.

- In the previous OT-based protocol, a larger value of the parameter max_β reduced the failure probability of the simple hashing procedure used by P_1, but increased the string size in the OTs. In the new protocol the value of max_β does not affect the overhead. Therefore P_1 can use arbitrarily large bins and ensure that the mapping that it performs never fails.

Recall that in the OT-based PSI protocol of [22] (cf. §3.5) the parties had inputs of t characters, where each character was μ bits long, and we used the notation $N = 2^\mu$. The parties performed OTs on strings of max_β masks per bin. Each mask had length $\ell = \lambda + \log_2(n_1) + \log_2(n_2)$ bits, corresponded to an element that P_1 mapped to the bin, and included a 1-out-of-N random-OT for each of the t characters of this element. P_1 was the sender, received all the N sender input-strings of each OT, and chose from them the one corresponding to the value of the character in its own element. P_2 was the receiver and received the string corresponding to the value of the character in its own element. Then P_1 computed the XOR of the t strings corresponding to the t characters of its element and sent this XOR value to P_2, which compared it to the XOR of its t outputs from OT.

The protocol can be improved by running the t 1-out-of-N OTs on a *single* mask per bin. Denote by u the actual number of items mapped by P_1 to a bin. The value of u is not revealed to P_2 in the new protocol and therefore there is no need to pad the bin with dummy items. Denote the single item that P_2 mapped to the bin as $y = y_1, \ldots, y_t$, and the u items that P_1 mapped to the bin as $x^1, \ldots, x^u$, where each x^i is defined as $x^i = x^i_1, \ldots, x^i_t$.

Define the input strings to the j-th OT as $\{s_{j,\ell}\}_{\ell=1\ldots N}$. The protocol that is executed is a random OT and therefore these strings are chosen by the protocol and not by P_1. The parties run a single set of t OTs and P_2 learns the t strings $s_{1,y_1}, \ldots, s_{t,y_t}$. It computes their XOR $S_{P_2} = s_{1,y_1} \oplus \cdots \oplus s_{t,y_t}$, and the value $H(S_{P_2})$, where $H()$ is a hash function modeled as a random oracle.

P_1 learns all the Nt strings generated in the random-OT protocols. For each input element x^i that P_1 mapped to the bin, it computes the XOR of the strings corresponding to the characters of the input, namely $S^i_{P_1} = s_{1,x^i_1} \oplus \cdots \oplus s_{t,x^i_t}$, and then computes the value $H(S^i_{P_1})$. Note that over all bins, P_1 needs to perform this computation only $O(n_1)$ times and compute $O(n_1)$ hash values. P_1 then sends all these values to P_2 in randomly permuted order. P_2 computes the intersection between these values and the $H(S_{P_2})$ values that it computed in the protocol.

Efficiency: P_2 computes only a single set of t OTs per bin on one mask, compared to t OTs on max_β masks in the OT-based protocol of [22]. As for P_1's work, it computes a single set of OTs per bin, and in addition computes a XOR of strings and a hash for each of its $O(n_1)$ input elements. This is a factor of $max_\beta = O(\log n_1)$ less work as before. Communication is only $O(n\sigma)$ strings, as before.

Security: Assuming that the OT protocols are secure and that the parties are semi-honest, the only information that is received by any party in the protocol is the $H(S^i_{P_1})$ values that are sent from P_1 to P_2. For all values in the intersection of the input sets of the two parties, P_1 sends to P_2 the same hash values as those computed by P_2. Consider the set of input elements $\bar{X}$ that are part of P_1's input and are not in P_2's input, and the set of XOR values corresponding to $\bar{X}$. There might be linear dependencies between the XOR values of $\bar{X}$, but it holds with overwhelming probability that all these values are different, and they are also all different from the XOR values computed by P_2. Therefore, the result of applying a random hash function $H()$ to these values is a set of random elements in the range of the hash function. This property enables to easily provide a simulation based proof of security for the protocol.

6.2 3-Way Cuckoo Hashing

The original OT-based PSI protocol of [22] uses Cuckoo hashing which employs two hash functions to map elements into bins. It was shown in [20] that if n elements are mapped to $2(1+\varepsilon)n$ bins, Cuckoo hashing succeeds with high probability for $\varepsilon > 0$. This means that Cuckoo hashing achieves around 50% utilization of the bins. If the number of hash functions h is increased to $h > 2$, a much better utilization of bins can be achieved [6]. However, using h hash functions in our protocol requires P_1 to map each element h times into its bins using simple hashing and requires P_1 to send hn_1 masks in the intersection step of the protocol.

We detail in Tab. 1 the utilization and total communication of our PSI protocol for $n_1 = n_2 = 2^{20}$ and $n_2 = 2^8 \ll n_1 = 2^{20}$, for $\sigma = 32$-bit elements with different numbers of hash functions. We observe that there is a tradeoff between the communication for the OTs and the communication for the masks that are sent by P_1. Our goal is to minimize the total communication, and this is achieved for $h = 3$ hash functions in the setting of $n_1 = n_2$ and for $h = 2$ in the setting of $n_2 \ll n_1$. For $n_1 = n_2$ using $h = 3$ instead of $h = 2$, as in the original protocol of [22], reduces the overall communication by 33%.

Hashing failures: We observe that with OT-Phasing, there is essentially no bound on the number of items that the server can map to each specific bin, since the client does not observe this value in any way (the message that the client receives only depends on the total number of items that the server has). However, the parameters used

h	Util. [%]	#OTs	#Masks	Comm. [MB]	
				$n_1 = n_2$	$n_2 \ll n_1$

5	**99.2**	$\mathbf{1.01}n_2$ **t**	$5n_1\ell$	114.6	42.5

Table 1: Overall communication for a larger number of hash functions h. Communication is given for a) $n_1 = n_2 = 2^{20}$ and b) $n_2 = 2^8 \ll n_1 = 2^{20}$ elements of $\sigma = 32$-bit length. Utilization according to [6].

in the protocol do need to ensure that the Cuckoo hashing procedure does not fail. The analysis appears in §7.

7 Hashing Failures

The PSI schemes we presented use simple hashing (by P_1), and Cuckoo hashing (by P_2). In both hashing schemes, the usage of bins (or a stash) of constant size, might result in hashing failures if the number of items mapped to a bin (or the stash) exceeds its capacity.

When hashing fails, the party which performed the hashing has two options: (1) Ignore the item that cannot be mapped by the hashing scheme. This essentially means that this item is removed from the party's input to the PSI protocol. Consequently, the output of the computation might not be correct (although, if this type of event happens rarely, the effect on correctness is likely to be marginal). (2) Attempt to use a different set of hash functions, and recompute the hash of all items. In this case the other party must be informed that new hash functions are used. This is essentially a privacy leak: for example, the other party can check if the input set S of the first party might be equal to a set S' (if a hashing failure does not occur for S' then clearly $S' \neq S$). The effect of this leak is likely to be weak, too, but it is hard to quantify.

The effect of hashing failures is likely to be marginal, and might be acceptable in many usage settings (for example, when measuring ad conversion rates it typically does not matter if the revenue from a single ad view is ignored). However, it is preferable to set the probability of hashing failures to be negligibly small.

In OT-Phasing, P_2 does not learn the number of items that P_1 maps to each bin, and therefore P_1 can set the size of the bins to be arbitrarily large. However, in that PSI protocol P_1 knows the size of the stash that is used in the Cuckoo hashing done by P_2. In Circuit-Phasing, each party knows the size of the bins (or stash) that is used by the other party. We are therefore interested in learning the failures probabilities of the following schemes, and bound them to be negligible, i.e., at most 2^{-40}:

- §7.1: Simple hashing in the Circuit-Phasing scheme, where n items are mapped using two independent functions to $2.4n$ bins. This is equivalent to mapping $2n$ items to $2.4n$ bins.
- §7.2: Cuckoo hashing, using $2.4n$ bins and either 2-way hashing (for Circuit-Phasing), or 3-way hashing (for OT-Phasing). The failure probability for 3-way hashing is smaller than for 2-way hashing (since there is an additional bin to which each item can be mapped), and therefore we will only examine the failure probability of 2-way Cuckoo hashing.

7.1 Simple Hashing

It was shown in [23] that when n balls are mapped at random to n bins then the maximum number of elements in a bin is with high probability $\frac{\ln n}{\ln \ln n}(1 + o(1))$. Let us examine in more detail the probability of the following event, "$2n$ balls are mapped at random to $2.4n$ bins, and the most occupied bin has at least k balls":

$$\begin{aligned} &\Pr(\exists \text{bin with} \geq k \text{ balls}) && (1)\\ &\leq 2.4n \cdot \Pr(\text{bin \#1 has} \geq k \text{ balls}) && (2)\\ &\leq 2.4n \binom{2n}{k} \left(\frac{1}{2.4n}\right)^k && (3)\\ &\leq \left(\frac{2ne}{k}\right)^k \left(\frac{1}{2.4n}\right)^{k-1} && (4)\\ &= n \left(\frac{2e}{k}\right)^k \left(\frac{1}{2.4}\right)^{k-1}. && (5) \end{aligned}$$

It is straightforward to see that this probability can be bounded to be at most 2^{-40} by setting

$$k \quad \geq \quad \max(6, 2e \log n / \log \log n). \qquad (6)$$

We calculated for some values of n the desired bin sizes based on the upper bound of Eq. (6) and the tighter calculation of Eq. (5), and chose the minimal value of k that reduces the failure probability to below 2^{-40}. The results are in Table 2. It is clear that Eq. (5) results in smaller bins for sufficiently large n, and therefore the maximal bin size should be set according to Eq. (5).

n	2^{12}	2^{16}	2^{20}	2^{24}
Eq. (5)	18	19	20	21
Eq. (6)	19	22	26	29

Table 2: The bin sizes max_β that are required to ensure that no overflow occurs when mapping $2n$ items to $2.4n$ bins, according to Eq. (5) and Eq. (6).

7.2 Cuckoo Hashing

It was shown in [16] that Cuckoo hashing with a stash of size s fails with probability $O(n^{-s})$. The constants in the big "O" notation are unclear, but it is obvious that $O(n^{-s}) \leq n^{-(s-1)}$ for sufficiently large values of n.

s	2^{11}	2^{12}	2^{13}	2^{14}
0	1,068,592,289	1,070,826,935	1,072,132,187	1,072,845,430
1	4,994,200	2,861,137	1,592,951	891,497
2	147,893	52,038	16,404	4,840
3	7,005	1,647	274	56
4	407	62	8	1
5	28	5	0	0
6	2	0	0	0

Table 3: Required stash sizes s accumulated over 2^{30} Cuckoo hashing repetitions mapping $n \in \{2^{11}, 2^{12}, 2^{13}, 2^{14}\}$ elements to $2.4n$ bins.

We would like to find the exact size of the stash that ensures that the failure probability is smaller than 2^{-40}. We ran 2^{30} repetitions of Cuckoo hashing, mapping n items to $2.4n$ bins, for $n \in \{2^{11}, 2^{12}, 2^{13}, 2^{14}\}$, and recorded the stash size s that was needed for Cuckoo hashing to be successful. Tab. 3 depicts the number of repetitions where we required a stash of size s. From the results we can observe that, to achieve 2^{-30} failure probability of Cuckoo hashing, we would require a stash of size $s = 6$ for $n = 2^{11}$, $s = 5$ for $n = 2^{12}$, and $s = 4$ for both $n = 2^{13}$ and $n = 2^{14}$ elements.

However, in our experiments we need the stash sizes for larger values of $n \geq 2^{14}$ to achieve a Cuckoo hashing failure probability of 2^{-40}. To obtain the failure probabilities for larger values of n, we extrapolate the results from Tab. 3 using linear regression and illustrate the results in Fig. 1. We observe that the stash size for achieving a failure probability of 2^{-40} is drastically reduced for higher values of n: for $n = 2^{16}$ we need a stash of size $s = 4$, for $n = 2^{20}$ we need $s = 3$, and for $n = 2^{24}$ we need $s = 2$. This observation is in line with the asymptotic failure probability of $O(n^{-s})$.

Finally, we extrapolate the required stash sizes s to achieve a failure probability of 2^{-40} for smaller values of $n \in \{2^8, 2^{12}\}$ and give the results together with the stash sizes for $n \in \{2^{16}, 2^{20}, 2^{24}\}$ in Tab. 4.

number of elements n	2^8	2^{12}	2^{16}	2^{20}	2^{24}
stash size s	12	6	4	3	2

Table 4: Required stash sizes s to achieve 2^{-40} error probability when mapping n elements into $2.4n$ bins.

8 Evaluation

We report on our empirical performance evaluation of Circuit-Phasing (§5) and OT-Phasing (§6) next. We evaluate their performance separately (§8.1 and §8.2), since special purpose protocols for set intersection were shown to greatly outperform circuit-based solutions in [22]. (The latter are nevertheless of independent interest because their functionality can be easily modified.)

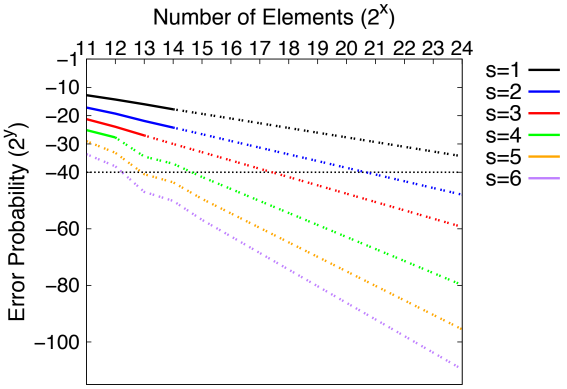

Figure 1: Error probability when mapping n elements to $2.4n$ bins using 2-way Cuckoo hashing for stash sizes $1 \leq s \leq 6$. The solid lines correspond to actual measurements, the dashed lines were extrapolated using linear regression. Both axes are in logarithmic scale.

Benchmarking Environment We consider two benchmark settings: a *LAN* setting and a *WAN* setting. The LAN setting consists of two desktop PCs (Intel Haswell i7-4770K with 3.5 GHz and 16GB RAM) connected by Gigabit LAN. The WAN setting consists of two Amazon EC2 m3.medium instances (Intel Xeon E5-2670 CPU with 2.6 GHz and 3.75 GB RAM) located in the US east coast (North Virginia) and Europe (Frankfurt) with an average bandwidth of 50 MB/s and average latency (round-trip time) of 96 ms.

We perform all experiments for a symmetric security parameter $\kappa = 128$-bit and statistical security parameter $\lambda = 40$ (cf. §2.1), using a single thread (except for GMW, where we use two threads to compute OT extension), and average the results over 10 executions. In our experiments, we frequently encountered outliers in the WAN setting with more than twice of the average run-time, for which we repeated the execution. The resulting variance decreased with increasing input set size; it was between $0.5\% - 8.0\%$ in the LAN setting and between $4\% - 16\%$ in the WAN setting. Note that all machines that we perform our experiments on are equipped with the AES-NI extensions which allows for very fast AES evaluation.

Implementation Details We instantiate the random oracle, the function for hashing into smaller domains, and the correlation-robust function in OT extension with SHA256. We instantiate the pseudo-random generator using AES-CTR and the pseudo-random permutation in the server-aided protocol of [15] using AES. To compute the $\binom{2^\mu}{1}$-OT^t_ℓ functionality, we use the random 1-

out-of-N OT extension of [17] and set $\mu = 8$, i.e., use $N = 256$, since this was shown to result in minimal overhead in [22]. We measure the times for the function evaluation including the cost for precomputing the OT extension protocol and build on the OT extension implementation of [2]. Our OT-Phasing implementation is available online at `https://github.com/encryptogroup/PSI` and our Circuit-Phasing implementation is available as part of the ABY framework of [5] at `https://github.com/encryptogroup/ABY`.

For simple hashing we use the maximum bin sizes that were computed using Equation 5 in §7.1 (cf. Tab. 2). For Cuckoo hashing, we set $\varepsilon = 0.2$ and map n elements to $2(1+\varepsilon)n$ bins for 2-way Cuckoo hashing and to $(1+\varepsilon)n$ bins for 3-way Cuckoo hashing with a stash size according to Tab. 4. The only exception for the stash size are the experiments with different set sizes in §8.2.2, where we use no stash for our OT-Phasing protocol.

For OT-based PSI [22] and OT-Phasing, where the performance depends on the bit-length of elements, we hash the σ-bit input elements into a $\ell = \lambda + \log_2(n_1) + \log_2(n_2)$-bit representation using SHA256 if $\sigma > \ell$.

We use a garbled circuits implementation with most recent optimizations (cf. full version [21] for details).

We emphasize that all implementations are done in the same programming language (C++), use the same underlying libraries for evaluating cryptographic operations (OpenSSL for symmetric cryptography and Miracl for elliptic curve cryptography), perform the plaintext-intersection of elements using a standard hash map, are all executed using a single thread (except for the GMW implementation which uses two threads), and run in the same benchmarking environment.

8.1 Generic Secure Computation-based PSI Protocols

For the generic secure computation-based PSI protocols, we perform the evaluation on a number of elements varying from 2^8 to 2^{20} and a fixed bit-length of $\sigma = 32$-bit. For $n = 2^{20}$ all implementations, except Circuit-Phasing with GMW, exceeded the available memory, which is due to the large number of AND gates in the SCS circuit (estimated 2 billion AND gates) and the requirement to represent bits as keys for Circuit-Phasing with Yao, where storing only the input wire labels to the circuit requires 1 GB. A more careful implementation, however, could allow the evaluation of these circuits. We compare the sort-compare-shuffle (SCS) circuit of [12] and its depth-optimized version of [22], with Circuit-Phasing (§5), by evaluating both constructions using Yao's garbled circuits protocol [25] and the GMW protocol [11] in the LAN and WAN setting. We use the size-optimized version of the SCS circuit in Yao's garbled circuit and the depth-optimized version of the circuit in the GMW protocol (cf. §3.4). For the evaluation in Circuit-Phasing, we set the maximum bin size in simple hashing according to Equation 5 (cf. Tab. 2, set $\varepsilon = 0.2$, set the stash size according to Tab. 4, and assume $n = n_1 = n_2$. The run-time of Circuit-Phasing would increase linear in the bin size max_β, while the stash size s would have a smaller impact on the total run-time as the concrete factors are smaller.

Run-Time (Tab. 5) Our main observation is that Circuit-Phasing outperforms the SCS circuit of [12] for all parameters except Yao's garbled circuits with small set sizes $n = 2^8$. In this case, the high stash size of $s = 12$ greatly impacts the run-time of Circuit-Phasing. When evaluated using Yao's garbled circuits, Circuit-Phasing outperforms the SCS circuit by a factor of 1-2, and when evaluated using GMW it outperforms SCS by a factor of 2-5. Furthermore, the run-time for Circuit-Phasing grows slower with n than for the SCS circuit for all settings except for GMW in the WAN setting. There, the run-time of the SCS circuit grows slower than that of Circuit-Phasing. This can be explained by the high number of communication rounds of the SCS based protocol, which are slowly being amortized with increasing values of n. The slower increase of the run-time of Circuit-Phasing with increasing n is due to the smaller increase of the bin size $max_\beta \in \mathsf{O}(\frac{\ln n}{\ln \ln n})$ vs. $\mathsf{O}(\log n)$ for the SCS circuit, and the use of permutation-based hashing, which reduces the bit-length of the inputs to the circuit. Note that our Yao's garbled circuits implementation suffers from similar performance drawbacks in the WAN setting as our GMW implementation, although being a constant round protocol. This can be explained by the pipelining optimization we implement, where the parties pipeline the garbled circuits generation and evaluation. The performance drawback could be reduced by using an implementation that uses independent threads for sending / receiving.

Communication (Tab. 6) Analogously to the run-time results, Circuit-Phasing improves the communication of the SCS circuit by factor of 1-4 and grows slower with increasing values of n. The improvement of the round complexity, which is mostly important for GMW, is even more drastic. Here, Circuit-Phasing outperforms the SCS circuit by a factor of 16-38. Note that the round complexity of Circuit-Phasing only depends on the bit-length of items and is independent of the number of elements.

8.2 Special Purpose PSI Protocols

For the special purpose PSI protocols we perform the experimental evaluation for equally sized sets $n_1 =$

Protocol	LAN				WAN			
	$n = 2^8$	$n = 2^{12}$	$n = 2^{16}$	$n = 2^{20}$	$n = 2^8$	$n = 2^{12}$	$n = 2^{16}$	$n = 2^{20}$

Circuit-Phasing §5	5	5	5	5	$\log_2(\sigma)$

Table 6: Number of AND gates, concrete communication in MB, round complexity, and failure probability for generic secure PSI protocols on $\sigma = 32$-bit elements. Numbers with * are estimated.

n_2 (§8.2.1) and differently sized sets $n_2 \ll n_1$ (§8.2.2), for set sizes ranging from 2^8 to 2^{24} in the LAN setting and from 2^8 to 2^{20} in the WAN setting.

We compare OT-Phasing (§6) to the original OT-based PSI protocol of [22], the naive hashing solution (§3.1), the semi-honest server-aided protocol of [15] (§3.2), and the Diffie-Hellmann (DH)-based protocol of [18] (§3.3) using elliptic curves. Note that the naive hashing protocol and the server-aided protocol of [15] have different security assumptions and cannot directly be compared to the remaining protocols. We nevertheless included them in our comparison to serve as a base-line on the efficiency of PSI. For the protocol of [15], we run the server routine that computes the intersection between the sets on the machine located at the US east coast (North Virginia) and the server and client routine on the machine in Europe (Frankfurt). For the original OT-based PSI and OT-Phasing, we give the run-time and communication for three bit-lengths: *short* $\sigma = 32$ (e.g., for IPv4 addresses), *medium* $\sigma = 64$ (e.g., for credit card numbers), and *long* $\sigma = 128$ (for set intersection between arbitrary inputs).

Note that the OT-based PSI protocol of [22] and our OT-Phasing protocol both evaluate public-key cryptography during the base-OTs, which dominates the run-time for small sets. However, these base-OTs only need to be computed once and can be re-used over multiple sessions. In the LAN setting, the average run-time for computing the 256 base-OTs was 125 ms while in the WAN setting the run-time was 245 ms. Nevertheless, our results all contain the time for the base-OTs to provide an estimation of the total run-time.

8.2.1 Experiments with Equal Input Sizes

In the experiments for input sets of equal size $n = n_1 = n_2$ we set $n \in \{2^8, 2^{12}, 2^{16}, 2^{20}, 2^{24}\}$ in the LAN setting and $n \in \{2^8, 2^{12}, 2^{16}, 2^{20}\}$ in the WAN setting. Note that for larger bit-lengths $\sigma \geq 64$ and for $n = 2^{24}$ elements, the memory needed for the OT-based PSI protocol of [22] exceeded the available memory.

Run-Time (Tab. 7) As expected, the lowest run-time for the equal set-size experiments is achieved by the (insecure) naive hashing protocol followed by the server-aided protocol of [15], which has around twice the run-time. In the LAN setting, however, for short bit-length $\sigma = 32$, our OT-Phasing protocol nearly achieves the same run-time as both of these solutions (which are in a different security model). In particular, when computing the intersection for $n = 2^{24}$ elements, our OT-Phasing protocol requires only 3.5 more time than the naive hashing protocol and 2.5 more time than the server-aided protocol. In comparison, for the same parameters, the original OT-based PSI protocol of [22] has a 68 times higher run-time than the naive hashing protocol, and the DH-based ECC protocol of [18] has a four orders of magnitude higher run-time compared to naive hashing.

While the run-time of our OT-Phasing protocol increases with the bit-length of elements, for $\sigma = 128$-bit its run-time is only 15 times higher than the naive hashing protocol, and is still nearly two orders of magnitude better than the DH-based ECC protocol.

Overall, in the LAN setting and for larger sets (e.g., $n = 2^{24}$), the run time of OT-Phasing is 20x better than that of the original OT-based PSI protocol of [22], and

Setting	**LAN**					**WAN**

Table 8: Communication in MB for PSI protocols with $n = n_1 = n_2$ elements. $\ell = \lambda + \log_2(n_1) + \log_2(n_2)$. Assuming intersection of size $1/2 \cdot n$ for TTP-based protocol. (Protocols with $^{(*)}$ are in a different security model.)

60-278x better than that of the DH-ECC protocol of [18].

When switching to the WAN setting, the run-times of the protocols are all increased by a factor of 2-6. Note that the faster protocols suffer from a greater performance loss (factors of 5 and 6 for 2^{20} elements, for the naive hashing protocol and server-aided protocol) than the slower protocols (factor 3 for the DH-based and our OT-Phasing protocol and 2.5 for the OT-based PSI protocol of [22]). This difference can be explained by the greater impact of the high latency of 97 ms on the run-time of the protocols. The relative performance among the protocols remains similar to the LAN setting.

Communication (Tab. 8) The amount of communication performed during protocol execution is often more limiting than the required computation power, since the latter can be scaled up more easily by using more machines. The naive hashing approach has the lowest communication among all protocols, followed by the server-aided solution of [15]. Among the secure two-party PSI protocols, the DH-based ECC protocol of [18] has the lowest communication. In the setting for $n = 2^{24}$ elements of short bit-length $\sigma = 32$ bit, our OT-Phasing protocol nearly achieves the same complexity as the DH-based ECC protocol, which is due to the use of permutation-based hashing. This is quite surprising, as protocols that use public-key cryptography, in particular elliptic curves, were believed to have much lower communication complexity than protocols based on other cryptographic techniques.

In comparison to the original OT-based PSI protocol of [22], OT-Phasing reduces the communication for all combinations of elements and bit-lengths by factor 2.5 - 4. We also observe that OT-Phasing reduces the impact when performing PSI on elements of longer bit-length. In fact, it even has a lower communication for $\sigma = 128$ than the original OT-based PSI protocol has for $\sigma = 32$.

8.2.2 Experiments with Different Input Sizes

For examining the setting where the two parties have different input sizes, we set $n_1 \in \{2^{16}, 2^{20}, 2^{24}\}$ and $n_2 \in \{2^8, 2^{12}\}$ and run the protocols on all combinations such that $n_2 \ll n_1$. Note that we excluded the original OT-based PSI protocol of [22] from the comparison, since the bin size max_β becomes large when $\beta \ll n$ and the memory requirement when padding all bins to max_β elements quickly exceeded the available memory. In this setting, unlike the equal input sizes experiments in §8.2.1, we use $h = 2$ hash functions instead of $h = 3$,

Setting	LAN						WAN			
Protocol	$n_2 = 2^8$			$n_2 = 2^{12}$			$n_2 = 2^8$		$n_2 = 2^{12}$	
	$n_1 = 2^{16}$	$n_1 = 2^{20}$	$n_1 = 2^{24}$	$n_1 = 2^{16}$	$n_1 = 2^{20}$	$n_1 = 2^{24}$	$n_1 = 2^{16}$	$n_1 = 2^{20}$	$n_1 = 2^{16}$	$n_1 = 2^{20}$

Bit-length $\sigma = 128$	1.1	18.2	288.2	3.5	20.4	322.7	$4.8n_2\kappa(\lceil\frac{\sigma-\lfloor\log_2(2.4n_2)\rfloor}{8}\rceil)+2n_1\ell$

Table 10: Communication in MB for special purpose PSI protocols with $n_2 \ll n_1$ elements. $\ell = \lambda + \log_2(n_1) + \log_2(n_2)$. Assuming intersection of size $1/2 \cdot n_2$ for the TTP-based protocol. (Protocols with $^{(*)}$ are in a different security model.)

since this results in less total computation and communication (cf. §6.2). Since we use $h = 2$ hash functions, we also increase the number of bins from $1.2n_2$ to $2.4n_2$. Furthermore, we do not use a stash for our OT-Phasing protocol with different input sizes, since the stash would greatly increase the overall communication. However, not using a stash reveals some information on P_2's set (cf. §7). We show how to secure our protocol at a much lower cost by increasing the number of bins in the full version [21].

Run-Time (Tab. 9) Similar to the results for equal set sizes, the naive hashing protocol is the fastest protocol for all parameters. The server-aided protocol of [15] is the second fastest protocol but it scales better than the naive hashing protocol for increasing number of elements. The best scaling protocol is our OT-Phasing protocol. It achieves the same performance as the server-aided protocol for $n_2 = 2^8$, $n_1 = 2^{24}$ with short bit-length $\sigma = 32$. For $n_1 = 2^{24}$ its run-time is at most twice that of the server-aided protocol in both network settings.

When switching to the WAN setting, the run-times of all protocols are increased by a factor 4-6 while the relative performance between the protocols remains similar, analogously to the equal set size experiments.

Communication (Tab. 10) As expected, the naive hashing solution again has the lowest communication overhead. Surprisingly, our OT-Phasing protocol achieves nearly the same communication as the server-aided protocol of [15] and has only two times the communication of the naive hashing protocol for all bit-lengths. Furthermore, our OT-Phasing protocol requires a factor of 2-3 less communication than the DH-based ECC protocol of [18] for nearly all parameters. The low communication of our OT-Phasing protocol for unequal set sizes is due to the low number of OTs performed.

Faster Secure Computation through Automatic Parallelization

Niklas Buescher
Technische Universität Darmstadt

Stefan Katzenbeisser
Technische Universität Darmstadt

Abstract

Secure two-party computation (TPC) based on Yao's garbled circuits has seen a lot of progress over the past decade. Yet, compared with generic computation, TPC is still multiple orders of magnitude slower. To improve the efficiency of secure computation based on Yao's protocol, we propose a practical parallelization scheme. Its advances over existing parallelization approaches are twofold. First, we present a compiler that detects parallelism at the source code level and automatically transforms C code into parallel circuits. Second, by switching the roles of circuit generator and evaluator between both computing parties in the semi-honest model, our scheme makes better use of computation and network resources. This *inter-party parallelization* approach leads to significant efficiency increases already on single-core hardware without compromising security. Multiple implementations illustrate the practicality of our approach. For instance, we report speed-ups of up to 2.18 on 2 cores and 4.36 on 4 cores for the example application of parallel modular exponentiation.

1 Introduction

In the thirty years since Yao's seminal paper [34], Secure Multiparty Computation (MPC) and Secure Two-Party Computation (TPC) have transitioned from purely theoretic constructions to practical tools. In TPC, two parties jointly evaluate a function f over two inputs x and y provided by the parties in such a way that each party keeps its input unknown to the other. TPC enables the construction of privacy-enhancing technologies which protect sensitive data during processing steps in untrusted environments.

Many privacy enhancing implementations use the approach of "garbled circuits" introduced by Yao in the 1980s, where f is transformed into a Boolean circuit C_f and encrypted in a special way. Beginning with the realization of the first practical implementation of Yao's protocol by Fairplay in 2004 [27], theoretical and practical advances, including Garbled-row-reduction [31], free-XOR [21], garbling from fixed-key blockciphers [5] and others have led to a significant speed-up of Yao's original protocol. Furthermore, high-level language compilers [14, 22, 23] that demonstrate the usability of Yao's protocol have been developed. Nowadays, millions of gates can be garbled on off-the-shelf hardware within seconds. Nonetheless, compared with generic computation, Yao's garbled circuits protocol is still multiple orders of magnitudes slower. Even worse, recently Zahur et al. [36] indicated that the information theoretic lower bound on the number of ciphertexts for gate-by-gate garbling techniques has been reached. Hence, further simplification of computations is unlikely.

Observing the ongoing trend towards parallel hardware, e.g., many-core architectures on a single chip, we investigate whether parallelism within Yao's protocol targeting security against semi-honest adversaries can be exploited to further enhance its performance. To the best of our knowledge, all previous parallelization efforts have focused on Yao's protocol secure against malicious adversaries, which is easily parallelizable by "design", or explored the parallelization possibilities of semi-honest Yao to only limited extent (see § 2) by using manually annotated parallism in handcrafted circuits.

Therefore, in this paper we systematically look at three different levels of automatic parallelization that have the potential to significantly speed up applications based on secure computation:

Fine-grained parallelization (FGP). As the first step, we observe that independent gates, i.e., gates that do not provide input to each other, can be garbled and evaluated in parallel. Therefore, a straight forward parallelization approach is to garble gates in parallel that are located at the same circuit depth, because these are guaranteed to be independent. We refer to this approach as *fine-grained parallelization (FGP)* and show that this approach can be efficient for circuits of suitable shape. For example, when securely computing a matrix-vector multiplication with 3 million gates, we report a speed-up of 2.4 on 4 cores and 7.5 on 16 cores. Nevertheless, the achievable speed-up heavily depends on circuit properties such as the average circuit width, which can be comparably low even for larger problems when compiling from a high-level language, as we show.

Coarse-grained parallelization (CGP). To overcome the limitations of FGP for inadequately shaped circuits, we make use of high-level circuit descriptions, such as program blocks, to automatically detect larger coherent clusters of gates that can be garbled independently. We refer to this parallelization as *coarse-grained parallelization (CGP)*. As one of our main contributions, we extend the CBMC-GC compiler of Holzer et al. [14], which translates functionalities described in ANSI-C into circuits, with the capability to detect concurrency at the source code level. This enables the compilation of parallel circuits. Hence, one large circuit is automatically divided into multiple smaller, independently executable circuits. We show that these circuits lead to more scalable and faster execution on parallel hardware. For example, the matrix-vector multiplication circuit, mentioned above, scales with a speed-up of 3.9 on 4 cores and a speed-up of 12 on 16 cores, thus, significantly outperforming FGP. Furthermore, integrating automatic detection of parallel regions into a circuit compiler gives potential users the opportunity to exploit parallelism without knowledge of the internals of Yao's garbled circuits and relieves them of writing parallel circuits.

Inter-party parallelization (IPP). Finally, we present an extension to Yao's garbled circuit protocol secure against semi-honest adversaries to balance the computation costs of both parties. In the original protocol (using the defacto standard point-and-permute optimization [4, 27]), the garbling party has to perform four times the cryptographic work than the evaluating party. Hence, assuming similar computational capabilities the overall execution time is dominated by the garbling costs. Given the identified coarse-grained parallelism, the idea of our protocol is to divide the work in a symmetric manner between both parties by switching the roles of the garbling and evaluating party to achieve better computational resource utilization without compromising security in the semi-honest model. This approach can greatly reduce the overall runtime. By combining CGP and IPP, we report a speed-up over a serial implementation of 2.14 when using 2 cores and a speed-up of 4.34 when using 4 cores for the example application of a modular exponentiation.

Summarizing our results, the performance of Yao's protocols secure against semi-honest adversaries can significantly be improved by using automatic parallelization.

Outline. Next, we discuss related work. An introduction of the used primitives and tools is given in § 3. In § 4 we discuss FGP, CGP, and present our parallel circuit compiler. Moreover, we introduce the IPP protocol in § 5. In § 6 we evaluate our approaches on practical example applications.

2 Related Work

We give a short overview on parallelization approaches for Yao's garbled circuits in the semi-honest model, before discussing solutions in the malicious model. Furthermore, we discuss parallel compilation approaches for multi-party computation.

Semi-honest model. Husted et al. [17] showed a CPU and GPU parallelization with significant speed-ups on both architectures. Their approach is based on the idea of integrating an additional encryption layer between every circuit level to enable efficient fine-grained parallelization. However, their approach significantly increases the communication costs by sending one additional ciphertext per XOR gate. Moreover, bandwidth saving optimizations, such as garbled row reduction, are incompatible. This is undesirable, as network bandwidth is already a significant bottleneck.

Barni et al. [3] proposed a parallelization scheme similar to ours, which distinguishes between fine- and coarse-grained parallelism. Their approach showed speed-ups for two example applications. However, their coarse-grained approach requires manual user interaction to annotate parallelism in handcrafted circuits. Unfortunately, their timing results are hardly comparable with other work, due to the missing implementation of concurrent circuit generation and evaluation, which is required to garble larger circuits.

Most recently, Nayak et al. [30] presented an orthogonal and complementary work to ours. Their framework *GraphSC* supports the parallel computation of graph oriented applications using RAM based secure computation. GraphSC shows very good scalability for data intensive computations. Parallelism has to be annotated manually and has to follow the Pregel [26] pattern. To exploit further parallelism within different computing nodes of GraphSC, the ideas presented in this work could be exploited.

Malicious model. The "Billion gates" framework by Kreuter et al. [23] was designed to execute large circuits on cluster architectures. The framework supports parallelization in the malicious model using message passing technologies. Frederiksen et al. [11] also addressed the malicious model, yet they targeted the GPU as execution environment. In both cases, the protocol is based upon the idea of *cut-and-choose*, which consists of multiple independent executions of Yao's protocol secure against semi-honest adversaries. This independence enables naive parallelization up to the constant number of circuits required for cut-and-choose. Unfortunately, this degree of parallelism cannot be transferred to the semi-honest setting considered in this paper.

Parallel compiler. Zhang et al. [37] presented a compiler for distributed secure computation with applications for parallelization. Their compiler converts manually annotated parallelism in an extension of C into secure implementations. Even so the compiler is targeting MPC and not TPC, it could be used as an additional front-end to the ideas presented in this work.

In summary, up to now there is no work that addresses parallelization of Yao's protocol in the semi-honest model without making compromises towards the communication costs or relying on manually annotated parallism in handcrafted circuits.

3 Preliminaries

In this section, we give a short introduction into existing tools and techniques required for our parallelization approach. First, we give a brief overview of Yao's protocol (§ 3.1). Next, we introduce the compiler CBMC-GC that transfers ANSI-C to garbled circuits (§ 3.2), followed by an introduction of the Par4all framework that detects parallelism on source code level (§ 3.3).

3.1 TPC and Yao's protocol

In the following paragraphs, we give a short introduction into Yao's TPC protocol. For a complete description, we refer the reader to the detailed work of Lindell and Pinkas [25].

Semi-honest adversary model. In this work, we use the *semi-honest* (passive) adversary model. TPC protocols secure against semi-honest adversaries ensure correctness and guarantee that the participating parties do not learn more about the other party's input than they could already derive from the observed output of the joint computation. The semi-honest model is opposed the *malicious model*, where the adversary is allowed to actively violate the protocol. TPC protocols in the semi-honest model are used for many privacy-preserving applications and are therefore interesting on their own. A discussion on example applications is given in § 5.3.

Oblivious transfers. An Oblivious transfer protocol (OT) is a protocol in which a sender transfers one of multiple messages to a receiver, but it remains oblivious which piece has been transferred. In this paper, we use 1-out-of-2 OTs, where the sender inputs two l-bit strings m_0, m_1 and the receiver inputs a bit $c \in \{0,1\}$. At the end of the protocol, the receiver obliviously receives m_c such that neither the sender learns the choice c nor the receiver learns anything about the other message m_{1-c}. In 2003 Ishai et al. [18] presented the idea of OT Extension, which significantly reduces the computational costs of OTs for most interesting applications of TPC. We use OT_l^n to denote a number n of 1-out-of-2 oblivious transfers with message bit length l.

Yao's protocol. Yao's garbled circuits protocol, proposed in the 1980s [35], is a TPC protocol secure in the semi-honest model. The protocol is executed by two parties P_A, P_B and operates on functionality descriptions in form of Boolean circuits denoted with C_f. A Boolean circuit consists of n Boolean gates, two sets of inputs wires (one for each party), and a set of output wires. A gate is described by two input wires w_l, w_r, one output wire w_o, and a Boolean function $\gamma = g(\alpha, \beta)$ mapping two input bits to one output bit. The output of each gate can be used as input to multiple subsequent gates.

During protocol execution, one party becomes the circuit generator (the garbling party), the other the circuit evaluator. The generator initializes the protocol by assigning each wire w_i in the circuit two random labels w_i^0 and w_i^1 of length κ (the security parameter) representing the respective values 0 and 1. For each gate the generator computes a *garbled truth table*. Each table consists of four encrypted entries of the output wire labels w_o^γ. These are encrypted according to the gate's Boolean functionality using the input wire labels w_l^α and w_r^β as keys. Thus, an entry in the table is encrypted as

$$E_{w_l^\alpha}(E_{w_r^\beta}(w_o^{g(\alpha,\beta)})).$$

After their creation, the garbled tables are randomly permuted and sent to the evaluator, who, so far, is unable to decrypt a single row of any garbled table due to the random choice of wire labels.

To initiate the circuit evaluation, the generator sends its input bits x in form of input wire labels to the evaluator. Moreover, the evaluator's input y is transferred via an OT_κ^m protocol with the generator being the OT sender and m being the number of input bits. After the OT step, the evaluator is in possession of the garbled circuit and one input label per input wire. With this information the evaluator is able to iteratively decrypt the circuit from input wires to output wires. Once all gates are evaluated, all output wire labels are known to the evaluator. In the last step of the protocol, the generator sends an output description table (ODT) to the evaluator, containing a mapping between output label and actual bit value. The decrypted output is then shared with the generator.

Optimizations. Yao's original protocol has seen multiple optimizations in the recent past. Most important are *pipe-lining* [15], which is nescessary for the evaluation of larger circuits and a faster online execution of Yao's protocol, *garbled-row-reduction (GRR)* [31], which reduces the number of ciphertexts that are needed to be transferred per gate, and *free-XOR* [21], which allows to evaluate linear gates (XOR/XNOR) essentially for "free" without any encryption or communication costs. Most recently, Zahur et al. [36] presented an communication optimal garbling scheme, which only requires two ciphertexts per non-linear gate while being compatible with free-XOR.

3.2 CBMC-GC

In 2012, Holzer et al. [14] presented the first compiler for a large subset of C to garbled circuits, named CBMC-GC. The compiler unrolls all loops and recursive statements present in the input program up to a given or statically determined bound. Afterwards, each statement is transformed to a Boolean formula preserving the bit-precise semantics of C. The Boolean formula is then translated into a circuit, which is optimized for Yao's garbled circuits [10].

The only difference between C code and code for TPC is a special naming convention introduced by CBMC-GC. Listing 1 shows example source code for the millionaires' problem. The shown procedure is a standard C procedure, where only the input and output variables are specifically marked as designated input of party P_A or P_B (Lines 2 and 3) or as output (Line 4). Aside from this naming convention, arbitrary C computations are allowed to produce the desired result, in this case a simple comparison (Line 5).

```
1 void millionaires() {
2  int INPUT_A_income;
3  int INPUT_B_income;
4  int OUTPUT_result = 0;
5  if (INPUT_A_income > INPUT_B_income)
6   OUTPUT_result = 1;
7 }
```

Listing 1: CBMC-GC Code for Yao's Millionaires' Problem.

3.3 Automatic source code parallelization

In 2012, Amini et al. [1] presented *Par4all*, an automatic parallelizing and optimizing compiler for C. It was developed to integrate several compilation tools into one single powerful compiler. Par4all is based on the Pips [6] source-to-source compiler infrastructure that detects parallelism and uses the POCC [32] polyhedral loop optimizer to perform memory access optimizations. Par4all is capable of producing parallel OpenMP [7], Cuda and OpenCL code. Par4all operates on any ANSI-C code as input, automatically detects parallel control flow and either annotates or exports parallel regions. Annotations are realized with the OpenMP language, parallel executable kernels for Cuda/OpenCL are exported using static code analysis techniques. In this work, we mainly build upon the OpenMP output.

4 Parallelizing of Yao's Garbled Circuits

To exploit parallelism in Yao's protocol, groups of gates that can be garbled independently need to be identified. Independent gates can be garbled in parallel by the generator, as well as evaluated in parallel by the evaluator. However, detecting independent, similar sized groups of gates is known as the NP-hard graph partitioning problem [28]. The common approach to circumvent the expensive search for an optimal solution is to use heuristics. In this section, we first discuss sequential and parallel composition of functionalities (§ 4.1) and show how circuits can be garbled in parallel (§ 4.2), before introducing the fine-grained parallelization heuristic (§ 4.3) and the coarse-grained parallelization heuristic (§ 4.4).

4.1 Parallel and sequential decomposition

Throughout this paper, we consider functionalities $f(x,y)$ with two input bit strings x, y and an output bit string o. Furthermore, we use C_f to denote the circuit that represents functionality f. We refer to a functionality f as *sequentially* decomposable into *sub functionalities* f_1 and f_2 iff $f(x,y) = f_2(f_1(x,y),x,y)$.

Moreover, we consider a functionality $f(x,y)$ as parallel decomposable into sub functionalities $f_1(x,y)$ and $f_2(x,y)$ with non-zero output bit length, if a bit string permutation σ_f exists such that $f(x,y) = \sigma_f(f_1(x,y)||f_2(x,y))$, where $||$ donates a bitwise concatenation operator. Thus, functionality f can directly be evaluated by independent evaluation of f_1 and f_2. We note that f_1 and f_2 do not necessarily have to be defined over all bits of x and y. Depending on f they could share none, some, or all input bits.

We use the operator $\diamond$ to express a parallel composition of two functionalities through the existence of a permutation σ. Thus, we write $f(x,y) = f_1(x,y,) \diamond f_2(x,y)$ if there exists a permutation σ_f such that $f(x,y) = \sigma_f(f_1(x,y)||f_2(x,y))$.

We call a parallelization of f to be *efficient* if the circuit size (i.e., number of gates) of the parallelized functionality is roughly equal to the circuit size of the sequential functionality: $size(C_f) \approx size(C_{f_1}) + size(C_{f_2})$. Due to the different garbling methods for linear and non-linear gates in Yao's protocol using the free-XOR technique, $size(C_f)$ is better measured by the number of non-linear gates. Furthermore, we refer to a parallelization as *symmetric* if sub functionalities have almost equal circuit sizes: $size(C_{f_1}) \approx size(C_{f_2})$.

Finally, we refer to functionalities that can be decomposed into a sequential and a parallel part as *mixed functionalities*. For example the functionality $f(x,y) = f_3(f_1(x,y) \diamond f_2(x,y), x, y)$ can first be decomposed sequentially in f_3 and $f_1 \diamond f_2$, where the latter part can then be further decomposed in f_1 and f_2.

Without an explicit definition, we note that all definitions can be extended from the dual case f_1 and f_2 to the general case $f_1, f_2, \dots, f_n$.

4.2 Parallel circuit creation and evaluation

A circuit that consists of annotated sequential and parallel parts can be garbled in parallel as follows. Sequential regions of a circuit can be garbled using standard techniques by iterating topologically over all gates. Once a parallel decomposable region of a circuit is reached, parallelization is applied. All independent sub circuits in every parallel region can be garbled in any order by any available thread (see Figure 1). We note that the garbling order has no impact on the security [25]. After every parallel region a synchronization between the different threads is needed to guarantee that all wire labels for the next region of the circuit are computed. Multiple subsequent parallel regions with different degrees of parallelism can be garbled, when ensuring synchronization in-between.

The circuit evaluation can be parallelized in the same manner. Sequential regions are computed sequentially, parallel regions are computed in parallel by different threads. After every parallel region a thread synchronization is required to ensure data consistency.

When using pipe-lining the garbled tables have to be transmitted in an identifiable order to ensure data consistency between generator and evaluator. We propose three different variants. First, all garbled tables can be enriched with a numbering, e.g., an index, which allows a unordered transfer to the evaluator. The evaluator is then able to reconstruct the original order based on the introduced numbering. This approach has the disadvantage of an increased communication cost. The second approach is that garbled tables are sent in a synchronized and predefined order. This approach functions without additional communication, yet can lead to an undesirable 'pulsed' communication pattern. The third approach functions by strictly separating the communication channels for every sub circuit. This can either be realized by multiplexing within the TPC framework or by exploiting the capabilities of the underlying operating system. Due to the aforementioned reasons, our implementation of a parallel framework (presented in § 6.1) builds upon the latter approach.

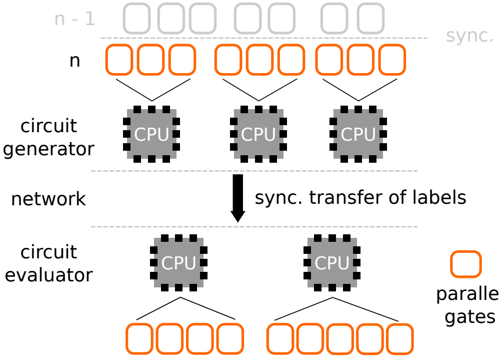

Figure 1: Interaction between a parallel circuit generator and evaluator. The layer n of the presented circuit is garbled and evaluated in parallel. The independent partitions of the circuit can be garbled and evaluated by different threads in any order.

4.3 Fine-grained parallelism

A first heuristic to decompose a circuit into parallel parts is the *fine-grained* gate level approach, described in the following. Similar to the evaluation of a standard Boolean circuit, gates in garbled circuits are processed in topological execution order. Gates provide input to other gates and hence, can be ordered by the circuit level (depth) when all their inputs are ready or the level when their output is required for succeeding gates. Consequently and as proposed by others [3, 17], gates on the same level can be garbled in parallel. Thus, a circuit is sequentially decomposable into different levels and each level is further decomposable in parallel with a granularity up to the number of gates. Figure 2 illustrates fine-grained decomposition of a circuit into three levels L1, L2 and L3.

To achieve an efficient distribution of gates onto threads during protocol execution, it is useful to identify the circuit levels during the circuit compilation process. Furthermore, a reasonable heuristic to symmetrically distribute the workload onto all threads when using the free-XOR optimization is to divide linear and non-linear gates independently. Hence, each thread gets assigned the same number of linear and non-linear gates to garble. Therefore, we extended the circuit compiler CBMC-GC with the capability to mark levels and to strictly separate linear from non-linear gates within each level. This information is stored in the circuit description.

Overhead. In practice, multi-threading introduces an computational overhead to enable thread management and thread synchronization. Therefore, it is useful to experimentally determine a system dependent threshold τ that describes the minimal number of gates that are required per level to profit from parallel execution. In practical settings (see § 6) we observe that at least ~ 8 non-

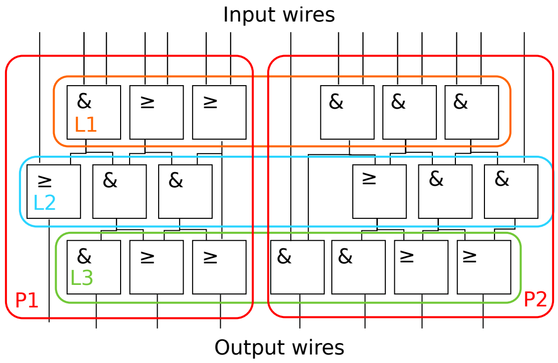

Figure 2: Circuit decomposition. Each level *L1, L2* and *L3* consists of multiple gates that can be garbled using FGP with synchronization in-between. The circuit can also be decomposed in two coarse-grained partitions *P1* and *P2*.

linear gates per core are required to observe first speedups. Achieving a parallelization efficiency of 90%, i.e, a speed up of 1.8 on 2 cores, requires at least 512 nonlinear gates per core. In the next section we present an approach that overcomes the limitations of FGP.

4.4 Coarse-grained parallelism

Another useful heuristic to partition a circuit is the usage of high-level functionality descriptions. Given a circuit description in a high-level language, parallelizable regions of the code can be identified using programming language techniques. These detected code regions can then be tracked during the circuit compilation process to produce parallel decomposable circuits. The different *sub circuits* are guaranteed to be independent of each other and therefore can be garbled in parallel. We refer to this parallelization scheme as *coarse-grained parallelization (CGP)*. Figure 2 illustrates an example decomposition in two coarse-grained partitions P1 and P2. Furthermore, we note that FGP and CGP can be combined by utilizing FGP within all coarse partations. In the following paragraphs, we introduce our CBMC-GC compiler extension that automatically produces coarse-grained parallel circuits.

Compiler for parallel circuits. Our parallel circuit complier *ParCC* extends the CBMC-GC compiler and builds on top of the Par4all compiler introduced in § 3. ParCC takes C code as input, which carries annotations according the CBMC-GC notation. Hence, TPC input and output variables of both parties are marked as such. ParCC detects parallelism within this code with the help of Par4all and produces one *global circuit* that is interrupted by one or multiple *sub circuits* for every parallel region. If a parallel region follows the single-instruction-multiple-data paradigm (SIMD), only one sub circuit per parallel region is compiled, which reduces the circuit storage costs. During protocol runtime, the sub circuit is unrolled and garbled in full extent. The global and sub circuits are interconnected by explicitly defining *inner* input and output wires. These are not exposed as TPC inputs or outputs, but have to be used by TPC frameworks to recompose the complete and parallel executable circuit. The compilation process itself consists of four different steps:

(1) In the first step, parallelism in C code is detected by Par4all and annotated using the OpenMP notation and source-to-source transformations.

(2) The annotated C code is parsed by ParCC in the second step. The source code is decomposed using source-to-source techniques into a *global* sequentially executable part, which is interrupted by one or multiple parallel executable *sub* parts. Additionally, functional OpenMP annotations, such as reduction statements, are replaced with C code that is compiled into the circuits. Furthermore, information about the degree of detected parallelism as well as the interconnection between the global and sub parts is extracted for later compilation steps.

(3) Given the decomposed source code, the different parts are compiled independently with CBMC-GC.

(4) In the final step information about the mapping of wires between gates in the global and the sub circuits is exported for use in TPC frameworks. For performance reasons, we distinguish static wires that are shared between parallel sub circuits and wires that are dedicated for each individual sub circuit.

Example. To illustrate the functionality of ParCC, we discuss the source-to-source compilation steps on a small *fork and join* task, namely the dot product of two vectors **a** and **b**:

$$r = \mathbf{a} \cdot \mathbf{b} = a_0 \cdot b_0 + \cdots + a_n \cdot b_n.$$

The source code of the function dot_product() is presented in Listing 2.

```
int mult(int a, int b) {
  return a * b;
}
void dot_product() {
  int INPUT_A_a[100], INPUT_B_b[100];
  int res = 0;
  for(i = 0; i < 100; i++)
    res += mult(INPUT_A_a[i], \
      INPUT_B_b[i]);
  int OUTPUT_res = res;
}
```

Listing 2: Dot vector product written in C with CBMC-GC input/output notation.

In this example code, two parties provide input for two vectors in form of constant length integer arrays (Line 5). A loop iterates pairwise over all array elements (Line 7), multiplies the elements and aggregates the result. In the first compilation step, Par4all detects the parallelism in the loop body and annotates this parallel region accordingly. Therefore, Par4all adds the statement `#pragma omp parallel for reduction(+:res)` before the `for` loop in Line 7.

ParCC parses the annotations in the second compilation step to export the loop body, in this case the sub function `mult()`, printed in Listing 3.

```
void mult(int INPUT_A_a, int INPUT_A_b,
    int OUTPUT_return)
{
  int a = INPUT_A_a;
  int b = INPUT_A_b;
  OUTPUT_return = a*b;
}
```

Listing 3: Exported sub function with CBMC-GC input-output notation.

The functions arguments are rewritten according the notation of CBMC-GC. Thus, the two arguments `a` and `b` of `mult()` become inner inputs of the sub circuit, and the return statement becomes an inner output variable. Note, that during the protocol execution all inner wires are not assigned to any party, instead they connect global and sub circuits. Yet, to keep compatibility with CBMC-GC a concrete assignment for the party P_A is specified. The later exported mapping information is used to distinguish between inner wires and actual input wires of both parties. In the same step, the global function `dot_product()`, printed in Listing 4, is transformed by ParCC to replace and unroll the loop.

```
1  void dot_product() {
2    int INPUT_A_a[100], INPUT_B_b[100];
3    int res = 0;
4    int OUTPUT_SUB_a[100];
5    int OUTPUT_SUB_b[100];
6    int i;
7    for(i = 0; i <= 99; i++) {
8      OUTPUT_SUB_a[i] = INPUT_A_a[i];
9      OUTPUT_SUB_b[i] = INPUT_B_b[i];
10   }
11   int INPUT_A_SUB_res[100];
12   for(i = 0; i <= 99; i++)
13     res += INPUT_A_SUB_res[i];
14   int OUTPUT_res = res;
15 }
```

Listing 4: Rewritten `dot_product()`. The loop has been replaced by inner input/output variables (marked with `SUB`).

Therefore, the two input arrays `INPUT_A_a` and `INPUT_B_b` are exposed as inner output variables beginning in Line 4. Therefore, two new output arrays using CBMC-GC notation are added based on the statically determined information about parallel variables. Furthermore, an inner input array for the intermediate results is introduced in Line 11. Finally, the reduction statement is substituted by synthesized additions over all intermediate results in Line 13.

In the third and fourth compilation step, the two circuits are compiled and the mapping of wires between global and sub circuits is exported.

5 Inter-Party Parallelization (IPP)

In this section, we describe a novel protocol extension to Yao's protocol to balance computation between parties, assuming *symmetric efficiently parallelizable* functionalities. We refer to this protocol extension as *inter-party parallelization* (IPP). Without compromising security, we show in § 6 that the protocol runtime can be reduced in practical applications when using IPP. This is also the case when using only one CPU core per party.

We recap the initial motivation: The computational costs that each party has to invest in semi-honest Yao is driven by the encryption and decryption costs of the garbled tables as well as the communication costs. Considering the garbling technique with the least number of cryptographic operations, namely GRR combined with free-XOR, the generator has to compute four ciphertexts per non-linear gate, whereas the evaluator has to compute only one ciphertext per non-linear gate. When considering the communication optimal half-gate approach [36], the generator has to compute four and the evaluator two ciphertexts per non-linear gate. Assuming two parties that are equipped with similar computational power, a better overall resource utilization would be achieved, if both parties could be equally involved in the computation process. This can be realized by sharing the roles generator and evaluator. Consequently, the overall protocol runtime could be decreased. Figure 3 illustrates this efficiency gain.

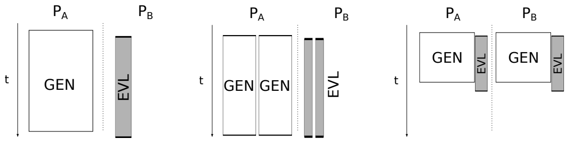
In the following sections we first discuss how to extend Yao's protocol to use IPP for purely parallel functionalities. In a second step we generalize this approach by showing how mixed functionalities profit from IPP.

5.1 Parallel functionalities

We assume that two parties P_A and P_B agree to compute a functionality $f(x,y)$ with x being P_A's input and y being P_B's input. Moreover, we assume $f(x,y)$ to be parallelizable into two (or more) sub functionalities $f_0,\dots,f_n$:

$$f(x,y) = f_0(x,y) \diamond f_1(x,y) \diamond \dots \diamond f_n(x,y).$$

Given such a decomposition, all sub functionalities can be computed independently with any TPC protocols (secure against semi-honest adversaries) without



(a) Original

(b) Independence analysis

(c) Inter-party Parallelization

Figure 3: The idea and performance gain of IPP visualized. The OT phase and output sharing are omitted. In Figure 3(a) the sequential execution of Yao's protocol is visualized. Given a parallel decomposition by two circuits representing parallal program regions as displayed in Figure 3(b), the protocol runtime can be reduced when sharing the roles generator and evaluator, as displayed in Figure 3(c).

any sacrifices towards the security [12]. This observation allows us to run two independent executions of Yao's protocol, each for one half of f's sub functionalities, instead of computing f with a single execution of Yao's protocol. Hence, P_A could garble one half of f's sub functionalities, for example $f_{even} = f_0, f_2, \dots$, and P_A could evaluate the other half $f_{odd} = f_1, f_3, \dots$. Vice versa, P_B could evaluate f_{even} and garble f_{odd}. Following this approach, P_A and P_B have to switch their roles for the OT phase of Yao's protocol. In the output phase, both parties share their output labels and description tables (ODT) with each other.

Analytical performance gain. As discussed, the computational costs for Yao's protocol are dominated by encrypting and decrypting garbled truth tables. Thus, idealizing and highly abstracted, the time spent to perform a computation t_{total} is dominated by the time to garble a circuit t_{garble}. Using GRR with free-XOR and assuming that t_{garble} is approximately four times the time to evaluate a circuit t_{eval}, by symmetrically sharing this task the total time could be reduced to:

$$t'_{total} \approx \frac{(t_{garble} + t_{eval})}{2} \approx \frac{(4 \cdot t_{eval} + t_{eval})}{2} \approx 2.5 \cdot t_{eval}.$$

This result translates to a theoretical speed-up of $t_{total}/t'_{total} = 4/2.5 = 1.6$. When using the half-gate approach the approximate computational speed-up is 1.33.

5.2 Mixed functionalities

To exploit IPP in mixed functionalities, a protocol extension is required, allowing to switch from sequential (dedicated roles) to IPP (shared roles) without violating the privacy property of TPC. Therefore, we introduce the notion of *transfering roles* to securely interchange between IPP and sequential execution.

Transferring roles We introduce the idea of transferring roles in two steps. First we sketch an insecure protocol, which is then made secure in a second step. To switch the roles of evaluator and generator during execution, we consider two parties P_A, P_B and the sequentially composed functionality $f(x,y) = f_2(f_1(x,y),x,y)$. In the following description, f_1 is computed using Yao's protocol with P_A being generator and P_B being evaluator, f_2 is computed with reversed roles.

The transfer protocol begins by computing $f_1(x,y)$ with Yao's original protocol. Once f_1 is computed, the roles have to be switched. Naïvely, the parties 'open' the circuit by interchanging output wires and the ODT. This reveals the intermediate result $o_1 = f_1(x,y)$ to both parties. In the second phase of the protocol, f_2 is computed using Yao's protocol. This time, P_A and P_B switch roles, such that P_B garbles f_2 and P_A evaluates f_2. The decrypted output bits $o_1 = f_1(x,y)$ are used by P_A as input in the OT protocol. After garbling f_2, the output labels and the ODT are shared between both parties. This protocol resembles a pause/continue pattern and preserves correctness. However, this protocol leaks o_1 to both parties, which violates the privacy requirement of TPC. Therefore, we propose to use an XOR-blinding during the role switch. The full protocol is printed below.

Protocol: Transferring Roles

P_A and P_B agree to securely compute the sequentially decomposable functionality $f(x,y) = f_2(f_1(x,y),x,y)$ without revealing the intermediate result $f_1(x,y)$ to either party, where x is P_A's input bit string, y is P_B's input bit string. The protocol consists of two phases, one per sub functionality.

Phase 1: Secure computation of $f_1(x,y)$

1. f_1 is extended with a XOR blinding for every output bit. Thus, the new output $o'_1 = f'_1(x,y||y_r) = f_1(x,y) \oplus y_r$ is calculated by xoring the output of f_1 with additional, randomly drawn input bits by the evaluator of f_1.

2. P_A and P_B securely compute f'_1 using Yao's protocol. We assume P_A to be the generator. Additional randomly drawn input bits are then input of P_B.

3. The blinded output o'_1 of the secure computation is only made visible to the generator P_A. This is realized by transmitting the output wire labels to P_A, but not sharing the ODT with P_B.

Phase 2: Secure computation of $f_2(o_1,x,y)$

1. The circuit representing f_2 is extended with a XOR unblinding for every input bit of o'_1. Hence, $f'_2(o'_1,x,y,y_r) = f_2(o'_1 \oplus y_r,x,y)$.

2. P_A and P_B securely compute f_2' using Yao's protocol. We assume P_B to be the generator. P_A provides the input o_1' and P_B provides the input bits for the blinding with y_r.

3. The output of the computation is shared with both parties.

We observe that, informally speaking the protocol preserves privacy, since the intermediate state o_1 is shared securely between both parties. A detailed formal proof on sequential decomposed functionalities is given by Hazay and Lindell [12, page 42ff]. Correctness is preserved due to blinding and unblinding with the equal bit string y_r:

$$\begin{aligned} f_2'(f_1'(x,y||y_r),x,y,y_r) &= f_2'(f_1(x,y)\oplus y_r,x,y,y_r) \\ &= f_2(f_1(x,y)\oplus y_r \oplus y_r,x,y) \\ &= f_2(f_1(x,y),x,y). \end{aligned}$$

Finally, we note that transferring roles protocol can further be improved. Demmler et al. [8] presented an approach to securely share a state of Yao's protocol that uses the point-and-permute bits [27] as a blinding. This approach has equivalent costs in the number of cryptographic operations, yet removes the need of an ODT transfer. Our implementation uses this optimization.

Transferring roles for mixed functionalities. With the idea of transferring roles, IPP can be realized for mixed functionalities. In the following paragraphs, we show how to switch from IPP to sequential computation. Switching into the other direction, namely from sequential to IPP can be realized analogously. With protocols to switch in both directions, it is possible to garble and evaluate any functionality that consists of an arbitrary number of sequential and parallel regions.

To show the switch from IPP to sequential computation, we assume a functionality that is sequentially decomposable into a parallel and a sequential functionality:

$$f(x,y) = f_3(f_1(x,y) \diamond f_2(x,y),x,y).$$

Note that f_1, f_2 and f_3 could further be composed of any sequential and parallel functionalities. We observe that f_3 can be merged with f_1 (or f_2) into one combined functionality f_c. Thus, $f(x,y)$ can also be decomposed as $f(x,y) = f_c(f_2(x,y),x,y)$ with f_c being the sequential composition of f_3 and f_1. Given such a decomposition, f_c and f_2 can be computed with alternating roles in Yao's protocol by following the transferring roles protocol. Hence, f_c could be garbled by P_A while f_2 could be garbled by P_B to securely compute f.

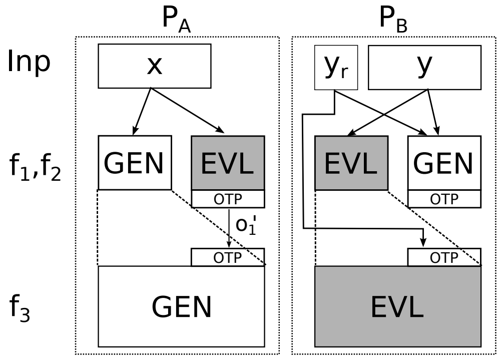


Figure 4: The IPP protocol for a mixed functionality with a switch from parallel to sequential computation. Functionality $f_1 \diamond f_2$ is garbled in parallel using IPP, f_3 is garbled sequentially in combination with f_1. No interaction between parties is shown. The blinded output o_1' of f_1 is only made visible to P_A and used as additional input for the computation of f_2 using the transferring roles protocol.

As a second observation we note that the output of f_2 is not required to start the computation of f_c. Therefore, the computation of f_c can start in parallel to the computation of f_2. This inter-party parallelism can be exploited to achieve further speed-ups. Figure 4 illustrates this approach. Party P_A garbles f_c and P_B garbles f_2. The first part of f_c, namely f_1 can be garbled in parallel to f_2. Once the blinded output o_1' of f_2 is computed, the parties can start computing the second part of f_c, namely f_3. Switching from sequential to IPP computation can be realized in the same manner.

We remark that FGP, CGP and IPP can be combined to achieve even further speed-ups. Therefore, every parallel region has first be decomposed in two parts for IPP. If the parts can further be decomposed in parallel functionalities, these could be garbled following the ideas of CGP and FGP.

Overhead. Investigating the overhead of IPP, we observe that during the cost intensive garbling and evaluation phase, no computational complexity is added. Particularly, the number of cryptographic operations and messages is left unchanged. However, when using OT Extension, a constant one-time overhead for base OTs in the size of the security parameter k is introduced to establish bi-directional OT Extension. To switch from and to IPP in mixed functionalities, additional OTs in the size of the intermediate state are required. Thus, the performance gain through IPP for mixed functionalities not only depends on the ratio between parallel and sequential regions, but also on the ratio of circuit size and shared state. These ratios are application dependent. A practical evaluation of the trade-off between overhead and performance gain is presented in § 6.5.

5.3 Security implications and applications

As discussed in the previous section, Yao's protocol and IPP are secure against semi-honest adversaries. Nevertheless, semi-honest Yao's garbled circuits are often used to bootstrap TPC protocols secure against active adversaries. Therefore, in this section, we sketch the security implications of IPP and its compatibility with the most common techniques to strengthen Yao's protocol. Furthermore, we depict applications and protocols the could profit from IPP.

Yao's original protocol is already secure against malicious evaluators (when using an OT protocol secure against malicious adversaries), yet not secure against malicious generators. We note that this one-sided security does not longer hold when using IPP because both parties incorporate the role of a circuit generator. Consequently, cut-and-choose protocols [24], which garble multiple copies of the same circuit to achieve active security, are incompatible with IPP because they are built on the assumption that only one party can actively manipulate the protocol. A similar observation can be made for Dual-execution protocols [29, 16] that prevent an active adversary from learning more than a small number of bits during the protocol execution. Even so the concept of Dual-execution is close the the idea of IPP, i.e., symmetrically sharing the roles of generator and evaluator, it also requires one-sided security against malicious evaluators and is therefore incompatible with IPP.

Applications of IPP. IPP can be applied in all application scenarios where semi-honest model is sufficient. These are scenarios where either the behaviour is otherwise restricted, e.g. limited physical access, or where the parties have sufficient trust into each other. Moreover, IPP can be used in all the scenarios where the parties inputs and seeds could be revealed at a later point to identify cheating parties. Examples might be negotiations (auctions) or games, such as online poker. Another field of application is the joint challenge creation, e.g. RSA factorization. Using secure computation, two parties could jointly create a problem instance without already knowing the solution. This allows them to create a problem and to participate in the challenge at the same time without a computational advantage. Once a solution is computed, all parts of the secure computation can be verified in hindsight.

For further work, we note that the core idea of IPP could be applied in other TPC protocols. To profit from IPP, a state sharing mechanism in the protocols security model is required as well as an asymmetric workload between the parties. One example might be the highly asymmetric STC protocol by Jarecki and Shmatikov [19] that uses zero-knowledge proofs over every gate.

6 Evaluation

In this section, we evaluate the three proposed parallelization schemes. We begin by introducing our parallel STC framework named UltraSFE and benchmark its performance on a single core in § 6.1. The applications and their circuit descriptions used for benchmarking are described in § 6.2. We evaluate the offline garbling performance of the proposed parallelization techniques in § 6.3, before integrating and evaluating the promising coarse-grained parallelization (CGP) in a online setting in § 6.4. Finally, in § 6.5 we benchmark the inter-party parallelization (IPP) approach.

6.1 UltraSFE

UltraSFE[1] is a parallel framework for Yao's garbled circuits built up on the *JustGarble (JG)* [5] garbling scheme. To realize efficient parallelization, data structures and memory layout are optimized with the purpose of parallelization in mind. This is, to the best of our knowledge, not the case with existing open source frameworks. Therefore, we adapted the JustGarble garbling scheme to support parallelization.

UltraSFE is written in C++ using SSE4, OpenMP and Pthreads to realize multi-core parallelization. Conceptually UltraSFE is using ideas from the Java based memory efficient *ME_SFE* framework [13], which itself is based on the popular *FastGC* framework [15]. The fast hardware AES extension in current CPU generations is exploited by the JustGarble garbling scheme. Oblivious transfers are realized with the help of the highly efficient and parallelized OTExtension library written by Asharov et al. [2]. Moreover, UltraSFE adopts techniques from many recent theoretical and practical advances of Yao's protocol. This includes pipe-lining, point-and-permute, garbled row reduction, free-XOR and the half-gate approach [15, 21, 27, 31, 36].

Framework comparison. To illustrate that UltraSFE is suited to evaluate the scalability of different parallelization approaches, we present a comparison of its garbling performance with other state of the art frameworks using a CPU architecture in Table 1. Namely, we compare the single core garbling speed of UltraSFE, which is practically identical to JG, with the parallel frameworks by Barni et al. (*BCPU*) [3], Husted et al. (*HCPU*) [17] and Kreuter et al. (*KSS*) [23]. Note, these results are compared in the *offline* setting, i.e., truth tables are written to memory. This is because circuit garbling is the most cost intensive part of Yao's protocol and therefore the most interesting when comparing the performance of different frameworks. The previous parallelization efforts HCPU

[1] UltraSFE will be made available as open source on http://www.seceng.informatik.tu-darmstadt.de/research/software/

	Ours / JG [5]	BCPU [3]	HCPU[17]	KSS [23]
gps	8.3M	0.11M	<0.25M	0.1M
cpg	108	>3500	-	>6500 [5]
arch	E5-2680	E5-2609	E5-2620	i7-970

Table 1: Single core garbling speed comparison of different frameworks on circuits with more than 5 million gates. Metrics are non-linear gates per second (*g*ps) in millions (M) and clocks per gate (*cpg*). All results have been observed on the Intel processor specified in row *arch*. Note, for HCPU [17] only circuit evaluation times have been reported on the CPU, the garbling speed can be assumed to be lower.

and BCPU actually abstained from implementing an *online* version of Yao's protocol that supports pipe-lining. As metrics we use garbled gates per second (*gps*) and the average number of CPU clock cycles per gate (*cpg*), as proposed in [5]. The numbers are taken from the cited publications and if not given, the cpq results are calculated based on the CPU specifications (*arch*). Even when considering theses numbers only as rough estimates, due to the different CPU types, we observe that UltraSFE performs approximately 1-2 orders of magnitude faster than existing parallelizations of Yao's protocol. This is mostly due to the efficient fixed-key garbling scheme using the AES-NI hardware extension and a carefully optimized implementation using SSE4. Summarizing, UltraSFE shows competitive garbling performance on a single core and hence, is a very promising candidate for parallelization.

6.2 Evaluation methodology

To evaluate the different parallelization approaches we use three example applications that have been used to benchmark and compare the performance of Yao's garbled circuits in the past.

Biometric matching (BioMatch). The first application that we use is privacy-preserving biometric matching. In this application a party matches one biometric sample against the other's party database of biometric templates. Example scenarios are face-recognition or fingerprint-matching [9]. One of the encompassing concepts is the computation of the Euclidean distance between the sample and all database entries. Once all distances have been computed, the minimal distance determines the best match. Thus, the task is to securely compute the minimal distance $min\left(\sum_{i=1}^{d}(s_{i,1}-e_i)^2,\ldots,\sum_{i=1}^{d}(s_{i,n}-e_i)^2\right)$ with s_i being the sample of degree d provided by the first party and $e_1,\ldots,e_n$ being the database elements with the same degree provided by the other party. Following the examples of [8, 20], the chosen parameters for this circuit are the number of elements in the database $n = 512$, the degree of each element $d = 4$ and the integer size $b = 64$bit.

	BioMatch	**MExp**	**MVMul**
Code size	22 LOC	28 LOC	10 LOC
Circuit size	66M	21.5M	3.3M
Non-linear gates	25%	41%	37%
# Input bits P_A/P_B	131K/256	1K/1K	17K/1K
Offline garbling time	2.07s	1.136s	0.154s

Table 2: *Circuit properties.* Presented are the code size, the overall circuit size in the number of gates, the fraction of non-linear gates that determine the majority of computing costs, the number of input bits as well as the sequential offline garbling time with UltraSFE.

Modular exponentiation (MExp). The second application that we benchmark is parallel modular exponentiation. Modular exponentiation has been used before to benchmark the performance of Yao's garbled circuits [5, 8, 23]. It has many applications in privacy-preserving computation. For example, blind signatures where the message to be signed should not be revealed to the signing party. For this application, we differentiate the circuit by the number of iterated executions $k = 32$, as well as the integer width $b = 32$.

Matrix-vector multiplication (MVMul). Algebraic operations such a matrix multiplication or the dot vector product are building blocks for many privacy-preserving applications and have been used before to benchmark Yao's garbled circuits [14, 22]. We use a Matrix-vector multiplication as required in the learning with errors (LWE) cryptosystem [33]. We parametrize this task according the size of the matrix $m \times k = 16 \times 16$ and vector $k = 16$, as well the integer size of each element $b = 64$ bit.

Circuit creation. All circuits are compiled twice, once with CBMC-GC and once with ParCC using textbook C implementations. The time limit for the circuit minimization through CBMC-GC is set to 10 minutes. The resulting circuits and their properties are shown in Table 2. The BioMatch circuit is the largest circuit and shows the most input bits. The MVMul circuit garbles in a fraction of a second and thus, fits to evaluated the performance of parallelelization on smaller circuits. The MExp circuit shows a large circuit complexity in comparison to the number of input bits. Even so not shown here, we note that the sequential (CBMC-GC) and parallel (ParCC) circuits slightly differ in the overall number of non-linear gates due to the circuit minimization techniques of CBMC-GC, which profit from decomposition.

Environment. As testing environment we used Amazon EC2 cloud instances. These provide a scalable number of CPUs and can be deployed at different sites around the globe. If not state otherwise, for all experiments instances of type `c3.8xlarge` have been used. These instances report 16 physical cores on 2 sockets with CPUs of type Intel Xeon E5-2680v2, and are equipped with a 10Gbps ethernet connection. A fresh installation of Ubuntu 14.04 was used to ensure as little background noise as possible. UltraSFE was compiled with `gcc 4.8 -O2` and `numactl` was utilized when benchmarking with only a fraction of the available CPUs. Numactl allows memory, core and socket binding of processes. Results have been averaged 10 executions.

Methodology. Circuit garbling is the most expensive task in Yao's protocol. Therefore, we begin by evaluating FGP and CGP for circuit garbling independent of other parts of Yao's protocol. This allows an isolated evaluation of the computational performance gains through parallelization. Following the offline circuit garbling phase is an evaluation of Yao's full protocol in an online LAN setting. This evaluation also considers the bandwidth requirements of Yao's protocol. Finally, we present an evaluation of the IPP approach in the same LAN setting. Therefore, we first evaluate the performance of IPP on a single core, before evaluating its performance in combination with CGP. The main metric in all experiments is the overall runtime and the number of non-linear gates that can be garbled per second.

6.3 Circuit garbling (offline)

We begin our evaluation of FGP and CGP with the offline task of circuit garbling. In practice the efficiency of any parallelization is driven by the ratio between computational workload per thread and synchronization between threads. When garbling a circuit with FGP, the workload is bound by the width of each level, when garbling with CGP the workload is bound by the size of parallel partitions. Both parameters are circuit and hence, application dependent.

Artificial circuits and thread utilization. To get a better insight, we first empirically evaluate the possible efficiency gain for different sized workloads, independent of any application. This also allows to observe a system dependent threshold τ, introduced in § 4.3, which describes the minimal number of gates required per thread to profit from parallelization. Therefore, we run the following experiment: For every level width $w = 2^4, 2^5, \ldots, 2^{10}$ we created artificial circuits of depth $d = 1000$. The width is kept homogeneous in all levels. Furthermore, the wiring between gates is randomized and only non-linear gates are used. Each circuit is garbled using FGP and we measured the parallelization efficiency (speed-up divided by the number of cores) when computing with a different numbers of threads. The results are illustrated in Figure 5.

The experiment shows that on the tested system $\tau \approx 8$ non-linear gates per thread are sufficient to observe first performance gains through parallelization. To achieve an efficiency of 90% approximately 512 non-linear gates per thread are required. Investigating the results for 16 parallel threads, we observe that a significantly larger workload per thread (at least one order of magnitude) is required to overcome the communication latency between the sockets on the testing hardware.

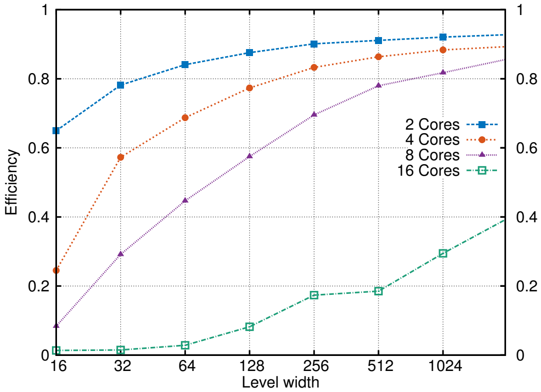

Figure 5: *Level-width experiment.* Displayed is the efficiency of FGP for different circuit level widths. A larger width increases the efficiency of parallelization. The gap between 8 (one socket) and 16 cores (two sockets) is due the communication latency between two sockets.

Example applications. We evaluated the speed-up of circuit garbling when using FGP and CGP for the three applications BioMatch, MExp and MVMul compiled with CBMC-GC (FGP) and ParCC (CGP). The speed-up is calculated in relation to the single core garbling performance given in Table 2. The results are presented in Figure 6. The results have been observed for a security level of $k = 128$ bit. We note, that in this experiment no significant differences where observable when using a smaller security level, e.g., $\kappa = 80$ bit, due to the fixed block size of AES-NI. Discussing the results for FGP, we observe that all applications profit from parallelization. BioMatch and MExp show very limited scalability, whereas the MVMul circuit is executable with a speed-up of 7.5 on 16 cores. Analyzing the performance of CGP, we observe that all applications achieve practically ideal parallelization when using up to 4 threads. In contrast to the FGP approach, scalability with high efficiency is observable with up to 8 threads. Further speed-ups when using the CPU located on the second socket are noticeable in the MExp and MVMul experiments, achieving a throughput of more than 100M non-linear gates per second.

In summary, for all presented applications the CGP approach significantly outperforms the FGP approach regarding scalability and efficiency due to its coarser granularity, which implies a better thread utilization.

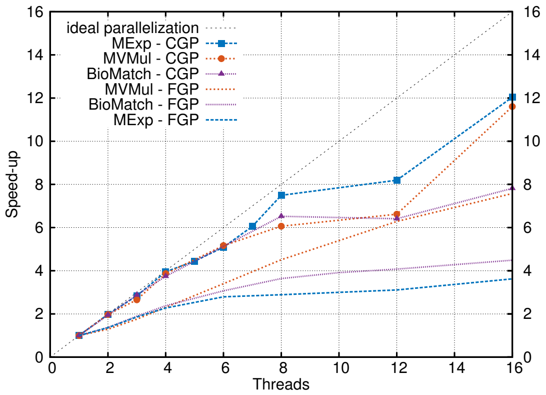

Figure 6: *Circuit garbling.* The speed-up of circuit garbling for all three applications when using the FGP, CGP and different numbers of computing threads. CGP significantly outperforms FGP for all applications.

Circuit width analysis. The limited scalability of FGP is explainable when investigating the different circuit properties. In Figure 7 the distribution of level widths for all circuits is illustrated.

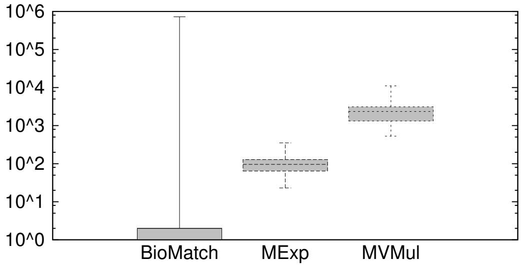

Figure 7: Number of non-linear gates per level and circuit.

For the MVMul application, the CBMC-GC compiler produces a circuit with a median level width of 2352 non-linear gates per level, whereas the BioMatch and MExp circuits only show a median width below 100 non-linear gates per level. The major reasons for small circuit widths in comparison to the overall circuit size is that high-level TPC compilers such as CBMC-GC or the compiler by Kreuter et al. [23] have been developed with a focus on minimizing the number of non-linear gates. Minimizing the circuit depth or maximizing the median circuit width barely influence the sequential runtime of Yao's protocol and is therefore not addressed in the first place. Looking at the building blocks that are used in CBMC-GC, we observe that arithmetic blocks (e.g. adder, multiplier) show a linear increase in the average circuit width when increasing the input size. However, multiplexers, as used for dynamic array accesses and for 'if' statements, show a circuit width that is independent (constant) of the number of choices. Thus, a 2-1 multiplexer and a n-1 multiplexer are compiled to circuits with similar sized levels, yet with different circuit depths. Moreover, comparisons have a constant circuit width for any input bit size. Based on these insights we deduce, that the MVMul circuit shows a significantly larger median circuit width, because of the absence of any dynamic array access, conditionals or comparisons. This is not the case with the BioMatch and MExp applications. Considering that every insufficient saturation of threads leads to an efficiency loss of parallelization, we conclude that scalability of FGP is not guaranteed when increasing input sizes.

6.4 Full protocol (online)

To motivate that the parallelization of circuit garbling can be used in Yao's full protocol, we evaluated the protocol for all applications running on two separated cloud instances in the same Amazon region (LAN setting). We observed an average round trip time of 0.6±0.3ms and a transfer bandwidth of 5.0±0.4 Gbps using `iperf`. Following the results of the offline experiments, we benchmark the more promising CGP approach in the online setting.

To measure the benefits of parallelization, we first benchmark the single core performance of Yao's protocol in the described network environment. Table 3 shows the sequential runtime for all applications using two security levels $\kappa = 80$ bit (short term) and $\kappa = 128$ bit (long term). This runtime includes the time spent on the input as well as the output phase. Furthermore, the observed throughput, measured in non-linear gates per second, as well as the required bandwidth are presented. We observe that for security levels of $\kappa = 80$ and $\kappa = 128$ a similar gate throughput is achieved. Consequently, we deduce that in this setup the available bandwidth is not stalling the computation. We also observe that that the time spent on OTs in all applications is practically negligible ($< 5\%$) in comparison with the time spent on circuit garbling.

In Figure 8 the performance gain of CGP is presented. The speed-up is measured in relation to the sequential total runtime. The timing results show that CGP scales almost linearly with up to 4 threads when using $\kappa = 80$ bit labels. Using $\kappa = 128$ bit labels, no further speed-up beyond 3 threads is noticeable. Thus, the impact of the network limits is immediately visible. Five ($\kappa = 80$ bit), respectively three ($\kappa = 128$ bit) threads are sufficient to saturate the available bandwidth in this experiment. Achieving further speed-ups is impossible without increasing the available bandwidth or developing new TPC techniques. However, to the best of our knowledge with 6M non-linear gates per second on a single core, as well as with approximately 32M non-linear gates per second on a single socket, we report the fastest garbling speed in

Circuits		BioMatch	MExp	MVMul
t_{total}	$\kappa = 128$	2.71±0.02	1.43±0.01	0.20±0.00
[s]	$\kappa = 80$	2.56±0.03	1.42±0.01	0.19±0.00
gps	$\kappa = 128$	6.23±0.04	6.17±0.05	6.22±0.00
[M]	$\kappa = 80$	6.56±0.07	6.21±0.04	6.43±0.00
bw	$\kappa = 128$	1.48±0.01	1.47±0.01	1.48±0.00

t_{input}	$\kappa = 128$	<0.02s	<0.01s	< 0.01s
[s]	$\kappa = 80$	<0.02s	<0.01s	< 0.01s

Table 3: *Yao's protocol, single-core performance.* The runtime (t_{total}), non-linear gate throughput in million gates per second (*gps*), required bandwidth (*bw*) and time spent in the input phase (t_{input}), including the OTs when executing Yao's protocol for all applications in a LAN setting.

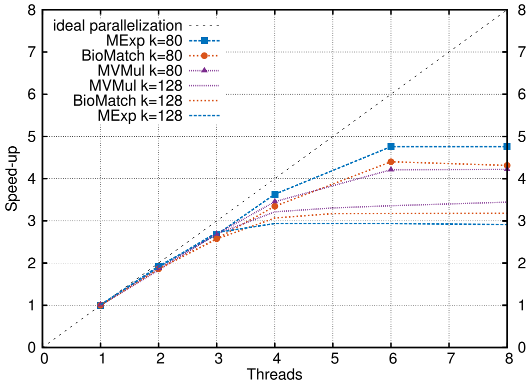

Figure 8: *Yao's protocol - CGP* The speed-up of all three applications in the LAN setting with $\kappa = 128$ bit and $\kappa = 80$ bit security.

an online setting of Yao's protocol. We abstain from an evaluation in a WAN setting due to the high bandwidth that is required to show the scalability of parallelization. The best bandwidth that we could observe during our experiments between two cloud regions was 350 Mbps, which is insufficient to benchmark parallel scalability.

6.5 Inter-party parallelization

A new application of parallelization in Yao's protocol is presented in § 5. We performed two experiments to show the applicability of IPP in practical settings. The first experiment measures the computational efficiency gain in the same setting as described in § 6.4. In the second experiment the benefits of IPP in a WAN setting with limited bandwidth are presented.

Computational efficiency gain. In this experiment the raw IPP performance for all example applications, as well as the combination of CGP and IPP techniques is explored. To realize IPP, our implementation uses multiple threads per core to utilize the load balancing capabilities of the underlying OS without implementing a sophisticated load balancer. Due to the heterogeneous hardware environment, e.g. unpredictable caching and networking behaviour, we evaluated three different workload distribution strategies. The first strategy uses one thread per core and thus only functions with at least two cores. Then, each party has exactly one garbling and one evaluating thread. The second and third strategy use two or four independent threads per core to garble and evaluate at the same time. Moreover, to illustrate that IPP is a modular concept, all circuits are evaluated using a sequential code block that exposes all inner input and output wires before and after every parallel region. This guarantees the evaluation of mixed functionalities. Consequently, all results include the time spent on transferring all required input bits to and from parallel regions. Otherwise applications such as the MVMul application, which is a pure parallel functionality, would profit more easily from IPP. Even though this weakens the results for the example applications, we are convinced that this procedure provides a better insight into the practical performance of IPP.

The results of this experiment are reported in Table 4. We first observe that only the MExp application significantly profits from IPP. This is due to the small sharing state in comparison to the circuit complexity. For both security levels IPP outperforms the raw CGP approach with an additional speed-up of 10-30% on all cores. The performance of the MVMul applications actually decreases when using IPP. This is because of the large state that needs to be transferred. The performance gain through IPP cannot overcome the newly introduced overhead of 31ms, which is more than 15% of the sequential run-time.

In summary, parallelizable applications that show a small switching surface (measured in number of bits compared to the overall circuit size) profit from IPP. Thus, IPP is a promising extension to Yao's protocol that utilizes circuit decomposition beyond naive parallelization, independently of other optimization techniques.

Bi-directional bandwidth exploitation. The second experiment aims towards increasing the available bandwidth by exploiting bidirectional data transfers. Commonly, Ethernet connections have support for full duplex (bi-directional) communication. When using standard Yao's garbled circuits, only one communication direction is fully utilized. However, with IPP the available bandwidth can be doubled by symmetrically exploiting both communication channels. This practical insight is evaluated in a WAN setting between two cloud instances of type `m3.xlarge` with $100 \pm 10ms$ latency and a measured bandwidth of 92 ± 27Mbps. Each hosts runs two threads (a garbling and a evaluating thread) using only

Table 4: Evaluation of IPP in a LAN setting. Column *IPP* specifies the number of threads used per core for load balancing. The total protocol run-time is measured in seconds and the speed-up in comparison with CGP is presented in column *S*. Marked in bold are settings, where IPP leads to performance gains. The time spent on the transferring roles protocol is presented in the last row.

a single core. The results of this experiment are illustrated in Table 5. IPP leads to significant speed-ups of BioMatch and MExp, showing the successful exploitation of bi-directional data transfers. MVMul shows limited performance gains because the time spent on the newly introduced communication rounds for the transferring roles protocol becomes significant. Summarizing, IPP can be very useful for TPC in bandwidth limited environments.

7 Conclusion and Future Work

TPC based on Yao's garbled circuits protocol can greatly benefit from automatic parallelization. The FGP approach can be efficient for some circuits, yet its scalability highly depends on the circuit's width. The CGP approach shows a more efficient parallelization, given parallel decomposable applications. In contrast to previous work, a complete compile chain, which takes C code as input and automatically compiles parallel circuits, supports the practicability of our parallelization scheme. Moreover, we proposed the idea of IPP to achieve a symmetric workload distribution between two computing parties. With this technique, IPP achieves speed-ups through parallelization, even when using a single physical core. Concluding, in this work we presented an efficient, versatile and practical parallelization scheme for Yao's garbled circuits.

Further work includes the investigation of different parallel compilation targets for ParCC, such as the GMW protocol or RAM based secure computation frameworks. Also worthwhile for future investigations is the compilation of circuits optimized for FGP. Likewise, the application of IPP to other protocols is of interest.

Abstract

Conventional cryptographic services such as hardware-security modules and software-based key-management systems offer the ability to apply a pseudorandom function (PRF) such as HMAC to inputs of a client's choosing. These services are used, for example, to harden stored password hashes against offline brute-force attacks.

We propose a modern PRF service called PYTHIA designed to offer a level of flexibility, security, and ease-of-deployability lacking in prior approaches. The keystone of PYTHIA is a new cryptographic primitive called a *verifiable partially-oblivious PRF* that reveals a portion of an input message to the service but hides the rest. We give a construction that additionally supports efficient bulk rotation of previously obtained PRF values to new keys. Performance measurements show that our construction, which relies on bilinear pairings and zero-knowledge proofs, is highly practical. We also give accompanying formal definitions and proofs of security.

We implement PYTHIA as a multi-tenant, scalable PRF service that can scale up to hundreds of millions of distinct client applications on commodity systems. In our prototype implementation, query latencies are 15 ms in local-area settings and throughput is within a factor of two of a standard HTTPS server. We further report on implementations of two applications using PYTHIA, showing how to bring its security benefits to a new enterprise password storage system and a new brainwallet system for Bitcoin.

1 Introduction

Security improves in a number of settings when applications can make use of a cryptographic key stored on a remote system. As an important example, consider the compromise of enterprise password databases. Best practice dictates that passwords be hashed and salted before storage, but attackers can still mount highly effective brute-force cracking attacks against stolen databases.

Well-resourced enterprises such as Facebook [38] have therefore incorporated remote cryptographic operations to harden password databases. Before a password is stored or verified, it is sent to a *PRF service* external to the database. The PRF service applies a cryptographic function such as HMAC to client-selected inputs under a service-held secret key. Barring compromise of the PRF service, its use ensures that stolen password hashes (due to web server compromise) cannot be cracked using an offline brute-force attack: an attacker must query the PRF service from a compromised server for each password guess. Such online cracking attempts can be monitored for anomalous volumes or patterns of access and throttled as needed.

While PRF services offer compelling security improvements, they are not without problems. Even large organizations can implement them incorrectly. For example, Adobe hardened passwords using 3DES but in ECB mode instead of CBC-MAC (or another secure PRF construction) [23], a poor choice that resulted in disclosure of many of its customers' passwords after a breach. Perhaps more fundamental is that existing PRF services do not offer graceful remediation if a compromise is detected by a client. Ideally it should be possible to cryptographically erase (i.e., render useless via key deletion) any PRF values previously used by the client, without requiring action by end users and without affecting other clients. In general, PRF services are so inaccessible and cumbersome today that their use is unfortunately rare.

In this paper, we present a next-generation PRF service called PYTHIA to democratize cryptographic hardening. PYTHIA can be deployed within an enterprise to solve the issues mentioned above, but also as a public, multi-tenant web service suitable for use by any type of organization or even individuals. PYTHIA offers several security features absent in today's conventional PRF services that are critical to achieving the scaling and flexibility required to simultaneously support a variety of clients and applications. As we now explain, achieving these features necessitated innovations in both cryptographic primitive design and system architecture.

Key features and challenges. We refer to an entity using PYTHIA as a *client*. For example, a client might be a web server that performs password-based authentication for all of its end users. Intuitively, PYTHIA allows such a client to query the service and obtain the PRF output $Y = F_k(t, m)$ for a message m and a tweak t of the client's choosing under a client-specific secret key k held by the service. Here, the tweak t is typically a unique identifier for an end user (e.g., a random salt). In our running password storage example, the web server stores Y in a database to authenticate subsequent logins.

PYTHIA offers security features that at, first glance, sound mutually exclusive. First, PYTHIA achieves message privacy for m while requiring clients to reveal t to the server. Message privacy ensures that the PRF service obtains no information about the message m; in our password-storage example, m is a user's password. At the same time, though, by revealing t to the PRF service, the service can perform fine-grained monitoring of related requests: a high volume or otherwise anomalous pattern of queries on the same t would in our running example be indicative of an ongoing brute-force attack and might trigger throttling by the PRF service.

By using a unique secret key k for each client, PYTHIA supports individual key rotation should the value Y be stolen (or feared to be stolen). With traditional PRF services and password storage, such key rotation is a headache, and in many settings impractical, because it requires transitioning stored values $Y_1, \ldots, Y_n$ (one for each user account) to a new PRF key. The only way to do so previously was to have all n users re-enter or reset their passwords. In contrast, the new primitive employed for F_k in PYTHIA supports fast key rotation: the server can erase k, replace it with a new key k', and issue a compact (constant-sized) token with which the client can quickly update all of its PRF outputs. This feature also enables forward-security in the sense that the client can proactively rotate k without disrupting its operation.

PYTHIA provides other features as well, but we defer their discussion to Section 2. Already, those listed above surface some of the challenging cryptographic tensions that PYTHIA resolves. For example, the most obvious primitive on which to base PYTHIA is an oblivious PRF (OPRF) [27], which provides message privacy. But for rate-limiting, PYTHIA requires clients to reveal t, and existing OPRFs cannot hide only a portion of a PRF input. Additionally, the most efficient OPRFs (c.f., [28]) are not amenable to key rotation. We discuss at length other related concepts (of which there are many) in Section 7.

Partially-oblivious PRFs. We introduce *partially oblivious PRFs* (PO-PRFs) to rectify the above tension between fine-grained key management and bulk key management and achieve a primitive that supports batch key rotation. We give a PO-PRF protocol in the random oracle model (ROM) similar to the core of the identity-based non-interactive key exchange protocol of Sakai, Ohgishi, and Kasahara [44]. This same construction was also considered as a left-or-right constrained PRF by Boneh and Waters [13]. That said, the functionality achieved by our PO-PRF is distinct from these prior works and new security analyses are required. Despite relying on pairings, we show that the full primitive is fast even in our prototype implementation.

In addition to a lack of well-matched cryptographic primitives, we find no supporting formal definitions that can be adapted for verifiable PO-PRFs. (Briefly, previous definitions and proofs for fast OPRFs rely on hashing in the ROM before outputting a value [16, 28]; in our setting, hashing breaks key rotation.) We propose a new assumption (a one-more bilinear decisional Diffie-Hellman assumption), give suitable security definitions, and prove the security of the core primitive in PYTHIA under these definitions (in the appendix; complete results in [25]). Our new definitions and technical approaches may be of independent interest.

Using PYTHIA in applications. We implement PYTHIA and show that it offers highly practical performance on Amazon EC2 instances. Our experiments demonstrate that PYTHIA is practical to deploy using off-the-shelf components, with combined computation cost of client and server under 12 milliseconds. A single 8-core virtualized server can comfortably support over 1,000 requests per second, which is already within a factor of two of a standard HTTPS server in the same configuration. (Our PYTHIA implementation performs all communication over TLS.) We discuss scaling to handle more traffic volume in the body; it is straightforward given current techniques.

We demonstrate the benefits and practicality of PYTHIA for use in a diverse set of applications. First is our running example above: we build a new password-database system using a password "onion" that combines parallelized calls to PYTHIA and a conventional key hashing mechanism. Our onion supports PYTHIA key rotation, hides back-end latency to PYTHIA during logins (which is particularly important when accessing PYTHIA as a remote third-party service), and achieves high security in a number of compromise scenarios.

Finally, we show that PYTHIA provides valuable features for different settings apart from enterprise password storage. We implement a client that hardens a type

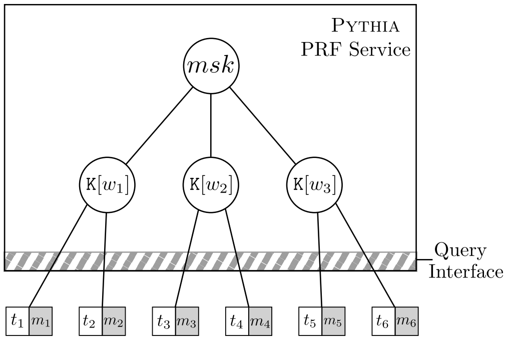

Figure 1: Diagram of PRF derivations enabled by Pythia. Everything inside the large box is operated by the server, which only learns tweaks and not the shaded messages.

of password-protected virtual-currency account called a "brainwallet" [14]; use of Pythia here prevents offline brute-force attacks of the type that have been common in Bitcoin.

Our prototype implementation of Pythia is built with open-source components and itself is open-source. We have also released Amazon EC2 images to allow companies, individuals, and researchers to spin-up Pythia instances for experimentation.

2 Overview and Challenges

We now give a high-level overview of Pythia, the motivations for its features, what prior approaches we investigated, and the threat models we assume. First we fix some terminology and a high-level conceptual view of what a PRF service would ideally provide. The service is provisioned with a master secret key msk. This will be used to build a tree that represents derived sub-keys and, finally, output values. See Figure 1, which depicts an example derivation tree associated with Pythia as well as which portions of the tree are held by the server (within the large box) and which are held by the client (the leaves). Keys of various kinds are denoted by circles and inputs by squares.

From the msk we derive a number of *ensemble keys*. Each ensemble key is used by a client for a set of related PRF invocations — the ensemble keys give rise to isolated PRF instances. We label each ensemble key in the diagram by $\texttt{K}[w]$. Here w indicates a client-chosen *ensemble selector*. An *ensemble pre-key* $\texttt{K}[w]$ is a large random value chosen and held by the server. Together, msk and $\texttt{K}[w]$ are used to derive the ensemble key $k_w = \text{HMAC}(msk, \texttt{K}[w])$. A table is necessary to support cryptographic erasure of (or updates to) individual ensemble keys, which amounts to deleting (or updating) a table entry.

Each ensemble key can be used to obtain PRF outputs of the form $F_{k_w}(t, m)$ where F is a (to-be-defined) PRF keyed by k_w, and the input is split into two parts. We call t a *tweak* following [30] and m the message. Looking ahead t will be made public to Pythia while m will be private. This is indicated by the shading of the PRF output boxes in the figure.

Deployment scenarios. To motivate our design choices and security goals, we relay several envisioned deployment scenarios for Pythia.

Enterprise deployment: A single enterprise can deploy Pythia internally, giving query access only to other systems they control. A typical setup is that Pythia fields queries from web servers and other public-facing systems that are, unfortunately, at high risk of compromise. PRF queries to Pythia harden values stored on these vulnerable servers. This is particularly suited to storing check-values for passwords or other low-entropy authentication tokens, where one can store $F_{k_w}(t, m)$ where t is a randomly chosen, per-user identifier (a salt) and m is the low-entropy password or authentication token. Here w can be distinct for each server using Pythia.

Public cloud service: A public cloud such as Amazon EC2, Google Compute Engine, or Microsoft Azure can deploy Pythia as an internal, multi-tenant service for their customers. Multi-tenant here means that different customers query the same Pythia service, and the cloud provider manages the service, ensemble pre-key table, etc. This enables smaller organizations to obtain the benefits of using Pythia for other cloud properties (e.g., web servers running on virtual machine instances) while leaving management of Pythia itself to experts.

Public Internet service: One can take the public cloud service deployment to the extreme and run Pythia instances that can be used from anywhere on the Internet. This raises additional performance concerns, as one cannot rely on fast intra-datacenter network latencies (sub-millisecond) but rather on wide-area latencies (tens of milliseconds). The benefit is that Pythia could then be used by arbitrary web clients, for example we will explore this scenario in the context of hardening brainwallets via Pythia.

One could tailor a PRF service to each of these settings, however it is better to design a single, application-agnostic service that supports all of these settings simultaneously. A single design permits reuse of open-source implementations; standardized, secure-by-default configurations; and simplifies the landscape of PRF services.

Security and functionality goals. Providing a single suitable design requires balancing a number of security and functionality goals. The most obvious requirements are for a service that: provides low-latency protocols (i.e., single round-trip and amenable for implementation as simple web interfaces); scales to hundreds of millions of ensembles; and produces outputs indistinguishable from random values even when adversaries can query the service. To this list of basic requirements we add:

- *Message privacy*: The PRF service must learn nothing about m. Message privacy supports clients that require sensitive values such as passwords to remain private even if the service is compromised, or to promote psychological acceptability in the case that a separate organization (e.g., a cloud provider) manages the service.
- *Tweak visibility*: The server must learn tweak t to permit fine-grained rate-limiting of requests.[1] In the password storage example, a distinct tweak is assigned to each user account, allowing the service to detect and limit guessing attempts against individual user accounts.
- *Verifiability:* A client must be able to verify that a PRF service has correctly computed F_{k_w} for a ensemble selector w and tweak/message pair t, m. This ensures, after first use of an ensemble by a client, that a subsequently compromised server cannot surreptitiously reply to PRF queries with incorrect values.[2]
- *Client-requested ensemble key rotations:* A client must be permitted to request a rotation of its ensemble pre-key $\mathtt{K}[w]$ to a new one $\widehat{\mathtt{K}[w]}$. The server must be able to provide an update token Δ_w to roll forward PRF outputs under $\mathtt{K}[w]$ to become PRF outputs under $\widehat{\mathtt{K}[w]}$, meaning that the PRF is *key-updatable* with respect to ensemble keys. Additionally, Δ_w must be *compact*, i.e., constant in the number of PRF invocations already performed under w. Clients can mandate that rotation requests be authenticated (to prevent malicious key deletion). A client must additionally be able to *transfer* an ensemble from one selector w to another selector w'.
- *Master secret rotations:* The server must be able to rotate the master secret key msk with minimal impact on clients. Specifically, the PRF must be key-updatable with respect to the master secret key msk so that PRF outputs under msk can be rolled forward to a new master secret $\widehat{msk}$. When such a rotation occurs, the server must provide a compact update token δ_w for each ensemble w.
- *Forward security:* Rotation of an ensemble key or master secret key results in complete erasure of the old key and the update token.

Two sets of challenges arise in designing PYTHIA. The first is cryptographic. It turns out that the combination of requirements above are not satisfied by any existing protocols we could find. Ultimately we realized a new type of cryptographic primitive was needed that proves to be a slight variant of oblivious PRFs and blind signatures. We discuss the new primitive, and our efficient protocol realizing it, in the next section. The second set of challenges surrounds building a full-featured service that provides the core cryptographic protocol, which we treat in Section 4.

3 Partially-oblivious PRFs

We introduce the notion of a (verifiable) partially-oblivious PRF. This is a two-party protocol that allows the secure computation of $F_{k_w}(t, m)$, where F is a PRF with server-held key k_w and t, m are the input values. The client can verify the correctness of $F_{k_w}(t, m)$ relative to a public key associated to k_w. Following our terminology, t is a tweak and m is a message. We say the PRF is partially oblivious because t is revealed to the server, but m is hidden from the server.

Partially oblivious PRFs are closely related to, but distinct from, a number of existing primitives. A standard oblivious PRF [27], or its verifiable version [28], would hide both t and m, but masking both prevents granular rate limiting by the server. Partially blind signatures [1] allow a client to obtain a signature on a similarly partially blinded input, but these signatures are randomized and the analysis is only for unforgeability which is insufficient for security in all of our applications.

We provide more comparisons with related work in Section 7 and a formal definition of the new primitive in Appendix B. Here we will present the protocol that suffices for PYTHIA. It uses an admissible bilinear pairing $e : \mathbb{G}_1 \times \mathbb{G}_2 \to \mathbb{G}_T$ over groups $\mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T$ of prime order q, and a pair of hash functions $H_1 : \{0,1\}^* \to \mathbb{G}_1$ and $H_2 : \{0,1\}^* \to \mathbb{G}_2$ (that we will model as random oracles). More details on pairings are provided in Appendix B. A secret key k_w is an element of $\mathbb{Z}_p$. The PRF F that the protocol computes is:

$$F_{k_w}(t, m) = e\big(H_1(t), H_2(m)\big)^{k_w} .$$

This construction coincides with the Sakai, Ohgishi, and Kasahara [44] construction for non-interactive identity-based key exchange, where t and m would be different identities and k_w a secret held by a trusted key authority. Likewise, this construction is equivalent to the left-or-right constrained PRF of Boneh and Waters [13]. The

[1] In principle, the server need only be able to link requests involving the same t, not learn t. Explicit presentation of t is the simplest mechanism that satisfies this requirement.

[2] This matters, for example, if an attacker compromises the communication channel but not the server's secrets (msk and $\mathtt{K}[w]$). Such an attacker must not be able to convince the client that arbitrary or incorrect values are correct.

```
                                  PRF-Srv ($msk$)
PRF-Cl ($w, t, m$)
$r \leftarrow\!\$\ \mathbb{Z}_q$
$x \leftarrow H_2(m)^r$
                    $\xrightarrow{w, t, x}$
                                  $\tilde{x} \leftarrow e(H_1(t), x)$
                                  $k_w \leftarrow \text{HMAC}(msk, \texttt{K}[w])$
                                  $p_w \leftarrow g^{k_w}$
                                  $y \leftarrow \tilde{x}^{k_w}$
                                  $\pi \leftarrow\!\$\ \text{ZKP}(\text{DL}_g(p_w) = \text{DL}_{\tilde{x}}(y))$
                    $\xleftarrow{p_w, y, \pi}$
If $p_w$ matches &
$\pi$ verifies then
    Ret $y^{1/r}$
Else Ret $\perp$
```

Figure 2: The partially-oblivious PRF protocol used in PYTHIA. The value π is a non-interactive zero-knowledge proof that the indicated discrete logs match. The client also checks that p_w matches ones seen previously when using selector w.

contexts of these prior works are distinct from ours and our analyses will necessarily be different, but we note that all three settings similarly exploit the algebraic structure of the bilinear pairing. See Section 7 for further discussion of related work.

The client-server protocol that computes $F_{k_w}(t, m)$ in a partially-oblivious manner is given in Figure 2. There we let g be a generator of $\mathbb{G}_1$. We now explain how the protocol achieves our requirements described in the last section.

Blinding the message: In our protocol, the client blinds the message m, hiding it from the server, by raising it to a randomly selected exponent $r \leftarrow\!\$\ \mathbb{Z}_q$. As $e\big(H_1(t), H_2(m)^r\big) = e\big(H_1(t), H_2(m)\big)^r$, the client can unblind the output y of PRF-Srv by raising it to $1/r$. This protocol hides m unconditionally, as $H_2(m)^r$ is a uniformly random element of $\mathbb{G}_2$.

Verifiability: The protocol enables a client to verify that the output of PRF-Srv is correct, assuming the client has previously stored p_w. The server accompanies the output y of the PRF with a zero-knowledge proof π of correctness.

Specifically, for a public key $p_w = g^{k_w}$, where g is a generator of $\mathbb{G}_1$, the server proves $\text{DL}_g(p_w) = \text{DL}_{\tilde{x}}(y)$. Standard techniques (see, e.g., Camenisch and Stadler [17]) permit efficient ZK proofs of this kind in the random oracle model. [3] The notable computational costs for the server are one pairing and one exponentiation in $\mathbb{G}_T$; for the client, one pairing and two exponentiations in $\mathbb{G}_T$. [4]

Efficient key updates: The server can quickly and easily update the key k_w for a given ensemble selector w by replacing the table entry $s = \texttt{K}[w]$ with a new, randomly selected value s', thereby changing $k_w = \text{HMAC}(msk, s)$ to $k'_w = \text{HMAC}(msk, s')$. It can then transmit to the client an update token of the form $\Delta_w = k'_w / k_w \in \mathbb{Z}_q$.

The client can update any stored PRF value $F_{k_w}(t, m) = e\big(H_1(t), H_2(m)\big)^{k_w}$ by raising it to Δ_w; it is easy to see that $F_{k_w}(t, m)^{\Delta_w} = F_{k'_w}(t, m)$.

The server can use the same mechanism to update msk, which requires generating a new update token for each w and pushing these tokens to clients as needed.

Unblinded variants. For deployments where obliviousness of messages is unnecessary, we can use a faster, unblinded variant of the PYTHIA protocol that dispenses with pairings. The only changes are that the client sends m to the server, there is no unblinding of the server's response, and, instead of computing

$$\tilde{x} \leftarrow e(H_1(t), x)$$

the server computes

$$\tilde{x} \leftarrow H_3(t \,\|\, m) \ .$$

All group operations in this unblinded variant are over a standard elliptic curve group $\mathbb{G} = \langle g \rangle$ of order q and we use a hash function $H_3 : \ \{0,1\}^* \to \mathbb{G}$.

An alternative unblinded construction would be to have the server apply the Boneh-Lynn-Shacham short signatures [12] to the client-submitted $t \,\|\, m$; verification of correctness can be done using the signature verification routine, and we can thereby avoid ZKPs. This BLS variant may save a small amount of bandwidth.

These unblinded variants provide the same services (verifiability and efficient key updates) and security with the obvious exception of the secrecy of the message m. In some deployment contexts an unblinded protocol may be sufficient, for example when the client can maintain state and submit a salted hash m instead of m directly. In this context, the salt should be held as a secret on the client and never sent to the server.

4 The PYTHIA Service Design

Figure 3 gives the high-level API exposed by PYTHIA to a client. We now describe its functions in terms of the lifecycle of an ensemble key. We assume a security parameter n specifying symmetric key lengths; a typical choice would be $n = 128$.

[3] Some details: The prover picks $v \leftarrow\!\$\ \mathbb{Z}_q$ and then computes $t_1 = g^v$ and $t_2 = \tilde{x}^v$ and $c \leftarrow H_3(g, p_w, \tilde{x}, y, t_1, t_2)$. Let $u = v - c \cdot k$. The proof is $\pi = (c, u)$. The verifier computes $t'_1 = g^u \cdot p_w^c$ and $t'_2 = \tilde{x}^u y^c$. It outputs true if $c = H_3(g, p_w, \tilde{x}, y, t'_1, t'_2)$.

[4] The client's pairing can be pre-computed while waiting for the server's reply.

Command	Description
$\mathsf{Init}(w\ [, options])$	Create table entry $\mathtt{K}[w]$ (for ensemble key k_w)
$\mathsf{Eval}(w, t, m)$	Return PRF output $F_{k_w}(t, m)$
$\mathsf{Reset}(w,\ authtoken)$	Update $\mathtt{K}[w]$ (and thus k_w); return update token Δ_w
$\mathsf{GetAuth}(w)$	Send one-time authentication token $authtoken$ to client

Figure 3: The basic PYTHIA API.

We defer to later sections the underlying client-server protocols and to Appendix A details on key lifecycle management options, additional API calls for token management and ensemble transfer, and a discussion of master secret key rotation.

Ensemble initialization. To begin using the PYTHIA service, a client creates an ensemble key for selector w by invoking $\mathsf{Init}(w\ [, options])$. PYTHIA generates a fresh, random table entry $\mathtt{K}[w]$. Recall that ensemble key $k_w = \text{HMAC}(msk, \mathtt{K}[w])$. So Init creates k_w as a byproduct.

Ideally, w should be an unguessable byte string. (An easily guessed one may allow attackers to squat on a key selector, thereby mounting a denial-of-service (DoS) attack.) For some applications, as we explain below, this isn't always possible. If an ensemble key for w already exists, then the PYTHIA service returns an error to the client. Otherwise, the client receives a message signifying that initialization is successful.

Init includes a number of options we detail in Appendix A.

PRF evaluation. To obtain a PRF value, a client can perform an evaluation query $\mathsf{Eval}(w, t, m)$, which returns $F_{k_w}(t, m)$. Here t is a tweak and m is a message. To compute the PRF output, the client and server perform a one-round cryptographic protocol (meaning a single message from client to server, and one message back). We present details in Section 3, but remind the reader that t is visible to the server in the client-server protocol invoked by Eval, while m is blinded.

The server rate-limits requests based on the tweak t, and can also raise an alert if the rate limit is exceeded. We give example rate limiting policies in Section 5.

Ensemble-key reset. A client can request that an ensemble key k_w be reset by invoking $\mathsf{Reset}(w)$. This reset is accomplished by overwriting $\mathtt{K}[w]$ with a fresh, random value. The name service returns a compact (e.g., 256-bit) update token Δ_w that the client may use to update all PRF outputs for the ensemble. It stores this token locally, encrypted under a public key specified by the client, as explained below.

Note that reset *results in erasure of the old value of* k_w. Thus a client that wishes to delete an ensemble key k_w permanently at the end of its lifecycle can do so with a Reset call.

Reset is an authenticated call, and thus requires the following capability.

Authentication. To authenticate itself for API calls, the client must first invoke GetAuth, which has the server transmit an (encrypted) authentication token $authtoken$ to the client out-of-band. The token expires after a period of time determined by a configuration parameter in PYTHIA. Our current implementation uses e-mail for this, see Appendix A for more details. Of course, in some deployments one may want authentication to be performed in other ways, such as tokens dispensed by administrators (for enterprise settings) or simply given out on a first-come-first-serve basis for each ensemble identifier (for public Internet services).

4.1 Implementation

We implemented a prototype PYTHIA PRF service as a web application accessed over HTTPS. All requests are first handled by an nginx web server with uWsgi as the application server gateway that relays requests to a Django back-end. The PRF-Srv functionality is implemented as a Django module written in Python. Storage for the server's key table and rate-limiting information is done in MongoDB.

We use the Relic cryptographic library [2] (written in C) with our own Python wrapper. We use Barreto-Naehrig 254-bit prime order curves (BN-254) [4]. These curves provide approximately 128-bits of security.

In our experiments the service is run on a single (virtual) machine, but our software stack permits components (web server, application sever, database) to be distributed among multiple machines with updates to configuration files.

For the purpose of comparison, we implemented three variants of the PYTHIA service. The first two are the unblinded protocols described in Section 3. In these two schemes, the client sends m in the clear (possibly hashed with a secret salt value first) and the server replies with $y = H_1(t \,\|\, m)^k$. In the first scheme, denoted UNB, the server provides $p = g_1^k$ and a zero-knowledge proof where g_1 is a generator of $\mathbb{G}_1$. The second scheme, denoted BLS, uses a BLS signature for verification. The server provides $p = g_2^k$ where g_2 is a generator of $\mathbb{G}_2$ and the client verifies the response by computing and comparing the values: $e(y, g_2) = e(H_1(t \,\|\, m), p)$.

Our partially-oblivious scheme is denoted PO.

For the evaluation below we use a Python client implementing PRF-Cl for all three schemes using the same

	Time (µs)		
Group	Group Op	Exp	Hashing
$\mathbb{G}_1$	5.7	175	77
$\mathbb{G}_2$	6.7	572	210
$\mathbb{G}_T$	9.8	1145	–
pairing operation (e) takes 1005 µs			

Figure 4: Time taken by each operation in BN-254 groups. Hashing times are for 64-byte inputs.

libraries indicated above for the server and httplib2 to perform HTTPS requests.

4.2 Performance

For performance and scalability evaluation we hosted our PYTHIA server implementation on Amazon's Elastic Compute Cloud (EC2) using a c4.xlarge instance which provides 8 virtual CPUs (Intel Xeon third generation, 2.9GHz), 15 GB of main memory, and solid state storage. The web server, nginx, was configured with basic settings recommended for production deployment including one worker process per CPU.

Latency. We measured client query latency for each protocol using two clients: one within the same Amazon Web Service (AWS) availability zone (also c4.xlarge) and one hosted at the University of Wisconsin–Madison with an Intel Core i7 CPU (3.4 GHz). We refer to the first as the LAN (local-area network) setting and the second as the WAN (wide-area network) setting. In the LAN settings we used the AWS internal IP address. All queries were made over TLS and measurements include the time required for clients to blind messages and unblind results (PO), as well as verify proofs provided by the server (unless indicated otherwise). All machines used for evaluation were running Ubuntu 14.04.

Microbenchmarks for group operations appear in Figure 4 and Figure 5 shows the timing of individual operations that comprise a single PRF evaluation. All results are mean values computed over 10,000 operations. These values were captured on an EC2 c4.xlarge instance using the Python profiling library line_profiler. The most expensive operations, by a large margin, are exponentiation in $\mathbb{G}_t$ and the pairing operation. By extension, PO sign, prove, and verify operations become expensive.

We measured latencies averaged over 1,000 PRF requests (with 100 warmup requests) for each scheme and the results appear in Figure 6. Computation time dominates in the LAN setting due to the almost negligible network latency. The WAN case with cold connections (no HTTP KeepAlive) pays a performance penalty due to the four round-trips required to set up a new TCP and TLS connection. While even 400 ms latencies are not prohibitive in our applications, straightforward engineering improvements would vastly improve WAN timing: using TLS session resumption, using lower-latency secure protocol like QUIC [43], or even switching to a custom UDP protocol (for an example one for oblivious PRFs, see [5]).

Server Op	Time (ms)		
Table	1.2		
Rate-limit	0.9		
	UNB	BLS	PO
Sign	0.3	0.3	1.5
Prove	0.5	0.3	2.5

Client Op	UNB	BLS	PO
Blind	-	-	0.3
Unblind	-	-	1.2
Verify	0.9	2.0	4.0

Figure 5: Computation time for major operations to perform a PRF evaluation. Table retrieves $K[w]$ from database; Rate-limit updates rate-limiting record in database; and Sign generates the PRF output;

	Latency (ms)					
	LAN			WAN		
Scheme	Cold	Hot	No π	Cold	Hot	No π
UNB	7.0	3.8	2.4	389	82	80
BLS	7.9	4.9	2.4	392	85	80
PO	14.9	11.8	5.2	403	96	84
RTT ping	0.1			82		

Figure 6: Average latency to complete a PRF-Cl with client-server communication over HTTPS. LAN: client and server in the same EC2 availability zone. WAN: server in EC2 US-West (California) and client in Madison, WI. Hot connections made with HTTP KeepAlive enabled; cold connections with KeepAlive disabled. No π: KeepAlive enabled; prove and verify computations are skipped.

Throughput. We used the distributed load testing tool autobench to measure maximum throughput for each scheme. We compare to a static page containing a typical PRF response served over HTTPS as a baseline. We used two clients in the same AWS region as the server. All connections were cold: no TLS session resumption or HTTP KeepAlive. The maximum throughput for a static page is 2,200 connections per second (cps); UNB and BLS 1,400 cps; and PO 1,350 cps. Thus our PYTHIA implementation can handle a large number of clients on a single EC2 instance. If needed, the implementation can be scaled with standard techniques (e.g., a larger number of web servers and application servers on the front-end with a distributed key-value store on the back-end).

Storage. Our implementation stores all ensemble prekey table (K) entries and rate-limiting information in MongoDB. A table entry is two 32 byte values: a SHA-

256 hash of the ensemble selector w and its associated value $\mathtt{K}[w]$. In MongoDB the average storage size is 195 bytes per entry (measured as the average of 100K entries), including database overheads and indexes. This implementation scales easily to 100 M clients with under 20 GB of storage.

To rate-limit queries, our implementation stores tweak values along with a counter and a timestamp (to expire old entries) in MongoDB. Tweak values are also hashed using SHA-256 which ensures entries are of constant length. In our implementation each distinct tweak requires an average of 144 bytes per entry (including overheads and indexes). Note however that rate limiting entries are purged periodically as counts are only required for one rate-limiting period. Our implementation imposes rate-limits at hour granularity. Assuming a maximum throughput of 2,000 requests per second, rate-limiting storage never exceeds 1 GB.

All told, with only 20 GB stored data, PYTHIA can serve over 100 M clients and perform rate-limiting at hour granularity. Thus fielding a database for PYTHIA can be accomplished on commodity hardware.

5 Password Onions

Web servers and other systems frequently store passwords in hashed form. A *password onion* is the result of additionally invoking a PRF service to harden the hash. In currently suggested onions, one sequentially combines local hashing and application of the PRF service.

We now present a service that we have implemented on top of PYTHIA for managing password onions. First, we describe the limitations of contemporary systems as exemplified by a recently disclosed architecture employed by Facebook [39]. Then we show how our password-onion system, which was easily engineered on top of PYTHIA, can address these limitations.

In what follows, we use the term “client” or “web server” to denote the server performing authentication and storing derived values from passwords and “PRF server” to denote the PYTHIA service.

5.1 Facebook password onion

An example of a contemporary system, used by Facebook, is given in Figure 7.[5] Their PRF service applies HMAC using a service-held secret and returns the result. In this architecture, an adversary that compromises the web server and the password hashes it stores must still mount an online attack against the PRF service to compromise accounts. This is a big advance on the hashing-only practices that are commonly used.

```
PW-Onion($pw$)
$h_1 \leftarrow$ MD5($pw$)
$sa \leftarrow_{\$} \{0,1\}^{160}$
$h_2 \leftarrow$ HMAC[SHA-1]($h_1, sa$)
$h_3 \leftarrow$ PRF-Cl($h_2$) = HMAC[SHA-256]($h_2, msk$)
$h_4 \leftarrow$ scrypt($h_3, sa$)
$h_5 \leftarrow$ HMAC[SHA-256]($h_4$)
Ret ($sa, h_5$)
```

Figure 7: The Facebook password onion. PRF-Cl(h_2) invokes the Facebook PRF service HMAC[SHA-256](h_2, K_s) with PRF-service secret key K_s.

The Facebook architecture nevertheless has some shortcomings. It is easy to see from Figure 7 that Facebook’s system, like most contemporary PRF services, lacks several important features present in PYTHIA. One is message privacy: the Facebook PRF service applies HMAC to h_2. This is the salted hash of the password, and so learning the salt as well as compromising the PRF service suffices to re-enable offline brute-force attacks. This threat is avoided by PYTHIA due to blinding.

Another feature is batch key updates. In fact, the Facebook PRF service doesn’t permit autonomous key updates at all, in the sense of an update to msk that can be propagated into PRF output updates. Should the client (password database) be compromised, the only way to reconstitute a hash in an existing password onion is to *wait until a user logs in and furnishes* pw. It is not clear whether the Facebook PRF service performs granular rate-limiting, although no such capability is indicated in [38]. PYTHIA, as we shall see, addresses all of these issues by design in our password onion system.

The Facebook onion also presents a subtle performance issue. By applying cryptographic primitives serially, the time to hash a password equals the time for local computations, call it t_{local}, *plus* the time for the round-trip PRF service call, call it t_{prf}. An attacker that compromises the web service and PRF service incurs no network latency, and thus may gain a considerable advantage in guessing time over an honest web server. In our PYTHIA-based password onion service, we address this issue by observing that it is possible to avoid serialization of key derivation functions on the web server and the PRF service call. That is, we introduce in our PYTHIA-based service the idea of *parallelizable password onions.*

[5] This figure is of “archaeological” interest. It appears that vulnerabilities in MD5 led to the addition of a layer of processing under SHA-1; when vulnerabilities were found in SHA-1, Facebook then added layers of SHA-256. As we explain later, full-blown replacement of MD5 and SHA-1 with SHA-256 was not easily accomplished.

```
UpParOnion$(w, sa, pw)$
$z \leftarrow$ PBKDF$(pw, sa)$
$u \leftarrow$ PRF-Cl$(w, sa, pw)$
$h \leftarrow u^z$
Ret $(h, sa)$
```

Figure 8: An updatable, parallelizable password onion. PRF-Cl returns elements of a group $\mathbb{G}$. The value w is a unique PRF-service identifier for the web server (e.g., a random 256-bit string) and sa is a random per-user salt value.

5.2 PYTHIA password onion

The onion algorithm we construct for PYTHIA is shown in Figure 8. For PYTHIA, the output of PRF-Cl is an element of a group $\mathbb{G}_T$. To use this service, a web server stores (h, sa) upon password registration; it verifies a proffered password pw' by checking that UpParOnion$(w, sa, pw') = h$. Written out we have that:

$$h = u^z = e(H_1(sa), H_2(pw))^{k_w z}.$$

This design ensures that the key update functions in the PYTHIA API may be used to update onions as well. For example, to update an ensemble key k_w to k'_w, the service computes and furnishes to the web server an update token $\Delta_w = k'_w/k_w$. The web server may compute h^{Δ_w} for each stored value h.

Parallelization. Password verification here is *parallelizable* in the sense that z and u may be computed independently and then combined. Such parallel implementation of the onion achieves a password verification latency of $\max\{t_{local}, t_{prf}\}$ (plus a single exponentiation), as opposed to $t_{local} + t_{prf}$ in a serialized implementation.

A web server generally aims to achieve a verification latency equal to some latency target T that is high enough to slow offline brute-force attacks, but low enough not to burden users. For a parallelized onion a web server can meet its latency target by setting $t_{local}, t_{prf} \approx T$. At the same time an offline attacker that has compromised the web server and PYTHIA must perform about $t_{local}+t_F > T$ work to check a single password guess, where t_F is the computation time of F_{k_w} (i.e., t_{prf} minus network latency). An attacker can parallelize, but her total work still goes up relative to the serial onion approach for the same latency target T.

We estimate the security improvement of parallel onions over serial onions using our benchmarks from Section 4.2. We fix a login latency budget of $T = 300$ ms.[6] The latency costs for a PYTHIA query with hot connections are 12 ms (LAN) and 96 ms (WAN). If one performs computations serially with a fixed T then PBKDF computations need to be reduced by 4% (LAN) and 32% (WAN) compared to the parallel approach. In the event that the PYTHIA server and password database are compromised, the serial onion enables speedup of offline dictionary attacks by the same percentages.

Rate limiting and logging. The transparency of tweaks enables the PYTHIA PRF service in this setting to execute any of a wide range of rate-limiting policies with per-account visibility (in contrast to what may be in Facebook an account-blind PRF service). As an example demonstrating the flexibility of our architecture, in our implementation PYTHIA performs a tiered rate-limiting: for a given account (t), it limits queries to at most 10 per hour per account, and at most 300 per month. (In expectation, guessing a random 4-digit PIN would require 1.4 years under this policy.) It logs violations of these thresholds. In a production environment, it could also send alerts to security administrators.

We emphasize that a wide range of other rate-limiting policies is possible. We also point out that PYTHIA's rate limiting supplements that normally implemented at the web server for remote login requests. PYTHIA performs rate limiting and may issue alerts even if the web server is compromised.

Key update. The key update calls in the PYTHIA API, and the ability to rotate either k_w or msk efficiently, propagates up to the password onion service. Key updates instantly invalidate the web server's existing password database—a useful capability in case of compromise. A compromised database becomes useless to an attacker attempting to recover passwords, even with the ability to query PYTHIA. Using a key update token, the web server can then recover from compromise by refreshing its database.

We created a client simulator with MongoDB and the mongoengine Python module. With this we benchmarked key updates with 100,000 database entries. The client requested a key update from PYTHIA, received the update token Δ_w, and updated each database entry. The complete update required less than 1 ms per entry, and terminated in less than 97 seconds for all 100,000 entries. For a larger database we assume updates scale linearly, and so an update for 1 million users completes in under 17 minutes.

The web server need not need lock the database to perform updates; it can execute them in parallel with normal login operations. Doing so does require additional versioning information for each entry to indicate the version of k_w (in the simplest form, whether or not it has received the latest update).

[6] This is the default setting for Python's bcrypt and scrypt modules, though all PBDKFs are tunable so one can choose T to be any value desired.

6 Hardened Brainwallets

Brainwallets are a common but dangerous way to secure accounts in the popular cryptocurrency Bitcoin, as well as in less popular cryptocurrencies such as Litecoin. Here we describe how the PYTHIA service can be used directly as a means to harden brainwallets. This application showcases the ease with which a wide variety of applications can be engineered around PYTHIA.

How brainwallets work. Every Bitcoin account has an associated private / public key pair (sk, pk). The private key sk is used to produce digital (ECDSA) signatures that authorize payments from the account. The public key pk permits verification of these signatures. It also acts as an account identifier; a Bitcoin address is derived by hashing pk (under SHA-256 and RIPEMD-160) and encoding it (in base 58, with a check value).

Knowledge of the private key sk equates with control of the account. If a user loses a private key, she therefore loses control over her account. For example, if a high entropy key sk is stored exclusively on a device such as a mobile phone or laptop, and the device is seized or physically destroyed, the account assets become irrecoverable.

Brainwallets offer an attractive remedy for such physical risks of key loss. A brainwallet is simply a password or passphrase P memorized by a Bitcoin account holder. The private key sk is generated directly from P. Thus the user's memory serves as the only instrument needed to authorize access to the account.

In more detail, the passphrase is typically hashed using SHA-256 to obtain a 256-bit string $sk =$ SHA-256(P). Bitcoin employs ECDSA signatures on the `secp256k1` elliptic curve; with high probability ($\approx 1 - 2^{-126}$), sk is less than the group order, and a valid ECDSA private key. (Some websites employ stronger key derivation functions. For example, WrapWallet by keybase.io [29] derives sk from an XOR of each of PBKDF2 and scrypt applied to P and permits use of a user-supplied salt.)

Since a brainwallet employs only P as a secret, and does not necessarily use any additional security measures, an attacker that guesses P can seize control of a user's account. As account addresses are posted publicly in the Bitcoin system (in the "blockchain"), an attacker can easily confirm a correct guess. Brainwallets are thus vulnerable to brute-force, offline guessing attacks. Numerous incidents have come to light showing that brainwallet cracking is pandemic [14].[7]

6.1 A PYTHIA-hardened brainwallet

PYTHIA offers a simple, powerful means of protecting brainwallets against offline attack. Hardening P in the same manner as an ordinary password yields a strong key $\tilde{P}$ that can serve in lieu of P to derive sk.

To use PYTHIA, a user chooses a unique identifier id, e.g., her e-mail address, an account identifier $acct$, and a passphrase P. The identifier $acct$ might be used to distinguish among Bitcoin accounts for users who wish to use the same password for multiple wallets. The client then sends $(w = id, t = id \,\|\, acct, m = P)$ to the PYTHIA service to obtain the hardened value $F_{k_w}(t, m) = \tilde{P}$. Here, id is used both as an account identifier and as part of the salt. Message privacy in PYTHIA ensures that the service learns nothing about P. Then $\tilde{P}$ is hashed with SHA-256 to yield sk. The corresponding public key pk and address are generated in the standard way from sk [7].

PYTHIA forces a would-be brainwallet attacker to mount an online attack to compromise an account. Not only is an online attack much slower, but it may be rate-limited by PYTHIA and detected and flagged. As the PYTHIA service derives $\tilde{P}$ using a user-specific key, it additionally prevents an attacker from mounting a dictionary attack against multiple accounts. While in the conventional brainwallet setting, two users who make use of the same secret P will end up controlling the same account, PYTHIA ensures that the same password P produces distinct per-user key pairs.

Should an attacker compromise the PYTHIA service and steal msk and K, the attacker must still perform an offline brute-force attack against the user's brainwallet. So in the worst case, a user obtains security with PYTHIA at least as good as without it.

Additional security issues. A few subtle security issues deserve brief discussion:

- *Stronger KDFs:* To protect against brute-force attack in the event of PYTHIA compromise, a resource-intensive key-derivation function may be desirable, as is normally used in password databases. This can be achieved by replacing the SHA-256 hash of $\tilde{P}$ above with an appropriate KDF computation, or alternatively using an onion approach described in Section 5.
- *Denial-of-service:* By performing rate-limiting, PYTHIA creates the risk of targeted denial-of-service attacks against Bitcoin users. As Bitcoin is pseudonymous, use of an e-mail address as a PYTHIA key-selector suffices to prevent such attacks against users based on their Bitcoin addresses alone. Users also have the option, of course, of using a semi-secret id. A general DoS attack against

[7] At one point, rumor had it that cracking brainwallets was more profitable than "mining,", the basic process of generating fresh Bitcoins.

the PYTHIA service is also possible, but of similar concern for Bitcoin itself [8].

- *Key rotation:* Rotation of an ensemble key k_w (or the master key msk) induces a new value of $\tilde{P}$ and thus a new (sk, pk) pair and account. A client can handle such rotations in the naïve way: transfer funds from the old address to the new one.
- *Catastrophic failure of* PYTHIA*:* If a PYTHIA service fails catastrophically, e.g., msk or $\mathtt{K}$ is lost, then in a typical setting, it is possible simply to reset users' passwords. In the brainwallet case, the result would be loss of virtual-currency assets protected by the server—a familiar event for Bitcoin users [35]. This problem can be avoided, for instance, using a threshold implementation of PYTHIA, as mentioned in Section 6.2 or storing sk in a secure, offline manner like a safe-deposit box for disaster recovery.

6.2 Threshold Security

In order to gain both redundancy and security, we give a threshold scheme that can be used with a number of Pythia servers to protect a secret under a single password. This scheme uses Shamir's secret sharing threshold scheme [45] and gives (k, n) threshold security. That is, initially, n Pythia servers are contacted and used to protect a secret s, and then any k servers can be used to recover s and any adversary that has compromised fewer than k Pythia servers learns no information about s.

Preparation. The client chooses an ensemble key selector w, tweak t, password P, and contacts n Pythia servers to compute $q_i = \text{PRF-Cl}_i(w, t, P) \mod p$ for $0 < i \leq n$. The client selects a random polynomial of degree $k - 1$ with coefficients from $\mathbb{Z}_p^*$ where p is a suitably large prime: $f(x) = \sum_{j=0}^{k-1} x^j a_j$. Let the secret $s = a_0$. Next the client computes the vector $\Phi = (\phi_1, ..., \phi_n)$ where $\phi_i = f(i) - q_i$. The client durably stores the value Φ, but does not need to protect it (it's not secret). The client also stores public keys p_i from each Pythia server to validate proofs when issuing future queries.

Recovery. The client can reconstruct s if she has Φ by querying any k Pythia servers giving k values q_i. These q_i values can be applied to the corresponding Φ values to retrieve k distinct points that lie on the curve $f(x)$. With k points on a degree $k - 1$ curve, the client can use interpolation to recover the unique polynomial $f(x)$, which includes the curve's intercept $a_0 = s$.

Security. If an adversary is given Φ, w, t, the public keys p_i, a ciphertext based on s, and the secrets from $m < k$ Pythia servers, the adversary has no information that will permit her to verify password guesses offline. Compared to [45], this scheme reduces the problem of storing n secrets to having access to n secure OPRFs and durable (but non-secret) storage of the values Φ and public keys p_i.

Verification. Verification of server responses occurs within the Pythia protocol. If a server is detected to be dishonest (or goes out of service), it can be easily replaced by the client without changing the secret s. To replace a Pythia server that is suspected to be compromised or detected as dishonest, the client reconstructs the secret s using any k servers, executes Reset operations on all remaining servers: this effects a cryptographic erasure on the values Φ and $f(x)$. The client then selects a new, random polynomial, keeping a_0 fixed, and generates and stores an updated Φ' that maps to the new polynomial.

7 Related Work

We investigated a number of designs based on existing cryptographic primitives in the course of our work, though as mentioned none satisfied all of our design goals. Conventional PRFs built from block ciphers or hash functions fail to offer message privacy or key rotation. Consider instead the construction $H(t \,\|\, m)^{k_w}$ for $H : \{0,1\}^* \to \mathbb{G}$ a cryptographic hash function mapping onto a group $\mathbb{G}$. This was shown secure as a conventional PRF by Naor, Pinkas, and Reingold assuming decisional Diffie-Hellman (DDH) is hard in $\mathbb{G}$ and when modeling H as a random oracle [40]. It supports key rotations (in fact it is key-homomorphic [11]) and verifiability can be handled using non-interactive zero-knowledge proofs (ZKP) as in PYTHIA. But this approach fails to provide message privacy if we submit both t and m to the server and have it compute the full hash.

One can achieve message-hiding by using blinding: have the client submit $X = H(t \,\|\, m)^r$ for random $r \in \mathbb{Z}_{|\mathbb{G}|}$ and the server reply with X^{k_w} as well as a ZKP proving this was done correctly. The resulting scheme is originally due to Chaum and Pedersen [19], and suggested for use by Ford and Kaliski [26] in the context of threshold password-authenticated secret sharing (see also [3, 15, 20, 34]). There an end user interacts with one or more blind signature servers to derive a secret authentication token. If $\mathbb{G}$ comes equipped with a bilinear pairing, one can dispense with ZKPs. The resulting scheme is Boldyreva's blinded version [10] of BLS signatures [12]. However, neither approach provides granular rate limiting when blinding is used: the tweak t is hidden from the server. Even if the client sends t as well, the server cannot verify that it matches the one used to compute X and attackers can thereby bypass rate limits.

To fix this, one might use Ford-Kaliski with a separate secret key for each tweak. This would result in having a different key for each unique w, t pair. Message privacy is maintained by the blinding, and querying $w, t, H(t' \| m)^r$ for $t \neq t'$ does not help an attacker circumvent per-tweak rate limiting. But now the server-side storage grows in the number of unique w, t pairs, a client using a single ensemble w must now track N public keys when they use the service for N different tweaks, and key rotation requires N interactions with the PRF server to get N separate update tokens (one per unique tweak for which a PRF output is stored). When N is large and the number of ensembles w is small as in our password storage application, these inefficiencies add significant overheads.

Another issue with the above suggestions is that their security was only previously analyzed in the context of one-more unforgeability [42] as targeted by blind signatures [18] and partially blind signatures [1]. (Some were analyzed as conventional PRFs, but that is in a model where adversaries do not get access to a blinded server oracle.) The password onion application requires more than unforgeability because message privacy is needed. (A signature could be unforgeable but include the entire message in its signature, and this would obviate the benefits of a PRF service for most applications.) These schemes, however, can be proven to be one-more PRFs, the notion we introduce, under suitable one-more DDH style assumptions using the same proof techniques found in Appendix B.

Fully oblivious PRFs [27] and their verifiable versions [28] also do not allow granular rate limiting. We note that the Jarecki, Kiayias, and Krawczyk constructions of verifiable OPRFs [28] in the RO model are essentially the Ford-Kaliski protocol above, but with an extra hash computation, making the PRF output $H'(t \| m \| H(t \| m)^{k_w})$. Our notion of one-more unpredictability in the appendix captures the necessary requirements on the inner cryptographic component, and might modularize and simplify their proofs. Their transform is similar to the unique blind signature to OPRF transformation of Camenisch, Neven, and shelat [16]. None of these efficient oblivious PRF protocols support key rotations (with compact tokens or otherwise) as the final hashing step destroys updatability.

The setting of capture-resilient devices shares with ours the use of an off-system key-holding server and the desire to perform cryptographic erasure [32, 33]. They only perform protocols for encryption and signing functionalities, however, and not (more broadly useful) PRFs. They also do not support granular rate limiting and master secret key rotation.

Our main construction coincides with prior ones for other contexts. The Sakai, Ohgishi, and Kasahara [44] identity-based non-interactive key exchange protocol computes a symmetric encryption key as $e(H_1(ID_1), H_2(ID_2))^k$ for k a master secret held by a trusted party and ID_1 and ID_2 being the identities of the parties. See [41] for a formal analysis of their scheme. Boneh and Waters suggest the same construction as a left-or-right constrained PRF [13]. The settings and their goals are different from ours, and in particular one cannot use either as-is for our applications. Naïvely one might hope that returning the constrained PRF key $H_1(t)^{k_w}$ to the client suffices for our applications, but in fact this totally breaks rate-limiting. Security analysis of our protocol requires new techniques, and in particular security must be shown to hold when the adversary has access to a half-blinded oracle — this rules out the techniques used in [13, 41].

Key-updatable encryption [11] and proxy re-encryption [9] both support key rotation, and could be used to encrypt password hashes in a way supporting compact update tokens and that prevents offline brute-force attacks. But this would require encryption and decryption to be handled by the hardening service, preventing message privacy.

Verifiable PRFs as defined by [21, 22, 31, 36] allow one to verify that a known PRF output is correct relative to a public key. Previous verifiable PRF constructions are not oblivious, let alone partially oblivious.

Threshold and distributed PRFs [21, 37, 40] as well as distributed key distribution centers [40] enable a sufficiently large subset of servers to compute a PRF output, but previous constructions do not provide the granular rate limiting and key rotation we desire. However, it is clear that there are situations where applications would benefit from a threshold implementation of PYTHIA, for both redundancy and distribution of trust, as discussed in Section 6.2 for the case of brainwallets.

8 Conclusion

We presented the design and implementation of PYTHIA, a modern PRF service. Prior works have explored the use of remote cryptographic services to harden keys derived from passwords or otherwise improve resilience to compromise. PYTHIA, however, transcends existing designs to simultaneously support granular rate limiting, efficient key rotation, and cryptographic erasure. This set of features, which stems from practical requirements in applications such as enterprise password storage, proves to require a new cryptographic primitive that we refer to as a partially oblivious PRF.

Unlike a (fully) oblivious PRF, a partially oblivious PRF causes one portion of an input to be revealed to the server to enable rate limiting and detection of online brute-force attacks. We provided a bilinear-pairing based construction for partially oblivious PRFs that is highly efficient and simple to implement (given a pairings library), and also supports efficient key rotations. A formal proof of security is unobtainable using existing techniques (such as those developed for fully oblivious PRFs). We thus gave new definitions and proof techniques that may be of independent interest.

We implemented PYTHIA and show how it may be easily integrated it into a range of applications. We designed a new enterprise "password onion" system that improves upon the one recently reported in use at Facebook. Our system permits fast key rotations, enabling practical reactive and proactive key management, and uses a parallelizable onion design which, for a given authentication latency, imposes more computational effort on attackers after a compromise. We also explored the use of PYTHIA to harden brainwallets for cryptocurrencies.

A Additional PYTHIA API details

Many PYTHIA-dependent services can benefit from additional API features and calls beyond the primary ones discussed in the body of the paper. (For example, the PYTHIA password onion system in Section 5 uses the Transfer API call.) We detail these other API features in this appendix.

Key-management options. The client can specify a number of options in the call Init regarding management of the ensemble key k_w. The client can provide a contact email address to which alerts and authentication tokens may be sent. (If no e-mail is given, no API calls requiring authentication are permitted at present and no alerts are provided. Later versions of PYTHIA will support other authentication and alerting methods.)

Selector option	Description
Email	Contact email for selector
Resettable	Whether client-requested rotations allowed
Limit	Establish rate-limit per t
Time-out	Date/time to delete k_w
Public-key	Key under which to encrypt and store update and authentication tokens
Alerts	Whether to email contact upon rate limit violation

Figure 9: Optional settings for establishing key selectors in PYTHIA.

Command	Description
$\mathsf{Transfer}(w, w' \, [, options])$	Creates new ensemble w'; outputs update token $\Delta_{w \to w'}$; resets k_w
$\mathsf{SendTokens}(w, authtoken)$	Sends stored update tokens to client
$\mathsf{PurgeTokens}(w, authtoken)$	Purges all stored update tokens for ensemble w

Figure 10: The PYTHIA API. The individual calls are explained in detail in the text.

The client can specify whether k_w should be resettable (default is "yes"). The client can specify a limit on the total number of F_{k_w} queries that should be allowed before resetting $\mathtt{K}[w]$ (default is unlimited) and/or an absolute expiration date and time in UTC at which point $\mathtt{K}[w]$ is deleted (default is no time-out). Either of these options overrides the resettable flag. The client can specify a public key pk_{cl} for a public-key encryption scheme under which to encrypt authentication tokens and update tokens (for Reset, Transfer, as described below, and for master secret key rotations). Finally, the client can request that alerts be sent to the contact email address in the case of rate limit violations. This option is ignored if no contact email is provided. The options are summarized in Figure 9.

PYTHIA also offers some additional API calls, given in Figure 10, which we now describe.

Ensemble transfer. A client can create a new ensemble w' (with the same options as in Init) while receiving an update token that allows PRF outputs under ensemble w to be rolled forward to w'. This is useful for importing a password database to a new server. The PYTHIA service returns an update token $\Delta_{w \to w'}$ for this purpose and stores it encrypted under pk_{cl}. For the case $w' = w$, this call also allows option updates on an existing ensemble w.

Update-token handling. The PYTHIA service stores update tokens encrypted under pk_{cl}, with accompanying timestamps for versioning. The API call SendTokens causes these to be e-mailed to the client, while PurgeTokens causes update-token ciphertexts to be deleted from PYTHIA.

Note that once an update token is deleted, old PRF values to which the token was not applied become cryptographically erased — they become random values unrelated to any messages. A client can therefore delete the key associated with an ensemble by calling Reset and PurgeTokens.

Master secret rotations. PYTHIA can also rotate its master secret key msk to a new key msk'. Recall that ensemble keys are computed as $k_w = \text{HMAC}(msk, \mathrm{K}[w])$, so rotation of msk results in rotation of all ensemble keys. To rotate to a new msk', the server computes k_w for all ensembles w with entries in K, and stores δ_w encrypted under pk_{cl}. If no encryption key is set, then the token is stored in the clear. This is a forward-security issue while it remains, but only for that particular key ensemble. At this point msk is safe to delete. Clients can be informed of the key rotation via e-mail.

Subsequent SendTokens requests will return the resulting update token, along with any other stored update tokens for the ensemble. If multiple rotations occur between client requests, then these can be aggregated in the stored update token for each ensemble. This is trivial if they are stored in the clear (just multiply the new token against the old) and also works if they are encrypted with an appropriately homomorphic encryption scheme such as ElGamal [24].

B Formal Security Analyses

We provide formal security notions for partially oblivious PRFs, and proofs of security relative to them for our scheme from Section 3.

Partially-oblivious PRFs. A partially oblivious PRF protocol $\Pi = (\mathcal{K}, \text{PRF-Cl}, \text{PRF-Srv}, F)$ consists of the following. The key generation algorithm $\mathcal{K}$ outputs a public key and private key pair (pk, sk). We assume that from sk one can compute pk easily. The PRF-Srv algorithm takes input the secret key sk and a client request message (a bit string) and returns a server response message (another bit string). The client algorithm PRF-Cl takes inputs a tweak t and message m, can make a single call to PRF-Srv, and outputs a value. Finally we associate to the protocol a keyed function $F_{sk}:\ \{0,1\}^* \times \{0,1\}^* \to \{0,1\}^*$. A scheme is correct if executing $\text{PRF-Cl}^{\text{PRF-Srv}_{sk}(\cdot)}(t,m)$ with fresh coins matches $F_{sk}(t,m)$ with probability one. In words, the protocol computes the appropriate function of t, m.

Bilinear pairing setups. Let $\mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T$ be groups all of order p that have associated to them an admissible bilinear pairing $e\colon\ \mathbb{G}_1 \times \mathbb{G}_2 \to \mathbb{G}_T$. Recall that for generators $g_1 \in \mathbb{G}_1$, $g_2 \in \mathbb{G}_2$, there exists a generator $g_T \in \mathbb{G}_T$ such that $e(g_1^\alpha, g_2^\beta) = g_T^{\alpha\beta}$ for all $\alpha, \beta \in \mathbb{Z}_p$. As shorthand for below we refer to a pairing setup $\mathbb{G} = (g_1, g_2, g_T, \mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, e)$ and assume some compact description of $\mathbb{G}$ as a bit-string where appropriate.

The scheme. The partially-oblivious PRF at the core[8] of our bilinear pairing scheme from Section 3 is as follows for some fixed pairing setup $\mathbb{G}$. Let $H_1:\ \{0,1\}^* \to \mathbb{G}_1$ and $H_2:\ \{0,1\}^* \to \mathbb{G}_2$ be hash functions that we will later model as random oracles.

Key generation $\mathcal{K}$ picks a random exponent sk and computes a public key $pk = g_1^sk$. The PRF-Cl(t,m) algorithm computes a mask $r \leftarrow\!\!\$\ \mathbb{Z}_p$ and sends t and $x = H_2(m)^r$ to the server. The PRF-Srv(sk,t,x) computes $y = e(H_1(t), x)^sk$ and a ZKP π that $\text{DL}_{g_1}(pk) = \text{DL}_{\tilde{x}}(y)$ where $\tilde{x} = e(H_1(t), x)$. It sends pk, y, π to the client, who verifies the ZKP, deletes it, and then outputs $y^{1/r}$. The correctness of the scheme follows from the correctness of the ZKP and the properties of the pairing.

The ZKP is used to ensure that a malicious server responds as per the protocol. In the following security analyses we focus primarily on malicious clients, and for simplicity analyze a simpler version of the protocol that omits the ZKP. The proofs found below can be extended to the full protocol by applying the zero-knowledge security of the proof systems that we use (i.e., use the zero-knowledge simulator to produce fake, but realistic-looking to the client, proofs).

B.1 Unpredictability Security

We define a one-more unpredictability security notion. It modifies one-more unforgeability [42] to be suitable for the setting of unpredictable functions (as opposed to publicly verifiable signatures). The game is shown in Figure 11. We associate to any protocol Π, adversary $\mathcal{A}$, and query number q the one-more-unpredictability advantage defined as

$$\mathbf{Adv}^{\text{om-unp}}_{\Pi,q}(\mathcal{A}) = \Pr\left[\,\text{om-UNP}^{\mathcal{A}}_{\Pi,q} \Rightarrow \mathsf{true}\,\right]\,.$$

The probability here (and for games defined later below) is over all random coins used by the procedures and the adversary. The event refers to the probability that the value returned by the main procedure is true. In words, the definition requires that an adversary cannot produce ℓ outputs of the PRF using less than ℓ queries on partially-blinded inputs to the server. One can easily extend this notion to deal with full blinded inputs as well, but we will not need this.

[8] For brevity we omit key selectors here, and instead focus on analyzing security for a single key instance. Assuming properly generated keys for each selector, one can show that security for a single key instance implies security for many.

```
Game om-UNP$_\Pi^\mathcal{A}$
$(pk, sk) \leftarrow\!\!\$\; \mathcal{K}$
$c \leftarrow 0$
$(t_1, m_1, \sigma_1), \ldots, (t_\ell, m_\ell, \sigma_\ell) \leftarrow\!\!\$\; \mathcal{A}^{\text{PRF-Srv}, H_1, H_2}$
If $\exists i \neq j \;.\; (t_i, m_i) = (t_j, m_j)$ then Ret false
Ret $(\wedge_i(\sigma_i = F_{sk}^{H_1,H_2}(t_i, m_i)) \wedge c < \ell)$

PRF-Srv$(t, Y)$
$c \leftarrow c + 1$
Ret PRF-Srv$_{sk}^{H_1,H_2}(t, Y)$
```

Figure 11: Security game for one-more unpredictability.

This notion of security is sufficient for PYTHIA in applications where the output of the protocol is not stored, but rather used as an unforgeable credential such as with our hardened Brainwallet application (Section 6).

The security of our scheme is based on the following one-more bilinear computational Diffie-Hellman (BCDH) problem, an extension of the one-more CDH assumption given by Boldyreva [10]. To the best of our knowledge this assumption is new, but it is a straightforward adaptation of previous one-more assumptions [6, 10] to our setting. For a pairing setup $\mathbb{G}$, game om-BCDH$_\mathbb{G}$ is defined in Figure 12. In words, the adversary gets a group element $g_1^sk \in \mathbb{G}_1$ as well as target oracles Targ$_1$, Targ$_2$ that return random group elements in $\mathbb{G}_1, \mathbb{G}_2$ respectively. Finally the adversary can query a helper oracle Help that raises $\mathbb{G}_T$ elements to the k. To win, it must compute ℓ values $e(X_i, Y_j)^k$ for ℓ larger than the number of helper queries and each X_i, Y_j a unique pair of (distinct) values returned by the target oracle. Let $\mathbf{Adv}_\mathbb{G}^{\text{om-cdh}}(\mathcal{B}) = \Pr\left[\text{om-BCDH}_\mathbb{G}^\mathcal{B} \Rightarrow \text{true}\right]$.

We have the following theorem establishing the one-more unpredictability of our scheme The proof is essentially identical to the proof of Boldyreva's blind signatures [10].

Theorem 1 *Let Π be the simplified partially oblivious PRF protocol for a pairing setup $\mathbb{G}$ and H_1, H_2 modeled as random oracles. Then for any one-more unpredictability adversary $\mathcal{A}$ making at most q* PRF-Srv *queries, we give in the proof below a one-more CDH adversary $\mathcal{B}$ such that*

$$\mathbf{Adv}_\Pi^{\text{om-unp}}(\mathcal{A}) \leq \mathbf{Adv}_\mathbb{G}^{\text{om-cdh}}(\mathcal{B})$$

where $\mathcal{B}$ runs in time that of $\mathcal{A}$ plus $\mathcal{O}(q)$ group operations.

Proof: We assume without loss of generality that $\mathcal{A}$ never repeats a query to either random oracle and makes a random oracle $H_1(t_i)$ and $H_2(m_i)$ query for each (t_i, m_i, σ_i) triple it outputs. The adversary $\mathcal{B}$ will work as follows when given inputs $\mathbb{G}, X$ and access to oracles Targ$_1$, Targ$_2$, Help. First, it runs $\mathcal{A}$. Whenever $\mathcal{A}$ makes an $H_1(t)$ query, $\mathcal{B}$ queries Targ$_1$ to obtain a $\mathbb{G}_1$-element that we will denote $X[t]$, sets c_t to be the number of H_1 queries so far (including the current), and returns $X[t]$ to $\mathcal{A}$. Whenever $\mathcal{A}$ makes an $H_2(m)$ server query, $\mathcal{B}$ queries Targ$_2$, obtains a $\mathbb{G}_2$-element that we will denote $Y[m]$, sets d_m to be the number of H_2 queries so far (including the current), and returns $Y[m]$ to $\mathcal{A}$. Whenever $\mathcal{A}$ makes a PRF-Srv(t, Y) query, the adversary $\mathcal{B}$ computes $Z \leftarrow e(H_1(t), Y)$, and then queries Z to its helper oracle Help to obtain a value $\sigma \in \mathbb{G}_T$. It returns σ to $\mathcal{A}$.

```
Game om-BCDH$_\mathbb{G}^\mathcal{B}$
$sk \leftarrow\!\!\$\; \mathbb{Z}_p$
$q_h, q_{1,t}, q_{2,t} \leftarrow 0$
$(i_1, j_1, \sigma_1), \ldots, (i_\ell, j_\ell, \sigma_\ell) \leftarrow\!\!\$\; \mathcal{A}^{\text{Targ}_1, \text{Targ}_2, \text{Help}}(\mathbb{G}, g_1^sk)$
If $q_h \geq \ell$ then Ret false
If $\exists \alpha \;.\; (i_\alpha > q_{1,t}) \vee (j_\alpha > q_{2,t})$ then Ret false
If $\exists \alpha \neq \beta \;.\; (i_\alpha, j_\alpha) = (i_\beta, j_\beta)$ then Ret false
Ret $\forall \alpha \;.\; e(X_{i_\alpha}, Y_{j_\alpha})^k = \sigma_\alpha$

Targ$_1$
$q_{1,t} \leftarrow q_{1,t} + 1$ ; $X_{q_{1,t}} \leftarrow\!\!\$\; \mathbb{G}_1$ ; Ret $X_{q_{1,t}}$

Targ$_2$
$q_{2,t} \leftarrow q_{2,t} + 1$ ; $Y_{q_{2,t}} \leftarrow\!\!\$\; \mathbb{G}_2$ ; Ret $Y_{q_{2,t}}$

Help$(Z)$
$q_h \leftarrow q_h + 1$ ; Ret $Z^{sk}$
```

Figure 12: Security game for a one-more BCDH assumption for bilinear pairing setting $\mathbb{G} = (g_1, g_2, g_t, \mathbb{G}_1, \mathbb{G}_2, \mathbb{G}_T, e)$.

Eventually $\mathcal{A}$ outputs a series of triples $(t_1, m_1, \sigma_1), \ldots, (t_q, m_q, \sigma_q)$. At this point adversary $\mathcal{B}$ outputs the sequence of pairs $(c_{t_1}, d_{m_1}, \sigma_1), \ldots, (c_{m_q}, d_{m_q}, \sigma_q)$.

Suppose $\mathcal{A}$ wins its game. Then it made at most $q - 1$ queries to PRF-Srv and so $\mathcal{B}$ makes at most $q - 1$ queries to Help. It is also the case that all predictions by $\mathcal{A}$ are for unique tag, message pairs, meaning that $\mathcal{B}$'s output will also be for unique pairs of targets. Finally, it is clear that correct predictions σ_i are also BCDH solutions. ▌

B.2 Pseudorandomness Security

See the full version of this paper [25] for *one-more PRF* security definitions and associated proofs.

EVILCOHORT: Detecting Communities of Malicious Accounts on Online Services

Abstract

Cybercriminals misuse accounts on online services (e.g., webmails and online social networks) to perform malicious activity, such as spreading malicious content or stealing sensitive information. In this paper, we show that accounts that are accessed by botnets are a popular choice by cybercriminals. Since botnets are composed of a finite number of infected computers, we observe that cybercriminals tend to have their bots connect to multiple online accounts to perform malicious activity.

We present EVILCOHORT, a system that detects online accounts that are accessed by a common set of infected machines. EVILCOHORT only needs the mapping between an online account and an IP address to operate, and can therefore detect malicious accounts on any online service (webmail services, online social networks, storage services) regardless of the type of malicious activity that these accounts perform. Unlike previous work, our system can identify malicious accounts that are controlled by botnets but do not post any malicious content (e.g., spam) on the service. We evaluated EVILCOHORT on multiple online services of different types (a webmail service and four online social networks), and show that it accurately identifies malicious accounts.

1 Introduction

Online services, such as online social networks (OSNs), webmail, and blogs, are frequently abused by cybercriminals. For example, miscreants create fake accounts on popular OSNs or webmail providers and then use these accounts to spread malicious content, such as links pointing to spam pages, malware, or phishing scams [27, 31, 40]. A large fraction of the malicious activity that occurs on online services is driven by *botnets*, networks of compromised computers acting under the control of the same cybercriminal [9].

Leveraging existing services to spread malicious content provides three advantages to the attacker. First, it is easy to reach many victims, since popular online services have many millions of users that are well connected. In traditional email spam operations miscreants have to harvest a large number of victim email addresses (on the web or from infected hosts) before they can start sending spam. On online services such as OSNs, on the other hand, cybercriminals can easily find and contact their victims or leverage existing friends of compromised accounts [15]. In some cases, such as blog and forum spam, cybercriminals do not even have to collect a list of victims, because their malicious content will be shown to anybody who is visiting the web page on which the spam comment is posted [21,31]. A second advantage of using online services to spread malicious content is that while users have become aware of the threats associated with email, they are not as familiar with scams and spam that spreads through other communication channels (such as social networks) [5, 18, 27]. The third advantage is that while online services have good defenses against threats coming from the outside (e.g., emails coming from different domains), they have a much harder time detecting misuse that originates from accounts within the service itself (e.g., emails sent by accounts on the service to other accounts on the same one) [28].

To carry out malicious campaigns via online services, attackers need two resources: *online accounts* and *connection points*. Almost all online services require users to sign up and create accounts before they can access the functionality that these services offer. Accounts allow online services to associate data with users (such as emails, posts, pictures, etc.), and they also serve as a convenient way to regulate and restrict access. Connection points are the means through which attackers access online accounts. They are the devices (hosts) that run the client software (e.g., web browsers or dedicated mobile applications) that allow the miscreants to connect to online services. Often, connection points are malware-infected machines (bots) that serve as a convenient way for the attacker to log into the targeted service and issue the necessary commands to send spam or harvest personal information of legitimate users. However, malicious connection points do not need to be bots. They can also be compromised servers, or even the personal device of a cybercriminal.

In this paper, we propose EVILCOHORT, a novel approach that detects accounts on online services that are controlled by cybercriminals. Our approach is based on the analysis of the interactions between attackers and an online service. More precisely, we look at the interplay between accounts, connection points, and actions. That is, we observe which account carries out what action, and which connection point is responsible for triggering it.

The intuition behind our approach is that cybercriminals use online services differently than regular users. Cybercriminals need to make money, and this often requires operations at a large scale. Thus, when such operations are carried out, they involve many accounts, connection points, and actions. Moreover, accounts and connection points are related in interesting ways that can be leveraged for detection. A key reason for these interesting relationships is the fact that attackers use bots (as connection points) to access the online accounts that participate in an orchestrated campaign. By linking accounts and the connection points that are used to access these accounts, we see that malicious *communities* emerge, and these communities can be detected.

EVILCOHORT works by identifying communities (sets) of online accounts that are all accessed from a number of shared connection points (we use IP addresses to identify these connection points). That is, we observe a number of IP addresses and accounts, and each account is accessed by a non-trivial portion of these IP addresses. Typically, these IP addresses correspond to bot-infected machines, and they are used to log into the accounts that are under the control of the attacker. To identify communities, we consume a log of *interaction events* that the online service records. An interaction event can be any action that a user performs in relation to an account on an online service, such as logging in, sending an email, or making a friend request. Each event also contains the account that is involved, as well as the IP address that sends the request. Our results show that the overwhelming majority of accounts that are identified by our community detection approach are actually malicious, and that therefore the detection by EVILCOHORT is reliable enough on its own. As an additional step to better understand the detected communities and help us assess potential false positives we present techniques to analyze the characteristics of accounts within a community and identify typical behaviors that are indicative of malicious activity. Such characteristics include suspicious activity frequencies over time, synchronized activity of the accounts in the community, and the distribution of the types of browsers used by the infected machines to connect to the online accounts.

One key advantage of our approach is that it is generic, as it does not rely on service-specific information. This is different from previous research, which typically leverages service-specific information to perform detection. For example, BOTGRAPH [39] looks at accounts that are accessed by multiple IP addresses, similarly to our approach, but relies on heuristics based on the email-sending behavior of such accounts to limit false positives. This fact not only makes deployment more problematic, but also limits the applicability of the system to accounts that are misused to send spam. Contrast this with our broad definition of interaction events that is satisfied by a large variety of data that naturally accumulates at online service providers, and makes our approach applicable to any online service that requires users to create an account to interact with it. We demonstrate this by leveraging our approach to detect spammers on a webmail service, as well as to identify malicious accounts on multiple OSNs.

An additional advantage of our approach is that it can be applied to different types of actions. These actions can include account generation and login operations. In these cases, it might be possible to detect malicious accounts before they distribute any malicious content, as an early warning system. Also, it can help to identify abuses where no malicious content is distributed at all. An example of this are botnets that use social networks as part of their command-and-control (C&C) infrastructure [26], or botnets that crawl the online profiles of users harvesting personal information [17]. To show the versatility of our approach, we apply it to two different types of interaction events: on the webmail service we look at events that correspond to the sending of emails, while on the OSNs an interaction event is recorded when a user logs into her account. Over a period of five months, EVILCOHORT detected more than one million online accounts as malicious on the analyzed services. In summary, this paper makes the following contributions:

- We show that a significant amount of malicious activity is carried out by accounts that form communities (when looking at the connection points that access them). We also find that these accounts tend to remain active for extended periods of time on a large webmail provider.
- We present EVILCOHORT, a novel approach to detect malicious communities (and hence, accounts controlled by cybercriminals) on online services. This approach works by detecting accounts that are accessed by a common, shared set of IP addresses.
- We evaluated EVILCOHORT on datasets of different types of interactions collected on five different online services. Over a period of five months, EVIL-

Cohort detected more than one million accounts used to perform malicious activities. We show that EvilCohort is effective in detecting malicious communities regardless of the type of accounts analyzed, making it a valuable tool to protect a variety of online services.

2 Motivation: Analysis of Malicious Activity on a Webmail Service

We want to understand the way in which cybercriminals abuse accounts on online services, to identify weak points that we could leverage for detection. To this end, we observed the email-sending activity on a large webmail service. Our dataset was composed of the emails generated by 21,387,006 distinct online accounts over a period of one day. In total, this dataset contained 72,471,992 emails. We call the dataset containing information about this email-sending activity **T**. For each email-sending event, the dataset **T** contains the IP address that accessed the account, the user ID of the account that sent the email, and a timestamp. In addition, each email-sending event contains information on whether the email was considered as spam by the webmail provider or not. Note that the dataset **T** only contains information about sent emails, and provides no insights on the number of times an account is accessed without sending any email (e.g., to check the account's inbox).

Two Types of Malicious Accounts. We analyzed the accounts that sent spam in the dataset **T**. We identify two types of malicious accounts:

1. *Accounts that are used in isolation*. Each account is accessed by a single IP address, which could be the attacker's computer or a single infected machine.
2. *Accounts that are accessed by multiple IP addresses*. The same account is accessed by multiple infected computers.

We looked at how many malicious accounts of each type are active on the webmail service. For this analysis we considered an account as malicious if the account sent at least 10 emails during the day under consideration, and the majority of these emails were flagged as spam by the webmail provider. We selected this threshold because we needed a set of "labeled" accounts that sent spam on the webmail provider. Picking accounts whose majority of emails was flagged as spam by the email provider gives us confidence that this dataset does not contain false positives. Note that this preliminary analysis was purely qualitative, and it was used to give us an idea on the behavior of malicious accounts on a webmail service. We call this set of labeled accounts **L**. In total, **L** is composed of 66,509 malicious accounts that were accessed by a single IP address, and 103,918 malicious accounts that were accessed by two or more.

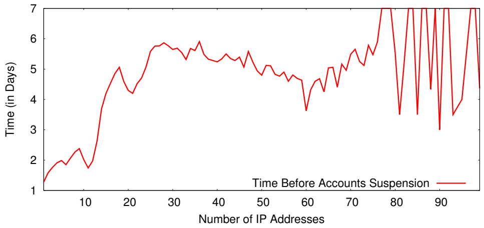

Figure 1: Average time (in days) before a spamming account was suspended in **L**, given the number of IP addresses accessing that account.

Accounts Shared by Many IP Addresses Are More Dangerous. We then investigated the effectiveness of the two identified types of spam accounts in sending emails, and their ability to evade detection by the webmail provider. With detection, we mean triggering a mechanism on the webmail provider that leads to the account being suspended. Figure 1 shows the average time (in days) that it took for a malicious account in **L** to be suspended after it sent the first spam email, given the number of IP addresses that accessed that account. As it can be seen, accounts that are used in isolation have a shorter lifespan than the ones that are used by multiple IP addresses: accounts that are only accessed by a single IP address are typically detected and suspended within a day, while ones that are accessed by many different IPs can survive for as long as a week.

We then studied the difference in the activity of the two types of accounts with regards to the number of spam emails sent. Figure 2 shows that accounts that are used in isolation are less effective for cybercriminals, as they send a smaller number of emails per day before being shut down. Alternatively, attackers can have each of their infected computers send a small number of emails and stay under the radar. Figure 3 shows that IP addresses accessing accounts used in isolation send 19 emails per day on average before being blocked, while having multiple computers accessing the same account allows cybercriminals to have each IP address send a lower number of emails, as low as one email per IP address in some cases. The longevity of the accounts that are accessed by more than one IP address suggests that the webmail service lacks effective countermeasures to prevent abuse of the service by such accounts. We acknowledge that this could be due to shortcomings in the countermeasures deployed by this particular webmail service, but it still shows us that accounts that are accessed by a multitude of infected computers are a problem for online services.

Detecting Malicious Accounts Shared by Many IP Addresses. Can we use the fact that malicious accounts tend to be accessed by many IP addresses to flag these

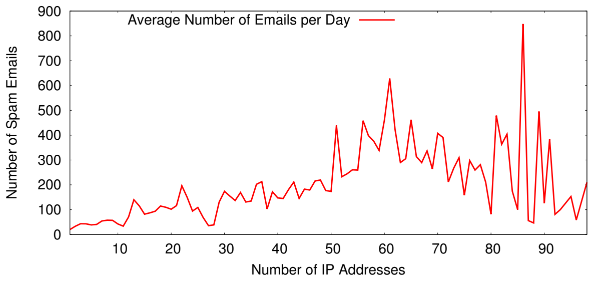

Figure 2: Average number of spam emails sent per day per *account* accessed by a certain number of IP addresses.

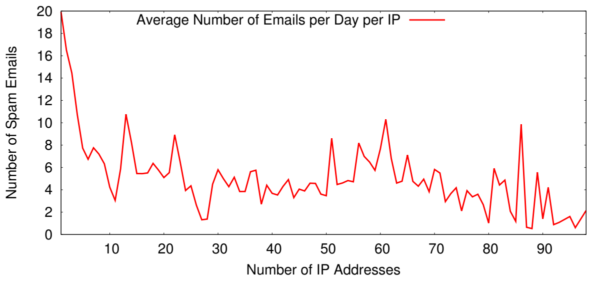

Figure 3: Average number of spam emails sent per day per *IP address* that accessed a certain account.

accounts as malicious? Unfortunately, the number of IP addresses that accessed an account is not a strong enough indicator and basing a detection system only on this element would generate a number of false positives that is too high for most practical purposes. For example, considering as malicious accounts that were accessed by two or more IP addresses in **T** would cause 77% of the total detections to be false positives (i.e., accounts that did not send any spam email). This makes sense, because many users access their webmail account from different devices, such as a mobile phone and a desktop computer. Even looking at accounts accessed by a higher number of IP addresses does not solve the false positive problem: looking at accounts that were accessed by ten or more distinct IP addresses in **T** 32% would be labeled malicious incorrectly (i.e., false positives); by increasing the number of required IP addresses false positives decrease, but they remain well above the level considered acceptable in a production environment.

To overcome the false positive problem, we leverage another property of cybercriminal operations that use online services: cybercriminals can only count on a limited number of infected machines (bots) [26], as well as a limited number of accounts on the online service. Because of this limitation, and to make their operations more resilient to takedowns, cybercriminals have multiple bots connect to the same set of accounts over time. We can think of a set of accounts that are accessed by the same set of bots as a *community*. In the following, we present EVILCOHORT, a system that detects communities of accounts that are accessed by a common set of IP addresses. We show that, by looking at these communities of accounts, we can detect most of the malicious accounts that are accessed by multiple IP addresses, while generating a false positive rate that is orders of magnitude lower than just looking at accounts in isolation. In Appendix 5.2, we compare the two methods in detail, and show that EVILCOHORT outperforms the method that looks at individual accounts only.

3 EVILCOHORT: Overview

EVILCOHORT operates on inputs in the form of *account interaction events*. Users create their own accounts and connect to online services to perform a number of actions. Depending on the service, these actions range from sending messages to the user's friends and colleagues, to performing friend requests, to browsing pictures, to updating the user's profile. Accounts allow the online service to attribute any activity performed to a specific user, in a more precise way than source IP addresses do. For instance, it is possible to correctly attribute the activity of a certain user regardless of the place she is connecting from (her home computer, her office, or her mobile phone). We define a user interaction with an online service as a tuple

$$\mathbf{A} = < H, U, T >,$$

where H is the host that the user is connecting from (identified by an IP address), U is her user ID on the online service, and T is a timestamp.

Approach Overview. EVILCOHORT works in three phases. First, it collects interaction events from the monitored online service, and builds a bipartite graph where one set of vertices is the online accounts observed and the other set of vertices is the list of IP addresses that accessed them. Then, it computes the weighted one-mode projection of the bipartite graph onto the account vertex set. The result of this phase is a graph, which we call *projected graph representation*, in which the vertices are the accounts and the edge labels (i.e., weights) indicate how many shared IP addresses connected to each pair of accounts. As a third phase, EVILCOHORT performs clustering on the projected graph representation to find communities of online accounts that were accessed by a common set of IP addresses. A last, optional step consists of analyzing the discovered communities, to characterize them and possibly identify security relevant activity, such as campaigns. In the remainder of this section, we provide more details about the three steps involved in identifying communities.

3.1 Data Collection

In the first phase, EVILCOHORT collects interaction events on an online service for a given observation period (a day in our current implementation). Based on these interaction events, EVILCOHORT builds a bipartite graph where the first set of vertices **A** are the online accounts that generated the events, while the second set of vertices **I** are the IP addresses that accessed these accounts. An account vertex has an edge to an IP address vertex if that account was accessed by that IP address. We call this bipartite graph $\mathbf{G}_A$.

3.2 Building the Projected Graph Representation

We expect that cybercriminals instruct their bots to connect to multiple accounts under their control. As discussed in Section 2, this is because they have control of a limited number of bots and want to optimize the effectiveness of their malicious operation. For this reason, we represent the relation between online accounts and IP addresses as a weighted graph. To this end, we perform the weighted one-mode projection of the bipartite graph $\mathbf{G}_A$ onto the account vertex set **A**. More precisely, we define the *projected graph representation* of the set of accounts **A** as

$$\mathbf{R} =< \mathbf{V}, \mathbf{E} >,$$

where each element in the set of vertices **V** is one of the accounts in **A**, and the set of edges **E** is weighted as follows: for each pair of accounts u_1, $u_2 \in \mathbf{V}$, the edge connecting them has a weight equal to the number of IP addresses that u_1 and u_2 share, based on the bipartite graph $\mathbf{G}_A$. If the accounts u_1 and u_2 do not share any IP address, there is no edge between them.

As we showed in Section 2, many legitimate accounts are accessed by more than one IP address. To focus on detecting communities of accounts that share a higher number of IP addresses, we filter the bipartite graph $\mathbf{G}_A$ on the in-degree of the accounts in **A**. More precisely, we introduce a threshold s, and consider as inputs for the projection only those accounts that have a degree higher than s, which means that they were accessed by more than s IP addresses during the observation period. Since the number of IP addresses that legitimate accounts share is low, communities of accounts sharing many IP addresses are suspicious. We investigate the possible choices for the threshold s in Section 5.1. By increasing the value of s we can reduce false positive considerably, but we also reduce the number of accounts that EVILCOHORT can detect as malicious. The graph **R** is then passed to the next phase of our approach, which finds communities of online accounts that are accessed by a common set of IP addresses.

3.3 Finding Communities

After obtaining the projected graph representation **R**, we identify communities of accounts. To this end, we use the "*Louvain Method*" [6]. This clustering method leverages an iterative algorithm based on modularity optimization, and is particularly well-suited to operate on sparse graphs, as most graphs obtained from "real life" situations are [12]. In their paper, Blondel et al. [6] show that their method outperforms several community-detection algorithms that are based on heuristics.

The Louvain method operates in two steps, which are iteratively repeated until convergence is reached. At the beginning, each vertex in **R** is assigned to its own community of size one. Each iteration of the algorithm proceeds as follows:

1. For each account u_1 in **U**, we consider each of its neighbors u_2, and we calculate a gain value g that represents the effect of removing u_1 from its community and adding it to u_2's community. We explain how we calculate g later in this section. If any of the gain values g is positive, we move u_1 to the community of the account that yields the highest gain.
2. We rebuild the graph **R**, whose nodes are now the communities built during the previous step. Each edge between two communities c_1 and c_2 is weighted with the number of IP addresses that are shared between the two communities.

The algorithm repeats these two steps until convergence. Blondel et al. [6] describe how the gain value g is calculated in detail. In a nutshell, the gain obtained by moving an account i to a community C is

$$g_{in} = [\frac{\sum_{in} + k_{i,in}}{2m} - (\frac{\sum_{tot} + k_i}{2m})^2] - [\frac{\sum_{in}}{2m} - (\frac{\sum_{tot}}{2m})^2 - (\frac{k_i}{2m})^2],$$

where $\sum_{in}$ is the sum of the weights of the edges between the accounts in C, $\sum_{tot}$ is the sum of the weights of the edges incident to the accounts in C, k_i is the sum of the weights of the edges incident to i, $k_{i,in}$ is the sum of the weights of the edges that connect i to the accounts in C, and m is the number of edges in **R**. Blondel et al. show how a similar weight is calculated for the gain obtained by removing an account i from its community (g_{out}) [6]. If the sum of the two gains g = $g_{in} + g_{out}$ is positive, the account i gets added to the community C.

3.4 Optional Step: Characterizing Communities

As an optional step, after the detection of (malicious) communities, we propose a number of techniques that extract interesting properties of these communities. These properties allow the operator of EVILCOHORT to easily characterize security-relevant behaviors of the communities. As we will see later, these properties can be useful to both assess false positives and identify whether the accounts in a community are fake (i.e., Sybils) or compromised accounts that are accessed both by cybercriminals and by their legitimate owners. To gain insight into the behavior of accounts associated with communities these properties can incorporate auxiliary sources of information that are not strictly part of the collected *account interaction events* (e.g., web-browser user agents).

User agent correlation. Regular users of online services likely connect to their accounts from a limited set of devices corresponding to a largely consistent set of connection points. During the course of a day, a typical user would access, for example, her account from home using her personal browser, then from work using the browser mandated by company policy, and finally from her phone using her mobile client. In other words, we expect to have a one-to-one relation between the connection points and the client programs (agents) that run on these machines and are used to perform the activity. When online services are accessed via the web, the client used to perform the activity can be identified by the HTTP user agent field. Proprietary clients often have similar attributes that can be used for this purpose. On iOS, for example, the system-provided HTTP library uses the application's name and version as the user agent string.

For malicious communities, the activity is no longer generated by humans operating a browser. Instead, the activity is frequently generated by autonomous programs, such as bots, or programs used to administer multiple accounts at once. These programs can be designed to use either hard-coded user agent strings, or, as we observed in recent malware, slight variations of legitimate user agent strings. Presumably, this is a technique aimed at evading detection mechanisms. However, these practices significantly change the distribution of user agent strings and their corresponding connection points.

To measure the correlation between connection points and user agents within a community c, we compute the following ratio:

$$log(c) = log\left(\frac{\text{number of user agents}}{\text{number of IP addresses}}\right) \qquad (1)$$

For a typical benign user, the correlation is very strong because there is a one-to-one relationship between connection point and user agent: That is, each connection point is associated with a different user agent, and as a result $log(c)$ tends towards 0. For malicious communities, where the relationship becomes one-to-n, negative values will be observed in case of hard-coded user agent strings, and positive values in case of permutations of the user agent strings. Note that we exclude from the computation user agent strings coming from mobile phones or tablets because these mobile devices can be connected to any network, meaning that no correlation can be expected in this case.

Event-based time series. This property captures *account interaction events* in a community over time. Time series represent the frequency of events per time period. As we will show in Section 6, the time series representations fundamentally differ for legitimate accounts and those in malicious communities. Time series for legitimate users commonly contain daily activity patterns depending on the night and day cycle. Furthermore, weekly patterns can often be identified too. Automated malicious activity, however, commonly results in either highly regular activity (e.g., botnets using the online service as their command and control service), or irregular bursts (e.g., during the execution of a spam campaign).

IP address and account usage. This analysis, similarly to the previous one, relies on timing analysis. The main difference is that events are no longer aggregated for the entire community but, instead, individual IP addresses and accounts are represented separately over time.

The IP addresses usage graph is generated in the following way: Time is represented on the x-axis, and each unique IP address is represented by a separate entry on the y-axis of the graph. Events are then plotted as points in the graph using this set of coordinates. The account usage graph is generated in a similar way, with unique accounts instead of IPs on the y-axis. We will show an example for IP address and account usage graphs in Section 6. Similar to the above time series representation, malicious communities show a high degree of synchronization, which is not present for communities formed by legitimate users. This observation has been confirmed by independent research that has been recently published [7]. Using this type of representation, any suspicious alignment in the events recorded for different IP addresses or different accounts can easily be identified.

Automated post-processing. In our current implementation we exclusively use the analysis of community properties to infer interesting characteristics of identified communities. Our analysis indicates that communities formed by malicious accounts exhibit vastly different characteristics than those formed by legitimate accounts, as we show in Section 6. Thus, the techniques described in this section could also be used to automatically distinguish malicious from legitimate communities. Similar to Jacob et al. [17], detection could be implemented based on automated classifiers working on statistical features characterizing the shape of a time series or plot. While such an automated post-processing approach would be a potential avenue for reducing the false positives of EVILCOHORT even further, our current false positives are already well within the range where a deployment would benefit an online service. An implementation of this automated post-processing step is, thus, left for future work.

4 Description of the Datasets

In Section 2, we analyzed **T**, a labeled dataset of email-sending events on an webmail provider. Since EvilCohort only takes into account the mapping between IP address and online account of an event, however, it can operate on any online service that allows users to create accounts. Such services include web-based email services, online social networks, blogs, forums, and many others. In addition, EvilCohort can operate on activities of different type, such as login events, message postings, message shares, etc. To show the versatility of our approach, we evaluated it on multiple datasets of activities on five different online services. The first dataset is composed of email sending events logged by a large webmail service, with similar characteristics to **T**. The second dataset is composed of login events recorded on four different online social networks. In the following, we describe these datasets in more detail.

4.1 Webmail Activity Dataset

Our first dataset is composed of email-sending events logged by a large webmail provider. Every time an email is sent, an activity is logged. We call this dataset $\mathbf{D}_1$. Note that the email-sending events in this dataset are generated by accounts on the webmail service, which send emails to other email addresses.

The dataset $\mathbf{D}_1$ contains the events logged over a five-month period by the webmail provider for a subset of the accounts that were active on the service during that period. In total, this dataset contains 1.2 billion email-sending events, generated by an average of 25 million accounts per day. This data was collected according to the webmail provider's terms of service, and was only accessed on their premises by a company's employee. Beyond the above-discussed information, no further email related information was accessible to our research team (i.e., no content, no recipients). In addition to the activity events, the webmail provider logged whether the email was flagged as spam by their anti-spam systems. The dataset **T** presented in Section 2 is a subset of $\mathbf{D}_1$. We used **T** to study in-depth the properties of legitimate and malicious accounts on a webmail service (see Section 2). As we explained in Section 2, **T** is a dataset containing email events observed on a large webmail provider over a period of one day, while **L** contains the accounts in **T** that are heavy senders of spam (meaning that they sent 10 or more emails during the day of observation, and that a majority of these emails was detected as spam by the defenses in place at the webmail provider).

It is worth noting that **L** does not contain all the accounts that sent spam in **T**. Such ground truth does not exist, because if a perfect detection system existed we would not need new approaches such as EvilCohort. Instead, **L** contains a set of "vetted" spam accounts that were detected by the webmail provider, and using this dataset as a reference allows us to get a good idea of how well EvilCohort works in detecting previously-unseen malicious accounts on online services.

4.2 Online Social Network Login Dataset

Online Social Network	**OSN$_1$**	**OSN$_2$**	**OSN$_3$**	**OSN$_4$**
Login events	14,077,316	311,144	83,128	42,655
Unique Accounts	6,491,452	16,056	25,090	21,066
Unique IPs	6,263,419	17,915	11,736	4,725
Avg. daily events	2,067,486	51,832	11,897	6,601
Account singletons	74.6%	40.0%	51.7%	72.2%

Table 1: Statistics of activity events of the dataset $\mathbf{D}_2$.

Our second dataset is composed of login events collected from four different OSNs, spanning a period of 8 days. We call this dataset $\mathbf{D}_2$. We obtained the dataset $\mathbf{D}_2$ from a security company. For each activity event, the dataset contained additional information such as the user agent of the web browser performing the login and the HTTP headers of the response. Sensitive information such as the user IDs and the IP addresses was anonymized. Note that this does not affect our community detection algorithm at all.

Statistics on the number of login events for each social network can be found in Table 1. These statistics reflect the size and activity observed on these networks, ranging from tens of thousands up to 14 million login events. One interesting observation is the high percentage of account singletons on a daily basis, i.e., the percentage of users connecting at most once a day. On a weekly basis, the percentage tends to drop but remain surprisingly high. These users are probably legitimate users that are not very active on the social network.

5 Evaluation

In this section, we analyze how EvilCohort performs in the real world. We first study the effectiveness of our approach by using the dataset **T** and its subset **L** of labeled malicious accounts. We then select a suitable threshold s that allows us to have a small number of false positives. Finally, we run EvilCohort on multiple real-world datasets, and we analyze the communities of malicious accounts that we detected.

Value of s	# of accounts	# of communities	Known accounts in L	Additional detections over L	FP communities	FP accounts
			(% of tot. accounts in L)	(% of add. detections over L)	(% of tot. communities)	(% of tot. accounts)
2	135,602	3,133	94,874 (58%)	40,728 (23.8%)	1,327 (42%)	12,350 (9.1%)
5	77,910	1,291	51,868 (30.4%)	26,042 (15.2%)	580 (44.9%)	2,337 (3%)
10	25,490	116	16,626 (9.7%)	8,864 (5.2%)	48 (41.3%)	433 (1.7%)
65	1,331	6	1,247 (0.7%)	84 (0.04%)	0	0

Table 2: Summary of the results reported by EvilCohort for different values of the threshold s.

5.1 In-degree Threshold Selection

As with every detection system, EvilCohort has to make a trade-off between false negatives and false positives. As we mentioned in Section 3.2, we can adjust the value of the minimum in-degree for account vertices that we use to generate the one-mode projection graph **R** to influence the quality of EvilCohort's results. We call this threshold s. In particular, increasing the value of s decreases the number of false positives of our system, but also reduces the number of accounts that can be detected. That is, any account that is accessed by less than s IP addresses during an observation period is excluded from evaluation for community membership, and thus cannot be detected as malicious by EvilCohort.

In this section we run EvilCohort on the datasets **T** and **L** and analyze the quality of its results. The goal is to identify a suitable value of s for running EvilCohort in the wild. Recall that **L** is the set of accounts that were classified as malicious as explained in Section 2. In the absence of complete ground-truth, we use **L** as a partial ground-truth to help us assess how well EvilCohort operates.

The first element that we use to evaluate the effectiveness of EvilCohort is the fraction of accounts in **L** that our system is able to detect. Ideally, we want EvilCohort to detect a large fraction of our labeled malicious accounts. Unfortunately, as discussed above, increasing the value of s decreases the number of accounts that EvilCohort can possibly detect. The percentage of malicious accounts in **L** detected by EvilCohort provides us with an estimate of the false negatives that EvilCohort would report if it was run in the wild.

As a second element of effectiveness, we look at the set of accounts that EvilCohort detects as malicious in **T**, but that were missed by the anti-spam systems deployed by the webmail provider. These are malicious accounts *not* in **L**. We refer to this number as *additional detections*. This value gives us an estimate on the overall effectiveness of EvilCohort. Ideally, we want this number to be high, so that if EvilCohort were to be deployed in conjunction with the defenses that are already in place on the online service, it would increase the number of malicious accounts that can be detected and blocked.

The third element that we consider is the *confidence* that the communities detected by EvilCohort are indeed malicious. To this end, we look at the fraction of accounts in **L** that are present in each detected community. We consider a community as malicious (i.e., a true positive) if at least 10% of the accounts belonging to it are part of our labeled dataset of malicious accounts. Otherwise, we consider it as a false positive of EvilCohort. We empirically found that this 10% fraction of vetted bad accounts gives us a good confidence that the communities are indeed malicious. Recall that **L** is a dataset composed of "repeated offenders." In other words it contains accounts that have a consistent history of sending spam, therefore having a small fraction of accounts from this set in a community is a strong indicator of the entire community being malicious. As we show in Section 5.3, if we relax the method that we use to assess true positives (for example we consider an account as malicious if it sent a single email flagged as spam by the webmail provider) then the majority of the accounts in communities detected by EvilCohort are confirmed as malicious. In Section 6 we show that by observing additional properties of the communities detected by EvilCohort we are able to confirm almost the totality of them as malicious.

Table 2 provides a summary of the results that we obtained when running EvilCohort on **T**, based on different values of the threshold s. As one can see, the fraction of accounts in **L** that our system detects decreases quickly as we increase s. With a threshold of 2, EvilCohort only detects 58% of the labeled accounts.With a threshold of 10 the fraction of accounts in **L** that are covered is only 10%. Once we reach higher thresholds, the fraction of detected accounts that are part of **L** becomes very small. The additional detections performed by EvilCohort over the webmail provider's detection system also decrease as we increase s. With a threshold of 2 we detect 23% malicious accounts that existing approaches miss. A threshold of 10 still ensures 5.5% additional detections over the dataset **L**. False positives decrease rapidly as we increase s as well. Setting s to 2 results in 9% false positives. A threshold of 10 reduces false positives to 1.7%. By setting s to 65, EvilCohort does not mistakenly flag any legitimate account as malicious. Unfortunately, the number of detections at this threshold is quite low.

Given the results reported in this section, we decided to use 10 as a value of s for our experiments. At this threshold false positives are low (1.7%), but the system is still able to significantly improve the detections performed by the existing countermeasures deployed by the webmail provider, and detects 116 communities.

It is interesting to notice that although the number of accounts misclassified by EVILCOHORT is generally low, percentages are higher when looking at communities: with a threshold of 10, for example, 40% of the detected communities are considered to be false positive accounts. Interestingly, however, the size of true positive and false positive communities varies consistently: false positive communities are composed of 9 accounts on average, while malicious ones are composed of 370 or more accounts. An explanation for this is that small communities could be a side effect of computers behind a NAT which constantly change their IP address through DHCP. As previous research showed, some ISPs change the IP address of their customers very often [26]. The small size of such communities, however, shows that filtering on the number of accounts in a community could be an effective filter to further reduce false positives. We did not include a threshold on the size of a community in EVILCOHORT because we wanted to keep the system general. However, in a production setting an additional threshold on the community size could be a straight-forward way to reduce false positives even further. In addition, Section 6 illustrates that false positive communities expose distinct behavioral characteristics. These characteristics can be leveraged to further reduce false positives.

5.2 Comparison between EVILCOHORT and the Single Account Method.

As we discussed in Section 2, EVILCOHORT outperforms detection approaches that look at single accounts accessed by a high number of IP addresses by orders of magnitude. At a threshold of 10, where EVILCOHORT reports a false positive rate of 1.7%, the single-account method has a false positive rate of 32%. Even by dramatically increasing the threshold, the number of false positives of the single-account method remains high. At a threshold of 65, at which EVILCOHORT reports no wrong detections, the single-account method has a false positive rate of 1.2%. Even at a threshold of 100, the single-account method has a small number of false positives.

The last question to answer is whether accounts that are accessed by a high number of IP addresses do form communities, in other words whether EVILCOHORT is able to detect most malicious accounts that were accessed by a number of IP addresses s. To answer this question, we looked at single accounts accessed by a number of IP addresses n (from one to 100), and labeled them as malicious or benign in the same way we labelled the communities in the previous experiment. We then proceeded as follows: for each value of n, we considered the single-account method to have perfect recall (i.e., no false negatives). We then looked at how many of the accounts detected by this method would have formed communities, and therefore be detected by EVILCOHORT. The fraction of malicious accounts that form communities is generally very high. With a threshold of 10, EVILCOHORT detected 93% of the malicious accounts detected by the single-account method. With a threshold of 20 this fraction becomes 95%, while with a threshold of 50 it becomes 98%. We conclude that the vast majority of accounts accessed by a high number of IP addresses form communities, and that therefore EVILCOHORT is a suitable alternative to the single-account method for what concerns false negatives, and it reduces false positives by orders of magnitude compared to the single account method.

5.3 Detection in the Wild

We applied EVILCOHORT to the datasets $\mathbf{D}_1$ and $\mathbf{D}_2$. In the following, we show that EVILCOHORT is able to detect a large number of malicious online service accounts, regardless of the type of online service that it is run on.

Detection on the webmail activity dataset. The dataset $\mathbf{D}_1$ is composed of email-sending activities logged on a large webmail provider. Over a period of 5 months, EVILCOHORT detected **M** = 1,217,830 accounts as malicious. In total, these accounts were part of 17,803 malicious communities.

We first wanted to understand the number of false positives generated by EVILCOHORT in the wild. We tried to answer this question from two vantage points. First, we performed the same false positive analysis explained in Section 5.1. That is, we considered an account to be vetted as malicious if the majority of the emails sent by it during the day of observation were detected as spam by the webmail operator. We then considered a community as a false positive by EVILCOHORT if less than 10% of the accounts in the community belonged to our set of vetted malicious accounts. In total, we found 23,269 accounts to be potential false positives (1.9% of the total accounts in **M**). This is in line with the validation results from Section 5.1, in which we reported 1.7% false positives by using the same threshold. As a second method of assessment, we manually analyzed 100 randomly picked communities among the ones detected by EVILCOHORT. For each of these communities we could identify signs of automated activity and possible maliciousness. For example, the user IDs of the accounts used by some communities had been clearly automatically generated: in one case, all the accounts belonging to the community were composed of two dictionary words concatenated with a four-digit number. In another case, all the user IDs were 20-letter random alphanumeric characters. In an-

Day	1	2	3	4	5	6	7	8
OSN_1	24	30	6	4	4	4	5	2
OSN_2	1	0	0	0	0	0	0	0
OSN_3	0	0	0	0	1	1	1	0
OSN_4	0	0	0	0	0	0	0	0

Table 3: Number of malicious communities detected per day by EvilCohort on the dataset $\mathbf{D}_2$.

Social Network	OSN_1	OSN_2	OSN_3	OSN_4
Accounts (Avg)	3,662	2	2	0
Accounts (Med)	13	2	2	0
Accounts (Max)	66,764	2	2	0
IPs (Avg)	2,381	14	10	0
IPs (Med)	19	14	10	0
IPs (Max)	3,9884	14	10	0

Table 4: Size of the malicious communities detected by EvilCohort on the dataset $\mathbf{D}_2$. Numbers (Average, Median and Maximum) are expressed per community.

other case, the accounts belonging to a community were accounts with a long history of legitimate activity, which suddenly started being accessed by a large, common set of IP addresses. We highly suspect that this community of accounts was composed of legitimate accounts that had been compromised by cybercriminals.

We then wanted to evaluate the false negatives reported by EvilCohort. 94.6% of the vetted malicious accounts used in the false positive analysis at the operating threshold formed communities, and were therefore detected by EvilCohort. The false negatives would therefore account for 5.4% of the total accounts in **M**. This shows that malicious accounts accessed by a large number of IP addresses are typically accessed by botnets, and confirms the usefulness of our approach.

We then looked at how many accounts detected by EvilCohort sent at least one email that was flagged as spam by the webmail provider during the day in which EvilCohort detected them. In total, 715,671 accounts fall in this category (i.e., 59% of **M**). This also shows that relaxing our ground truth assumptions and looking at accounts that sent a single spam email as malicious instead of a vetted dataset results in having the majority of the accounts detected by EvilCohort confirmed by the defenses already in place at the webmail provider. Conversely, EvilCohort proves to be able to grow the set of malicious accounts detected by the webmail provider consistently, since it detected 502,159 additional accounts as malicious (41% of the total).

On average, our prototype implementation of EvilCohort processes one day of data in about ten minutes using a COTS server with 16GB of RAM.

Detection on the social network login dataset. The dataset $\mathbf{D}_2$ is composed of login events from online social networks. In the following, we applied EvilCohort to this second dataset to demonstrate the viability of the approach for different types of services. We used the same threshold as selected in Section 5.1 on this dataset too. Unfortunately, no labeled dataset was available for these experiments. To confirm that the accounts belonging to the identified communities were indeed malicious, we performed a post-processing analysis. We discuss the results of these experiments in Section 6.

Over eight days, EvilCohort was able to detect a total of 83 communities, which represents a total of 111,647 unique accounts. The number of detected communities and the size of these communities evolve daily, as one can see in Table 3 and Table 4. Unsurprisingly, our numbers heavily depend on the size of the social network. OSN_1 is by far the largest network; consequently, this is where we observed the highest number of communities, as well as the largest communities. Interestingly, we observe an important drop in the number of communities on the third day. This might indicate that accounts were taken down by the network. The remaining communities tend to be of smaller size. In OSN_2 and OSN_3, we only detect isolated communities of very small size: two accounts accessed by ten different IP addresses. The activity for OSN_4 was too little to detect any interesting community with the selected threshold.

To understand the evolution of the detected communities, we studied their similarity over time. A community remains stable over time if it is found similar to a community detected the day before. We qualitatively consider two communities as similar if they share more than 50% of their accounts. In OSN_1, one of the largest communities, with more than 66,000 accounts, was stable over five days, with a similarity ranging between 53% to 85%. Two communities of smaller size, with about 10,000 accounts each, were found stable over the two first days but they disappeared on the third day as previously observed. The community detected in OSN_3 is only made up of two accounts and it is stable over three days before being brought down.

6 Application of Post-processing Techniques

As we mentioned in Section 2, EvilCohort was motivated by observations performed on a webmail service. Given the generality of our approach, however, we can apply it to any online service that makes use of accounts. For this reason, we tested EvilCohort on the OSN dataset $\mathbf{D}_2$. The question remains on how well EvilCohort works on such a different dataset. Unfortunately, the dataset $\mathbf{D}_2$ came without ground truth. For this reason, we used the techniques described in Section 3.4 to assess the maliciousness of the detected communities. In a nutshell, we analyze the communities detected by

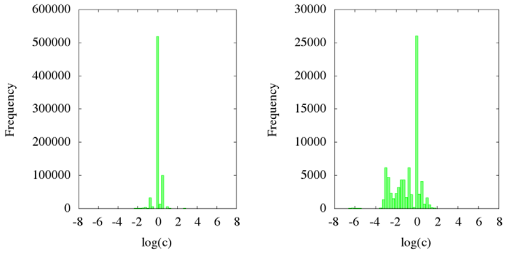

Figure 4: Correlation between user agents and IPs: legitimate accounts (left) and malicious accounts (right).

EvilCohort on the dataset $\mathbf{D}_2$, and consider them as true positives if the accounts belonging to it show patterns that are indicative of automated activity or of botnet use. These techniques are not part of EvilCohort's core detection, but as we will show they are helpful in assessing how well our approach performs.

The results show that most communities of accounts detected by EvilCohort show very different characteristics than legitimate accounts, and are, therefore, very likely malicious. Specifically, of the 83 malicious communities detected by EvilCohort on $\mathbf{D}_2$ only 5 showed characteristics that are similar to regular accounts and are therefore possibly false positives. In particular, we observed a very large community of 5,727 accounts, and four smaller ones of 7, 3, 3, and 2 accounts respectively. Given the size of the largest community, we wanted to understand whether it was really a false positive. Looking at its characteristics, we observed a mix of IP address accessing a single account and a large population of IP addresses accessing many different accounts, which makes us believe that such accounts might have been compromised and being accessed by both their legitimate owners and the hijackers. As such, this community is not a false positive, as it was actually accessed by a botnet. We provide further evidence that this is the case in the following sections. The other communities, on the other hand, are very likely to be false positives by EvilCohort, because they show a consistent human like behavior. Given their small size (15 accounts in total, out of 111,647 total detected accounts), however, we can conclude that the false positives generated by EvilCohort on the dataset $\mathbf{D}_2$ are minimal. In the following, we describe our analysis in detail.

User-agent correlation. Information about user agents was only available for OSN_1 and OSN_2 in $\mathbf{D}_2$. Consequently, we excluded OSN_3 and OSN_4 from this analysis. We also excluded all the account singletons, because the notion of ratio then becomes meaningless.

Based on the description in Section 3.4, we plot the correlation between user agents and IP addresses in Figure 4. The left distribution is generated for legitimate accounts that do not form communities, whereas the right distribution corresponds to accounts in identified malicious communities. The distribution for malicious communities is shifted and no longer aligned on the origin. For legitimate accounts, the average of $log(c)$ was 0.08, which is close to zero, as expected (with a standard deviation of 0.43). For malicious communities, the average shifts to -0.85 with a standard deviation of 1.24.

For the accounts in two of the potential false positive communities described before, the correlation index $log(c)$ was very close to zero, making them very similar to what is expected for regular accounts. For the remaining potential false positive communities this metric did not reveal any anomalous behavior.

Event-based time series. Time series become only significant if the amount of data is sufficiently large to make a measure statistically meaningful. For this reason, we only computed the event-based time series (introduced in Section 3.4) for OSN_1. Unfortunately, the volume of login events observed for OSN_2, OSN_3 and OSN_4 made this approach impractical for these networks.

The assumption behind the time series analysis is that part of the events observed in malicious communities are the result of automation. This results in a distinct shape of activity from communities of legitimate users where events are triggered by humans [17]. To verify this assumption, we plotted the time series associated with the activity of the biggest malicious communities detected in OSN_1. The experiments show that the time series generated for malicious communities differ fundamentally in shape from regular user activity, even when users are grouped behind a NAT.

Concrete examples are plotted in Figure 5 The left time series represents the activity of all users from OSN_1 over 8 days. The reader can clearly see the daily patterns in the activity. The middle time series represents the activity generated by the largest community detected in OSN_1. As can be seen, there are fundamental differences: disappearance of the daily patterns and higher stability on the long term. The right time series is representative of most of the time series obtained for smaller communities of OSN_1: the volume of events remains low but one can clearly observe regular bursts of activity. This bursty shape is also observed for the potential false positive community of 5,727 accounts mentioned previously, which supports our assumption that this community might be composed of compromised accounts that alternate legitimate and malicious activity. The smaller false positive communities, on the other hand, show diurnal patterns similar to the ones observed for legitimate accounts, which support the conclusions that these communities are false positives.

IP addresses and account usage. An alternative representation of account activity over time is to plot the usage graphs for IP addresses and accounts as detailed

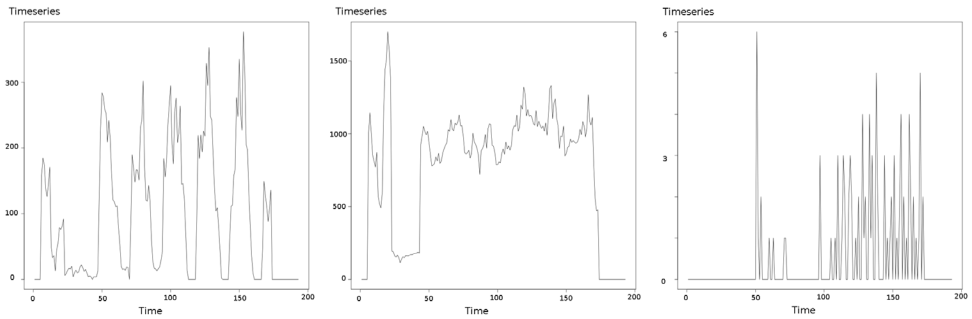

Figure 5: Time series plotting login event over time: legitimate accounts behind a NAT (left plot) and malicious communities (center and right plots).

in Section 3.4. For malicious communities, the usage graphs will exhibit suspicious patterns, indicating synchronization across accounts and IP addresses. For reference, Figure 6 presents the usage graphs for the users behind a NAT. IP address usage is not really relevant for a single IP address, but one can clearly see the daily interruptions over night, as well as the randomness of the events during day time. If we look at malicious communities as plotted in Figure 8, one can see the suspicious vertical patterns appearing. Looking at the IP addresses usage graphs, IP addresses are active in synchronized groups. Previous research already observed that malicious accounts are often used in a synchronized fashion by cybercriminals, and leveraged this property for detection [7]. This gives us additional confidence that the detection performed by EVILCOHORT on the dataset $\mathbf{D}_2$ identifies accounts that are indeed malicious. This anomalous synchronization can be observed for all detected communities of OSN$_1$, OSN$_2$, and OSN$_3$ with the exception of the five potential false positive communities previously mentioned, for which the usage resembles the one of legitimate accounts.

If we look at the large false positive community, however, one can see in Figure 7 that the usage graphs are overall similar to the behavior shown by regular users behind a NAT. However, looking more closely, one can observe multiple darker vertical patterns in the graphs. The mix of legitimate and malicious activities makes us even more confident that such community is indeed composed of compromised accounts accessed by a botnet, and is therefore a true positive detected by EVILCOHORT.

7 Discussion

We showed that EVILCOHORT can be applied to a variety of online services and to any type of activity on these services. This versatility, together with the fact that it complements detections by state-of-the-art systems, makes EVILCOHORT a useful tool in the fight against malicious activity on online services. We hope that, in the future, other researchers will be able to apply the techniques presented in this paper to other online services and types of activity.

As any detection system, EVILCOHORT has some limitations. The main limitation of EVILCOHORT, as we already mentioned, is that it can only detect malicious accounts that are accessed by communities of IP addresses. As we showed in Section 2, however, such accounts are more dangerous than the ones that are accessed by single IP addresses, and existing countermeasures are able to shut down this second type of accounts much quicker.

Another shortcoming is that EVILCOHORT relies on a threshold to limit the number of false positives. An online service that decided to use our approach would have to select a value of s that suits their needs. In this paper we showed that the number of false positives decreases rapidly as we increase s. Applied to our dataset, consisting of millions of events every day, this observation allowed us to reduce false positives to practically zero. Operators can easily tune the value of s by performing sensitivity analysis similar to what we did in Section 5.1.

A last shortcoming is that the accounts used by cybercriminals are not necessarily fake accounts, but could be legitimate accounts that have been compromised. In our current implementation, EVILCOHORT cannot distinguish between the two types of accounts. Dealing with compromised accounts is more difficult, because the online service cannot just suspend them, but has to go through expensive password-reset operations. As we showed in Section 6, it is possible detect whether the detected accounts are fake or compromised by using the postprocessing techniques. A human operator could then decide how to deal with the malicious accounts, depending on their nature.

As with any detection system, a cybercriminal who is aware of EVILCOHORT could attempt to evade it. A straightforward way of doing this would be to have each of the online accounts under his control accessed by a

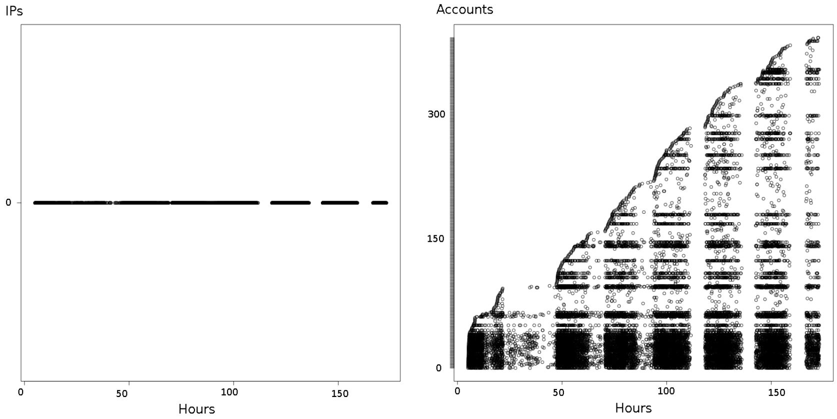

Figure 6: Activity of legitimate users behind a NAT: IP address usage (left) and account usage (right).

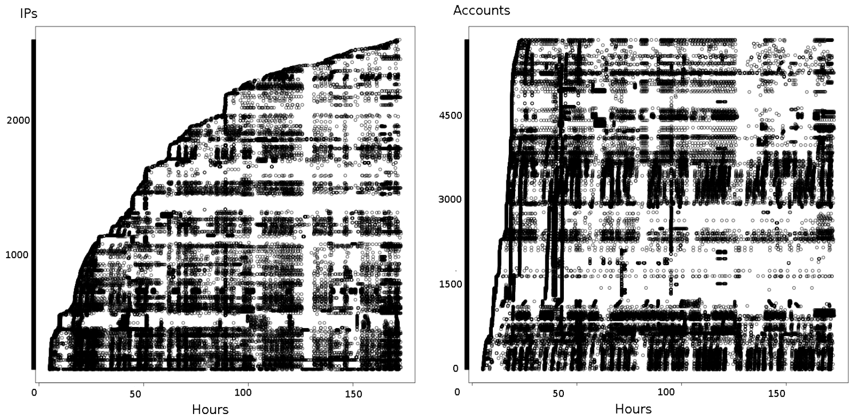

Figure 7: Activity of false positive community: IP address usage (left) and account usage (right). The fact that synchronized activity is interleaved to regular user activity makes us believe that this community is made of compromised accounts.

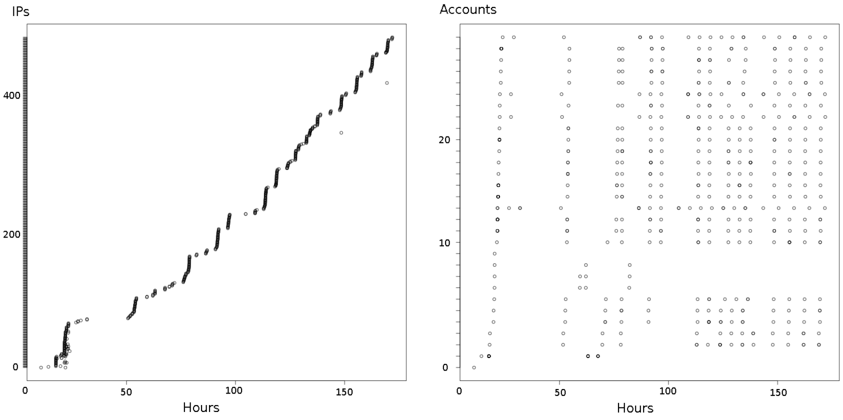

Figure 8: Activity of malicious communities: IP address usage (left) and accounts usage (right).

single IP address. Although this would evade detection by our system, it would make the cybercriminal operation less robust: every time the online service detects and shuts down an account as malicious one of the bots in the botnet becomes useless, while conversely every time a bot is taken offline there is an account on the online service that is not used any more. For this reason EVILCOHORT can be evaded, but by doing so a cybercriminal makes his operation less efficient and profitable.

Since EVILCOHORT can work on any type of activity events, including login events, it has the potential of detecting an account as malicious and blocking it before it performs any malicious activity. In our current implementation, the system works in batches, on time intervals of one day. In the future, we plan to extend it to handle a stream of data, and operate in real time. This way, the system could continuously build communities, and flag an account as malicious as soon as it joins a community.

A source of false alarms for EVILCOHORT could be users who access a service via an IP anonymization service such as Tor. In this case, the set of exit nodes would appear as a community. To mitigate these false positives, we could use the post-processing techniques that we described in Section 3.4. Also, Tor-related communities can be easily identified by comparing the set of IP addresses to the known list of Tor exit nodes. As future work, we plan to explore different tradeoffs between the number of IP addresses accessing a community and the characteristics of such communities.

8 Related Work

A wealth of research has been conducted on detecting malicious activity on online services. Previous work falls into three categories: *content analysis*, *detection of malicious hosts*, and *detection of malicious accounts*.

Content analysis. A corpus of work focuses on detecting malicious content that is shared on online services. Multiple papers dealt with detecting email content that is typical of spam by using machine learning [10, 25]. Other works check whether the URLs posted on an online service are malicious [29,34]. Pitsillidis et al. developed a system that extracts templates from spam [22].

Content analysis systems are effective in detecting and blocking malicious content posted on online services. However, they suffer from two major limitations. The first limitation is that such techniques are typically resource-intensive, and this limits their applicability on busy online services [28]. The second limitation is that such systems can make a detection only when the malicious party tries to posts their content. On the other hand, EVILCOHORT can detect an account (or an IP address) as malicious even if the account does not post any content on the online service.

Detection of malicious hosts (bots). Online services can check in real time if an IP address is known to be a bot by querying DNS blacklists [1]. DNS blacklists are heavily used in anti-spam systems for emails because, unlike content analysis systems, they are lightweight. However, previous research showed that DNS blacklists have a very high number of false negatives [23]. To improve the coverage offered by DNS blacklists, several methods have been proposed. Sinha et al. [24] propose to determine the reputation of an IP address on a global scale, instead of doing it on a local (provider-scale) one. Hao et al. presented SNARE, a system that establishes the reputation of an IP address based on a number of behavioral features (such as the geographical distance between the sender and the recipient) [16].

Detection of malicious accounts. To perform malicious activity on online services, miscreants have to get access to accounts on such services. To this end, they can pay workers to create account for them [33], purchase mass-created fake accounts [30], or buy credentials to compromised accounts on such services [26]. Given the magnitude of the problem, numerous approaches have been proposed to detect accounts that perform malicious activities on online services.

A number of systems analyze the characteristics of accounts on online services, looking for indicators that are typical of mass-created fake accounts (such as the number of people that an account follows) [3, 14, 19, 27, 36, 38]. Yu et al. [37] proposed a system to detect fake social network accounts; the system looks at the network structure, and flags accounts that are not well-connected with their peers in the network as possibly malicious. Benevenuto et al. presented a system to detect accounts that leverage the Youtube service to spread malicious content [4]. Gao et al. [13] developed a system that clusters messages posted on social networks, looking for large-scale spam campaigns. Other approaches look at how messages propagate on social networks, looking for messages that spread anomalously, such as worms [8, 35]. Wang et al. [32] proposed a technique to detect malicious accounts on social networks, based on the sequence of clicks that the people (or the programs) controlling such accounts perform. Jacob et al. [17] presented PUBCRAWL, a system that detects accounts that are used to crawl online services. Egele et al. [11] developed COMPA, a system that learns they typical behavior of social network accounts, and considers any change in behavior as the sign of a possible compromise. Cao et al. presented SynchroTrap [7], a system that detects malicious activity by grouping together social network accounts that performed similar actions during the same period of time. EVILCOHORT improves over SynchroTrap, because accounts do not have to act synchronously to be detected.

Although systems that detect malicious accounts are useful to detect and block malicious activity on online services, they typically rely on a single threat model, and can only detect malicious accounts that operate following that threat model. Conversely, EVILCOHORT leverages the observation that cybercriminals use a set of (compromised) IP addresses and a set of online accounts. For this reason, EVILCOHORT can detect online accounts controlled by cybercriminals, regardless of the purpose for which these accounts are used.

Studying communities of interest. A large corpus of research has been conducted over the years to study communities of interest in networks [2, 20]. Such communities are collections of hosts that share the same goal. Studying communities of interest is useful to model the typical behavior of related hosts, and detect anomalies in their behavior that can be indicative of malicious activity. The communities that we study in this paper are different in nature, because they are composed of online accounts instead of hosts and are consistently used for malicious purposes by miscreants.

The closest work to EVILCOHORT is BOTGRAPH [39]. Similar to EVILCOHORT, this system looks at accounts that are accessed by a common set of IP addresses. However, BOTGRAPH relies on heuristics that are dependent on the email-sending habits of accounts to perform detection, and therefore limit its applicability to the spam-fighting domain. Conversely, EVILCOHORT is principled, and can be applied on any online service without pre-existing domain knowledge. In addition, the fact that EVILCOHORT can be applied on activity other than email-sending events (for example login events) allows us to detect malicious activity other than sending malicious content (e.g., online accounts used as a C&C channel). Another difference is that BOTGRAPH calculates its threshold over a 30-day period, and therefore is not suited to perform detection on freshly-created accounts. In this paper, on the other hand, we showed that EVILCOHORT can work in one-day batches, and detect as malicious accounts that were created during that same day.

9 Conclusions

We presented EVILCOHORT, a system that detects malicious accounts on online services by identifying communities of accounts that are accessed by a common set of computers. Our results show that the vast majority of the accounts that form such communities are used for malicious purposes. In the rare cases in which legitimate communities of accounts form, we show that such communities present characteristics that are very different than the ones of malicious communities. These differences can be used to perform more accurate detection. We ran EVILCOHORT on two real-world datasets, and detected more than one million malicious accounts.

Abstract

In this work we expose wide-spread efforts by criminals to abuse the Chrome Web Store as a platform for distributing malicious extensions. A central component of our study is the design and implementation of WebEval, the first system that broadly identifies malicious extensions with a concrete, measurable detection rate of 96.5%. Over the last three years we detected 9,523 malicious extensions: nearly 10% of every extension submitted to the store. Despite a short window of operation—we removed 50% of malware within 25 minutes of creation— a handful of under 100 extensions escaped immediate detection and infected over 50 million Chrome users. Our results highlight that the extension abuse ecosystem is drastically different from malicious binaries: miscreants profit from *web traffic* and *user tracking* rather than email spam or banking theft.

1 Introduction

Browsers have evolved over recent years to mediate a wealth of user interactions with sensitive data. Part of this rich engagement includes extensions: add-ons that allow clients to customize their browsing experience by altering the core functionality of Chrome, Firefox, and Internet Explorer. Canonical examples include search toolbars, password managers, and ad blockers that once installed intercept webpage content through well-defined APIs to modify every page a user visits.

Criminals have responded in kind by developing malicious extensions that interpose on a victim's browsing sessions to steal information, forge authenticated requests, or otherwise tamper with page content for financial gain. Poignant malware strains include Facebook account hijackers, ad injectors, and password stealers that exist purely as *man-in-the-browser* attacks [21, 25, 37, 41]. While many of these threats have binary-based equivalents—for instance the Torpig banking trojan that injected rogue phishing forms into banking webpages or the ZeroAccess bot that tampered with page advertisements [27, 34]—extensions bridge the semantic gap between binaries and browsers, trivializing broad access to complex web interactions.

In this paper we expose wide-spread efforts by criminals to abuse the Chrome Web Store as a platform for distributing malicious extensions. Our evaluation covers roughly 100,000 unique extensions submitted to the Chrome Web Store over a three year span from January 2012–2015. Of these, we deem nearly *one in ten* to be malicious. This threat is part of a larger movement among malware authors to pollute official marketplaces provided by Chrome, Firefox, iOS, and Android with malware [7, 10, 42].

A central component of our study is the design and implementation of WebEval, the first system that broadly identifies malicious extensions with a concrete, measurable detection rate of 96.5%. We arrive at a verdict by classifying an extension's behaviors, code base, and developer reputation. In the process, we incorporate existing techniques that detect specific malware strains and suspicious extension behaviors and evaluate each of their effectiveness in comparison to our own [21, 37, 41]. WebEval also faces a unique challenge: live deployment protecting the Chrome Web Store where attackers have a strong incentive to adapt to our infrastructure. We explore the impact that evasive threats have on our overall accuracy throughout our deployment and the necessity of human experts to correct for model drift.

In total, we removed 9,523 malicious extensions from the Chrome Web Store. The most prominent threats included social network session hijackers that generated synthetic likes, friend requests, and fans; ad injectors that rewrote DOM content to laden pages with additional advertisements; and information stealers that injected rogue tracking pixels and covertly siphoned search keywords. Despite a short window of operation—we reported 50% of malware within 25 minutes of creation—a handful of under 100 malicious extensions distributed via binary payloads were able to infect nearly 50 million users before removal. We distill these observations into a number of key challenges facing app marketplaces that extend beyond just the Chrome Web Store.

In summary, we frame our contributions as follows:

- We present a comprehensive view of how malicious extensions in the Chrome Web Store have evolved and monetized victims over the last three years.
- We detail the design and implementation of our security framework that combines dynamic analysis, static analysis, and reputation tracking to detect 96.5% of all known malicious extensions.
- We highlight the importance of human experts in operating any large-scale, live deployment of a security scanner to address evasive malware strains.
- We explore the virulent impact of malicious extensions that garner over 50 million installs; the single largest threat infecting 10.7 million Chrome users.

2 Background

We provide a brief background on how users obtain extensions and the control extensions have over the Chrome browser that simplify malware development.

2.1 Chrome Web Store

The Chrome Web Store is the central repository of all Chrome extensions. While initially the store was an optional ecosystem, rampant abuse outside of the store lead to Chrome locking down all Windows machines in May 2014 [13]. With this policy decision, Chrome now automatically blocks all extensions not present in the store from installation.

The Chrome Web Store relies on built in protections against malware that subject every extension to an abuse review. This approach is not unique to Chrome: Firefox, iOS, and Android all rely on application reviews to protect their user base from malware [1, 14, 17]. Malicious extensions detected during preliminary review are never exposed to the public. In the event the Chrome Web Store retroactively detects a malicious extension, the store can take down the offending code and signal for all Chrome clients to expunge the extension [16]. This defense layer provides a homogeneous enforcement policy for all Chrome users compared to the heterogeneous security environments of their desktop systems that may have no recourse against malicious extensions.[1]

2.2 Chrome Extension Architecture

Developers author extensions much like websites using a combination of JavaScript, CSS, and HTML. Unlike websites, extensions are exempt from same origin protections and are afforded a range of Chrome and document-level controls that allow customizing how users interact with the Internet.

Permissions: Extensions may interact with privileged Chrome resources such as tabs, cookies, and network traffic through a Chrome-specific API. Chrome mediates these sensitive capabilities through a coarsely defined permission model where a permission consists of a resource (e.g., cookies) and a scope (e.g., *https://mail.google.com*) [4]. When a developer authors an extension, she lists all desired permissions in a static manifest. As discussed by Carlini *et al.*, this design favors "benign but buggy" extensions where the author adheres to a principle of least privilege [9]. The model provides no protection against malicious extensions beyond explicitly signaling broad capabilities (e.g., intercepting all network traffic).

Background Page & Content Scripts: Chrome loads an extension's core logic into a long running process called a background page. This privileged process obtains access to all of the Chrome API resources specified in the extension's permission manifest. To prevent permission re-delegation attacks, Chrome isolates background pages from all other extensions and web sites. Chrome eases this isolation by allowing extensions to register content scripts that run directly in the context of a web page as though part of the same origin (and thus with access to all of the origin's DOM content, DOM methods, and session cookies). Background pages communicate with content scripts through a thin message passing layer provided by Chrome. As with the Chrome API, extensions must specify content scripts and the targeted domains in an extension's manifest.

3 System Overview

We develop our system called WebEval to protect the Chrome Web Store from malicious extensions. The challenge is messy and fraught with evasive malware strains that adapt to our detection techniques. We rely on a blend of automated systems and human experts who work in conjunction to identify threats and correct for failures surfaced by user reports of abuse. Before diving into detailed system operations, we highlight the design principles that guided our development and offer a birds eye view of the entire architecture's operation.

[1] Chrome extensions are not supported on Android or other mobile platforms. As such, we limit our discussion of malicious extensions to desktop environments.

3.1 Design Goals

At its heart, WebEval is designed to return a verdict for whether an extension is malicious. If the extension is pending publication, the Chrome Web Store should *block* the extension from release. Previously published extensions must be *taken down* and uninstalled from all affected Chrome instances. Arriving at a malware verdict is constrained by multiple requirements:

1. *Minimize malware installs.* Our foremost goal with WebEval is to minimize the number of users exposed to malicious extensions. However, near-zero false positives are imperative as Chrome expunges an extension's entire user base if we return a malware verdict incorrectly. We design our system such that human experts vet every verdict prior to actioning.

2. *Simplify human verification.* Whenever possible, our system should be fully automated to minimize the time required from human experts to confirm an extension is malicious.

3. *Time-constrained.* Our system embargoes extensions from public release until we reach a verdict. Its critical that we return a decision within one hour. Relatedly, our system must scale to the throughput of newly submitted items to the Chrome Web Store and weekly re-evaluated extensions that we estimate at roughly 19,000 reviews/day.

4. *Comprehensible, historical reports.* Any automated reports produced by our system must be comprehensible to human analysts, including machine learning verdicts. Similarly, all reports should contain some annotation to allow a historical perspective on the evolution of malicious extensions.

5. *Tolerant to feature drift.* Finally, our system must keep pace with the evasive nature of malware and adaptations in monetization strategies. This includes allowing experts to easily deploy new rules to capture emerging threats that are then automatically incorporated into long-running detection modules.

3.2 System Flow

WebEval is a living system that has evolved over the last three years in response to threats facing the Chrome Web Store. We describe our current pipeline for classifying an extension as malicious in Figure 1. The system consists of four stages: (❶) a scheduler that submits extensions for evaluation; (❷) our extension execution framework that captures behavioral signals; (❸) an annotation phase that incorporates content similarity, domain reputation, and anti-virus signatures; and finally (❹) scoring where manually curated rules, an automated classifier, and human experts reach a verdict for whether an extension is malicious.

Scheduler: We feed every extension uploaded to the Chrome Web Store, either new or updated, into our system and analyze it within one hour of submission. In total, we analyzed 99,818 Chrome extensions submitted over the course of January 2012–January 2015. This set includes extensions that were blocked prior to public release.[2] Furthermore, we have access to each revision of the extension's code base: over 472,978 unique variants (measured by SHA1 sums). Each revision triggers a rescan in addition to a weekly re-scan aimed at extensions that fetch dynamic, remote resources that can become malicious.

Evaluation: We subject every extension to an evaluation phase that extracts behavioral signals for classification. This includes a reputation scan of the publisher, static analysis of the extension's code base, and dynamic analysis that emulates common tasks performed in Chrome: querying search engines, visiting social media, and browsing popular news sites. We store all raw features for posterity, totaling over 45 TB. Our philosophy is to retain everything (even packet contents) in order to enable offline analysis in the event an extension becomes defunct due to dead or broken remotely fetched resources. This storage simultaneously enables tracking trends in malware behavior over time and retroactively applying new malware signatures. We present the full details of our evaluation framework in Section 4.

Annotation: We practice a defense in depth strategy that incorporates domain blacklists, anti-virus engines, and content similarity that contextualizes an extension's behaviors against the larger ecosystem of malicious developers and extensions. We include these signals as annotations to an extension's evaluation in the event our own behavioral suites fail to surface any malicious logic. We present the annotation process in greater detail at the end of Section 4.

Scoring: The final step of WebEval returns a verdict for whether to expunge a malicious extension. We use a combination of manually curated rules and a logistic regression classifier re-trained daily over all previously detected malicious extensions to generate a score. A human expert then confirms our automated verdict before passing our decision on to the Chrome Web Store to take action. We present our technique for training, regulariza-

[2] We note that any extensions blocked prior to release are absent from the previous work by Kapravelos *et al.* [21] that studied malicious extensions found in the Chrome Web Store.

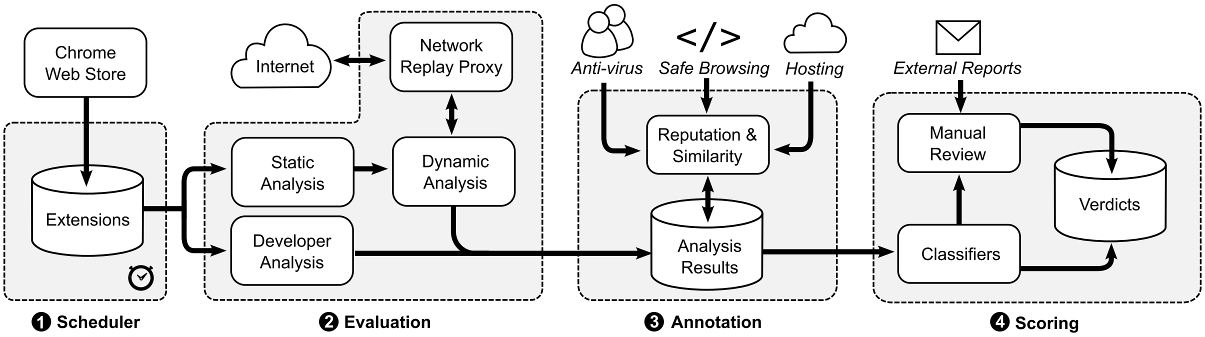

Figure 1: Our pipeline for detecting malicious extensions. WebEval's architecture consists of a scheduler, extension execution framework, an annotator that incorporates third-party security intelligence, and finally scoring where we return a malware verdict.

tion, and manual decision rules in Section 5. We discuss our approach for obtaining labeled data and evaluating our system's accuracy later in Section 6.

4 Evaluating Extensions

WebEval's core automation systems generate a report that surfaces signals about an extension's code base, the impact it has a user's browsing experience, and who developed the extension. With a few exceptions, none of these signals in isolation indicate outright malice: we leave it up to our classifier and human experts to determine which combinations of features clearly distinguish malware.

4.1 Static Analysis

Apart from remotely fetched resources, all of an extension's HTML, CSS, JavaScript, and manifest are self-contained and available to the Chrome Web Store upon submission. We scan through these components to identify potential threats.

Permissions & Content Scripts: We enumerate all an extension's permissions, content scripts, and contexts. Permissions in particular offer some indication of an extension's capabilities such as intercepting and modifying traffic (*proxy, webRequest*), triggering on a page load (*tabs*), introspecting on all cookies (*cookies*), and uninstalling or disabling other extensions (*management*). As part of this process we also identify broad contexts (e.g., <all_urls>, *https://**) that allow an extension to interact with every page.

Code Obfuscation: We scan for the presence of three types of code obfuscation: minification, encoding, and packing. We build on the detection strategy of Kaplan *et al.* that identifies common character substrings found in obfuscated vs. unobfuscated code [20]. Instead of detecting individual characters, we develop a set of regular expressions that identifies boilerplate initialization tied to the most prominent packers (e.g., *jsmini.com*, *jscompress.com*, and */packer/*). We employ a similar approach for detecting long encoded character strings. Finally, we detect minification by measuring the distance between a prettified version of an extension's JavaScript against the original supplied by the developer.

Files and Directory Structure: We extract the file names and directory structure of an extension as well as text shingles of the contents of every file. We rely on these features for detecting near-duplicate extensions (discussed in Section 4.4) as well as identifying commonly imported libraries and malicious files.

4.2 Dynamic Analysis

We collect the majority of our malware signals by black-box testing each extension with a barrage of behavioral suites that simulate common browsing experiences as well as custom tailored detection modules that trigger malicious logic. While more exhaustive approaches such as symbolic JavaScript execution exist [32], in practice we obtain sufficient enough behavioral coverage to reach accurate malware verdicts as discussed in Section 6.

Sandbox Environment: Our testing environment consists of a Windows virtual machine outfitted with two logging components: (1) a *system monitor* that captures low-level environment changes such as Windows settings, Chrome settings, and file creation; and (2) an *in-browser activity logger* that interposes on and logs all DOM events and Chrome API calls. This activity logger is natively built into Chrome explicitly for monitoring the behavior of extensions [28]. We note that Chrome isolates extensions from this logging infrastructure. Extensions cannot tamper with our results unless they compromise Chrome itself.

We supplement our monitoring infrastructure by routing all network traffic through a *network logging proxy*. This proxy also serves as a replay cache. For each test suite we develop, we first record the network events produced by Chrome absent any extension installed. During dynamic evaluation we replay any network events from the cache that match. If a cache miss occurs, we route requests out of our sandbox to the Internet. This proxy allows us to minimize page dynamism, guarantee that test suites are consistent across executions absent new dynamic behavior, and reduce overall network round trip time. Similarly, we can easily flag network requests produced by our test actions (e.g., a click or fetching ad content) versus those produced by an extension.

The output of our dynamic analysis is a list of all network requests, DOM operations, and Chrome API calls made by an extension. Each of these include the page the event occurred on as well as the remote target of XHR requests and injected scripts. We supply all of these as raw features to our classifier as well as to human experts who can generate manual rules that capture sequences of events tied to known malware strains.

Behavioral Suites: The event driven nature of extensions requires that we replay realistic browsing scenarios to trigger malware. Our system allows human experts to record complex interactions (e.g., clicks, text entry, etc) with webpages that we then replay against every extension to detect malicious behaviors. These simulations, called behavioral suites, cover querying *google.com* with multiple searches; logging into *facebook.com* via a test account and viewing the account's news feed; shopping on *amazon.com* and *walmart.com*; and lastly browsing popular media sites including *nytimes.com* and *youtube.com*. As new threats arise, analysts can easily deploy new behavioral suites to trigger a malicious extension's logic.

Generic Suites: Our replay suites are by no means exhaustive; we rely on a generic set of test suites to simulate a wider variety of browser events. These tests are duplicates of the techniques previously discussed by Kapravelos *et al.* for Hulk [21] and include simulating network requests to popular news, video, shopping, and banking sites to trigger an extension's *webRequest* handler as well as using HoneyPages that create dummy elements on the fly to satisfy JavaScript requests from extensions.

Malicious Logic Suites: We supplement our browsing actions by explicitly testing an extension's logic against known threats: uninstalling other extensions (e.g., anti-virus, Facebook malware remover); preventing uninstallation by terminating or redirecting tabs opening *chrome://extensions*; and stripping or modifying Content Security Policy headers. We explicitly flag each of these activities in addition to the log signals produced throughout the extension's evaluation.

4.3 Developer Analysis

The closed-garden nature of the Chrome Web Store enables tracking fine-grained reputation about developers and the extensions they author. We monitor where developers log in from, the email domain they use to register, the age of the developer account, and the total number of extensions authored thus far. These signals help us detect fake developer accounts that miscreants register via commonly abused email providers and proxies, staples of abusive account creation [39]. We note that newly registered developers must pay a nominal one-time fee of $5 that increases the overhead of churning out fake accounts [15].

In the event a malicious extension escapes initial detection, we also incorporate signals generated from users interacting with the Chrome Web Store. These includes the number of installs an extension receives, the number of users who have rated the extension, and the average rating. Our intuition is that highly used extensions that never receive any feedback are suspicious as are extensions that receive many low ratings.

4.4 Annotation

In the event the signals we collect during evaluation are insufficient, we rely on a defense in depth strategy that incorporates intelligence from the broader security community. In particular, we scan all of the files included in an extension with multiple anti-virus engines similar to VirusTotal.[3] If any single anti-virus vendor reports a file as malicious we flag the file in our report. We extend a similar strategy to all of the outgoing network requests produced by an extension where we scan the domains contacted against Google Safe Browsing and a collection of domain blacklists.

We also evaluate an extension in the context of all previously scanned extensions. We take the text shingles of an extension's code base computed during static analysis and identify near-duplicate extensions that share 80% of the same code. This approach allows us to detect extension developers that routinely re-upload previously detected malicious extensions. We extend this clustering logic to group extensions based on common embedded strings such as Google Analytics UIDs, Facebook App IDs, and Amazon Affiliate IDs. Finally, for extensions that evade initial detection and are released to the Chrome Web Store, we cluster the extensions based on the referrer of all incoming install requests to identify common websites involved in social engineering. We surface these clusters to human experts along with the ratio of known malware in each cluster.

[3] Due to licensing agreements, we are unable to disclose which anti-virus software we scan with.

5 Scoring Extensions

We reach a concrete verdict of an extension's malice by flagging any extension caught by our automated classifier or manually constructed heuristics. A human expert then verifies our decision and removes the offending extension from the Chrome Web Store if appropriate.

5.1 Automated Detection

Our automated detection uses a proprietary implementation of an online gradient descent logistic regression with L1 regularization to reduce the size of our feature space [6]. We believe similar accuracy can be achieved in a distributed fashion with the open source machine learning libraries provided by Spark [33]. We train a model daily over all previously scanned extensions with labeled training data originating from human experts (discussed shortly in Section 6).

Our feature set for classification consist of a collection of over 20 million signals. For each extension we construct a sparse string feature vector that contains every requested permission, the contexts the extension operates on, whether obfuscation was present, and a string representation of all of the extension's file names and directory structure. From dynamic analysis we include a feature for every DOM operation, Chrome API call, XHR request, remotely contacted domain, and a bit for whether the extension uninstalled a security related extension, prevented uninstallation, or modified CSP headers. From the developer analysis we include the email domain, last login geolocation, and a discretized bucket of the developer account's age.

We exclude annotation signals from learning; they are only used by human experts for manually curating rules and analyzing clusters of badness. We also exclude text shingles both to limit our feature space and retain meaningful signals. Our philosophy is that any input to the classifier should have a direct translation to an activity that analysts can recognize rather than loosely contextualized text blobs.

As part of the learning stage, we assign each feature a weight which we optimize using a gradient descent on a logistic regression model. In particular, we use L1 regularization to reduce our feature set to roughly 1,000 of the most impactful features. These features become decision rules, which we use to classify new extensions. Because human reviewers cannot look at every single extensions in the Web Store, we have variable confidence in the malware or benign labels assigned to training instances. To compensate for this, we multiply the gradient descent learning rate with a correction factor that is proportional to an approximate confidence level. Every known malware items gets a correction factor of 1.0 due to prior vetting by a human expert. On the other hand, the learning rate for benign items is scaled down by the following factor:

$$f = \frac{min(\frac{P}{P_t}, 1.0) + min(\frac{A}{A_t}, 1.0)}{2}$$

We represent the popularity of an extension P as the number of existing installs and the age of an extension A as the number of days since the extension was published. P_t and A_t represent thresholds above which we omit any penalty. This correction factor captures the risk that a new extensions with no user base is malicious and yet to be identified, while seasoned extensions with tens of thousands of users are likely benign.

For the sake of tuning the learning pipeline, we use 5-folds cross validation to confirm we do not overfit the model. The final model we use in production is trained on 100% of the data available. For the purposes of our study, we evaluate our model based on its accuracy the next day rather than relying on a holdout golden dataset.

5.2 Manual Rules

We supplement our automated detection with manually curated rules generated by human experts that address many of the most prominent threats facing the Chrome Web Store (discussed later in Section 7). While these rules are fall backs in the event our automated classifier fails, they are immensely helpful in contextualizing the monetization strategy of malicious extensions that we track over time. We note that all extensions surfaced by these rules are still subject to expert verification.

Facebook Hijacking: Initial reports of malicious extensions hijacking a victim's Facebook account to post status updates, send chat messages, befriend users, or "like" content without consent first emerged in 2012 and have persisted ever since [29]. We detect these extensions by scanning network logs produced during dynamic evaluation for outgoing network POSTs to resources (e.g., *ajax/follow/follow_profile.php*) that may indicate unauthorized account behavior.

Ad Injection: Ad injection extensions insert or replace web advertisements. We identify this behavior by comparing the origin of inserted DOM elements and injected scripts against a list of known advertisers derived from third party ad block software, previous reports on ad injection affiliate programs [37, 41], and domains surfaced during manual review. We also scan for DOM operations that replace existing advertisements on any of the pages visited during our behavioral suites where we know ad positions *a priori*.

Search Leakage: Search leakage broadly refers to any extension that funnels search queries to third parties, typically for modifying search results, injecting advertisements, or tracking user interests. We detect search leakage by scanning outgoing network requests to determine whether they contain the same keywords our behavioral suite supplies to *google.com*. This module may potentially miss term leakage in the event of encrypted or obfuscated network parameters.

User Tracking: We rely on a heuristic to detect user tracking that involves scanning all DOM operations for the insertion of 0×0, 1×1, or hidden image during dynamic analysis. We consider any such operation a likely indicator of inserting a tracking pixel.

6 Evaluation

We evaluate WebEval under a live deployment and track daily accuracy as vetted by human experts. As part of our analysis we offer insights into the most important features for classification and the role of human experts in correcting for evasive strains.

6.1 Dataset

Our evaluation dataset consists of 99,818 extensions scored by WebEval between January 2012–2015. Human experts provided our ground truth labels. Due to the possibility of delayed detection we continue to update labels one month after the cut off for our dataset. In total, experts identified 9,523 malicious extensions (9.4% of all extensions created during the same window). For the purposes of our evaluation, we define WebEval's verdict as a *false positive* if WebEval returned a malware label that was either rejected as incorrect by human experts or later refuted by the extension's developer and overturned upon secondary review. Similarly, we define a *false negative* as any extensions surfaced by human experts or external reports despite our system returning a benign verdict. We likely underestimate false negatives as some threats are bound to escape both automated and external review.

6.2 Overall Accuracy

We measure the precision and recall of WebEval as a function of all scored extensions over the last three years. In total, our machine learning pipeline and manually curated rule sets surfaced 93.3% of all known malicious extensions to human experts (recall). Of the extension's that WebEval flagged as potentially malicious, human experts agreed 73.7% of the time (precision). If we restrict our calculation to the last year, WebEval had a recall of 96.5% and a precision of 81%. We find that accuracy is a living process that we detail in Figure 2.

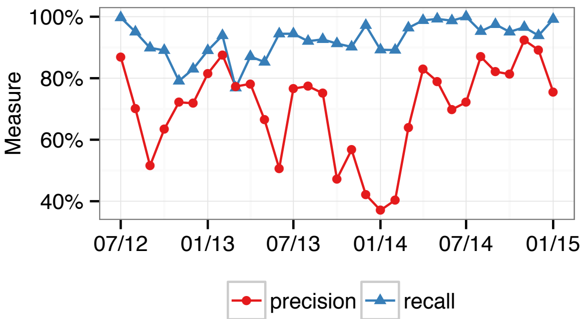

Figure 2: Monthly precision and recall of all scoring systems in aggregate from 2012–2015.

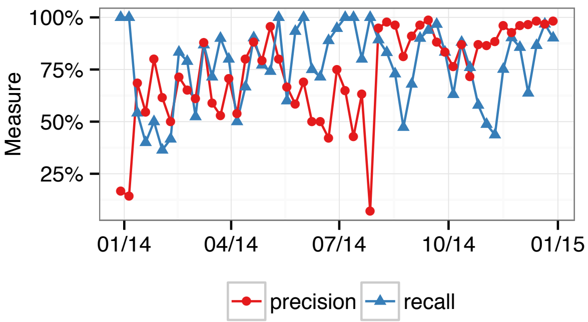

Figure 3: Weekly precision and recall of logistic regression classifier from 2014–2015.

We experience drops in recall when new threats emerge which we subsequently recover from via updated rules and daily retraining of our classifier with new samples. We consistently value recall over precision: we would rather burden human experts with more reviews rather than expose users to malicious extensions. Nevertheless, our precision is reasonable enough as to not force human experts to review every extension in our dataset.

6.3 Automated Classifier Accuracy

Ideally WebEval can run in a purely automated fashion without curated rules or expert verification. We evaluate this possibility by calculating the precision and recall of our logistic model, shown in Figure 3. Over the last year our classifier surfaced 77% of known threats. Human experts agreed with our model's verdict 86% of the time. Overall performance has steadily increased over time with the addition of new features, an increasing training corpus, and increasingly frequent model retraining. Accuracy of the classifier during the final two weeks of our evaluation boasted 98% precision and 91% recall—on par with human experts. However, new threats always require human intervention as indicated by consistent drops in recall throughout time: while the model can quickly recover with daily retraining, we maintain that

Requested Permission	Precision	Recall
tabs	12%	84%
webRequest	23%	39%
webRequestBlocking	22%	27%
notifications	14%	27%
contextMenus	15%	26%
storage	9%	25%
webNavigation	21%	19%
cookies	10%	14%
unlimitedStorage	14%	13%
idle	27%	10%

Table 1: Top 10 permissions requested in extension manifest.

Chrome API	Precision	Recall
runtime.onInstalled	12%	79%
tabs.onUpdated	29%	61%
runtime.connect	21%	50%
extension.getURL	25%	34%

DOM Operation	Precision	Recall
eval	10%	76%
Window.navigator	19%	59%
XMLHttpRequest.onreadystatechange	31%	56%
XMLHttpRequest.open	21%	53%
Document.createElement	20%	47%
Window.setTimeout	18%	46%
Node.appendChild	20%	45%
HTMLElement.onload	25%	30%
HTMLScriptElement.src	51%	25%
Window.location	23%	12%

Table 3: Top 10 DOM operations performed during dynamic execution.

Behavioral Signal	Precision	Recall
XHR Request	30%	52%
Code Obfucsation	21%	25%
Script Injected	50%	19%
HTTP 400 Error	41%	9%
Modifies CSP Headers	86%	2%
Uninstalls Extension	96%	0.5%
Prevents Uninstallation	100%	0.1%

Table 4: Precision and recall of individual behavioral signatures.

experts must always be part of our pipeline to minimize both false positives and false negatives. This is an immediate consequence of a centralized market for extensions where there are limited external sources of labeled training data. In contrast, email and telephony spam systems can rely on honeypots and informed users to readily generate representative daily training data. While our human throughput currently scales to the size of the Chrome Web Store, larger ecosystems face a significant challenge for sustainable accuracy.

6.4 Relevance of Individual Signals

WebEval is an amalgam of behavioral signals where no single feature captures the majority of malicious extensions. We examine assumptions we had of certain behaviors, whether they are unique to malware, and which signals are the most important to classification.

Requested Permissions: We list the most popular permissions used by malware and benign extensions in Table 1. These permissions include allowing an extension to trigger when Chrome creates a new tab (84% of all malware) or when Chrome generates a network request (39%). While these behaviors appear fundamental to malware they are equally prevalent in benign applications. This observation captures a significant limitation of the current Chrome permission model as applied towards security judgments: coarse permissions required by all extensions provide no indication that an extension is malicious. Similarly, 93% of all malicious extensions request to interact with every URL as do 57% of all other extensions. These broad contexts make it difficult to determine the pages an extension interacts with, further complicating dynamic analysis.

Chrome API Calls & DOM Operations: We find the strongest features for detecting malware originate from a mixture of Chrome API calls and DOM operations. We provide a list of the most common operations in Table 2 and Table 3. The majority of malware (and benign extensions) rely on injecting scripts, generating XHR requests, and adding new DOM elements that target newly created tabs. What distinguishes the two are the aggregate set of events triggered as well as the domains of remote resources loaded into a page (e.g., injected scripts or content). Our model effectively learns which resources are commonly fetched by malware in addition to common strategies for tampering with pages.

Malicious Logic: Recent work by Kapravelos *et al.* proposed a number of behavioral flags they deemed “suspicious” for extensions. We evaluate the effectiveness of

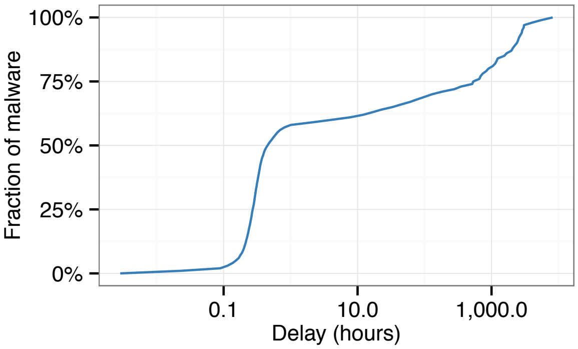

Figure 4: CDF of the delay before catching a malicious extension after it is first submitted to the Chrome Web Store. We catch malicious extensions within a median of 25 minutes.

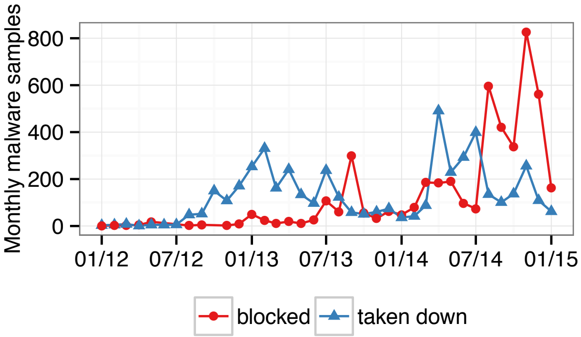

Figure 5: Actions taken against malicious extensions in the Chrome Web Store over time. Our systems are becoming increasingly proactive at blocking malware rather than reactive.

these signals in Table 4. We find that behaviors such as modifying CSP headers, uninstalling extensions, or preventing uninstallation are exclusive to malware, though rare. Contrastingly, Hulk's decision to surface extensions that produce network request errors or inject scripts would overly burden human experts due to low precision. These signals still have value, but they must be combined with the other features collected by our system in order to generate a precise verdict.

6.5 Detection Latency

A critical metric of WebEval's performance is our vulnerability window: the time between when a developer submits a malicious extension to the Chrome Web Store until its detection. This metric represents a worst case scenario where we assume an extension is malicious from its onset rather than after an update or a remote resource begins including malicious functions. Over the last year it took a median of 25 minutes before we flagged an extension as malicious—within the one hour window an extension is embargoed from public access. However, this delay has a long tail as shown in Figure 4. We catch 70% of malicious extensions within 5 days and 90% within 3 months. During this period, users are exposed to malicious content, the impact of which we evaluate in Section 7. Over time, our verdicts have become increasingly proactive rather than reactive as shown in Figure 5. Blocked extensions never reach the public, while extensions taken down by the Chrome Web Store leave users vulnerable for a short period. As we discuss shortly, proactive blocking has a substantial impact on reducing the number of known victims exposed to malware.

6.6 Manual Review Effort

WebEval relies heavily on human experts to validate the verdicts of automated classification and manual rules to guarantee high precision. In the last year, we surfaced 10,120 suspicious extensions for review, entailing a total of 464 hours of analysis—an average of 2.75 minutes per extension. This process is simplified by access to all of WebEval's dynamic and static analysis and concrete training features as previously discussed in Section 4 and Section 5. We recognize that manual review by experts represents a scarce resource that is challenging to scale. Consequently, we continuously look for ways to improve automated verdicts to achieve a precision on par with human experts.

7 Trends in Malicious Extensions

Consistently high recall over the last three years allows us to provide a retrospective on how malicious extensions have evolved over time. This includes the monetization vectors used, the breadth of users impacted, and the developers responsible.

7.1 Abuse Vectors

Despite hundreds of new monthly malicious extensions, we find the strategies for abusing Chrome users have remained largely constant. Figure 6 shows a breakdown of abuse strategies of extensions per month where a manually curated label is available;[4] we categorize extensions flagged by automated systems that provide no context on abuse vectors as "other". Noticeably absent from the top threats are banking trojans, password theft, and email spam. While these are all within the realm of a malicious extension's capabilities—and have cropped up from time to time—such threats are dwarfed by Facebook hijacking, ad injection, and information theft.

[4] Labels are not guaranteed to be unique; an extension can simultaneously hijack Facebook credentials, inject ads, and insert tracking pixels.

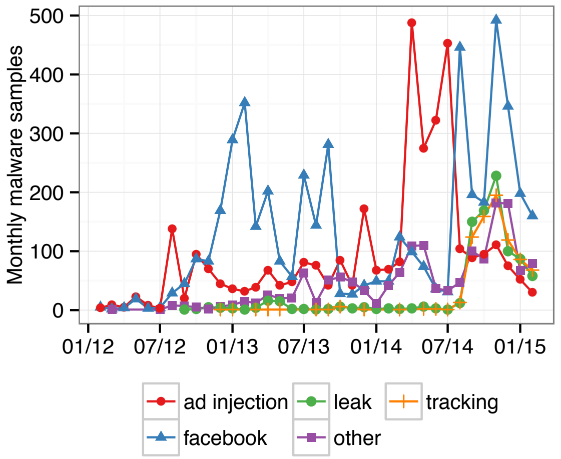

Figure 6: Malware varietals detected each month from 2012–2015.

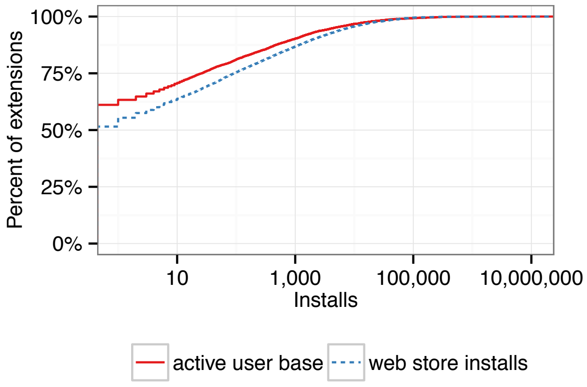

Figure 7: CDF of installs broken down by those originating from the Chrome Web Store and an extension's active pings that capture both store-based and sideloaded installs.

Facebook Hijacking: Our findings show that Facebook malware remains a persistent threat with over 4,809 variants in the last three years. These malicious extensions purport to offer enhancements such as removing the Facebook Timeline, adding a "dislike" button, or changing the theme of the Facebook interface. The hook has evolved over time. The latest rendition tricks users into installing an extension masquerading as a video codec required to view a video posted by a friend. Once installed, the extension hijacks the victim's credentials to post status updates that propagate the malware. How the extensions monetize Facebook accounts is not entirely clear, but appears to involve inflating likes, fans, and friend counts much like previously studied fake engagement contagions on Twitter [36, 38].

Ad Injection: Ad injection is the second most prevalent threat in the Chrome Web Store comprising 3,496 extensions. These extensions rely on content scripts that run on every page that allow the extension to scan DOMs for common banners to replace with rogue advertisements or simply insert new ads into pages. We note that ad injection is not expressly prohibited by the Chrome Web Store: the extensions flagged also performed some other malicious behavior or violated one of the store's policies as determined by a human expert.

Other Variants: In recent months we have witnessed a larger variety of abuse vectors. In depth investigations of a sample of these extensions reveal malware tampering with bitcoin wallets, injecting into banking sessions for Brazilian institutions, and modifying Amazon affiliate URLs. While we lack manual rules for these specific abuse vectors, we are nevertheless able to catch them via our classifier.

7.2 Installs

Malicious extensions obtain installs in one of two fashions: (1) via binaries that modify Chrome's user profile to sideload extensions,[5] or (2) via social engineering where miscreants direct users to the Chrome Web Store or prompt users with an install dialogue on a third-party site. We measure both approaches using two metrics. We define an extension's *active user base* as the total number of Chrome clients who ping the Chrome Web Store with update requests (sent by all extensions, including sideloaded extensions). This value changes each day as users install or uninstall extensions, so we select the all-time maximum. We define an extension's *web store installs* as the total number of install dialogues Chrome clients initiate with the Chrome Web Store. We note that a third option exists for miscreants to obtain installs: paying an existing, legitimate extension developer to hand over their app. In practice, we found only 6 malicious extensions (0.06%) that involved an ownership transfer.

Evidence of Side Loading: We provide a breakdown of both install metrics in Figure 7. We find that 51% of malicious extensions never received any active user base or Web Store installs due to early detection. Evidence of sideloading is relatively rare: only 290 extensions had a larger active user base than Web Store installs. However, these extensions were immensely popular with over 43.5 million combined active users. In contrast, all malicious extensions combined received 29.6 million installs via the Chrome Web Store. As such, it would appear that binary distribution of malicious extensions contributed substantially to user infections. This allows malware authors to rely on the same distribution models of the past (e.g., drive-by downloads [30], exploit packs [18], pay-per-install [8]) while tapping into the extension API as a means for simplifying exploitation.

[5] The extension still must be in the Chrome Web Store due to the lockdown policy discussed previously in Section 2

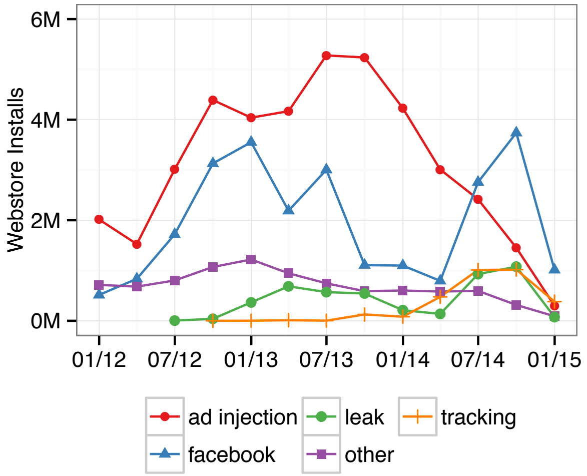

Figure 8: Malware installations via the Chrome Web Store for the past three years broken down by abuse vector. This excludes binaries sideloading extensions.

Country	Infected Users	Popularity
United States	2,375,363	8%
Brazil	1,982,570	7%
Mexico	1,942,288	6%
Colombia	1,634,933	5%
Turkey	1,569,949	5%
Argentina	1,525,364	5%
India	1,475,228	5%
Russia	1,244,932	4%
Peru	955,695	3%
Vietnam	806,625	3%

Table 5: Top 10 regions impacted by malicious extensions downloaded via the Chrome Web Store.

Equally problematic, installs follow a long tail distribution. We find that 64 extensions (1% of all malware) attained an aggregate 46.6 million active users, 83% of all installations. The top two most popular threats were ad injectors and search hijackers that each garnered over 10 million active users. Miscreants distributed each extension solely via binaries flagged as malware by Google Safe Browsing. Our results emphasize that seemingly small false negative detection rates can have substantial negative impact on Chrome users. This drastically differs from email and telephony spam where an incorrectly labeled message typically impacts only a single user—not millions.

Popular Social Engineering Campaigns: Focusing exclusively on installs mediated by the Chrome Web Store, we investigate which abuse vectors achieved the most new installs per month and the country of origin of installs. Figure 8 tracks the rise and fall of various monetization strategies over time. Despite a short window before catching malicious extensions we still find that social engineering campaigns enticed millions of new users each month to install Facebook malware, ad injection software, and information stealers. The downward trend in recent months is the result of proactive blocking rather than retroactive takedowns that expose users to malware for a short window. We find no single country is disproportionately represented as the source of installs, as shown in Table 5. Our results highlight the global scale and negative impact that malicious extensions have on users and the need for greater research attention to the problem.

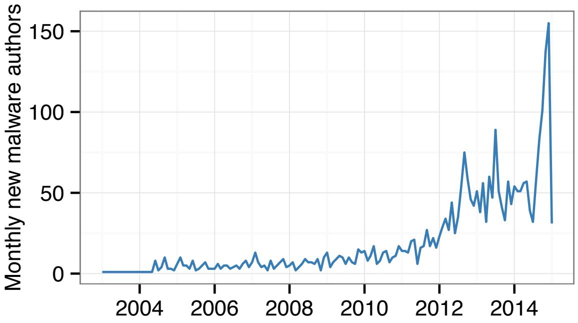

Figure 9: Registration time of malware authors. Most authors rely on accounts created in the last three years.

7.3 Malicious Developers

We identify 2,339 malicious extension developers throughout the course of our study. While 50% of developers authored their malicious extension within 3 to 4 months of registering, there is a long tail of potentially compromised accounts used to interact with the Chrome Web Store as shown in Figure 9. We find miscreants access 31% of developer accounts from IPs within Turkey followed in popularity by range of other countries detailed in Table 6. Many of the countries with the highest infection counts were also prominent locations for malicious developers indicating threats were likely localized. Re-use of malicious developer accounts was fairly limited: 50% of accounts authored fewer than 2 malicious extensions while 90% authored fewer than 10.

8 Discussion

With multiple years spent fighting malicious extensions, we reflect on some of the lessons we have learned, limitations of our approach, and potential technical and policy improvements that can help prevent malicious extensions in the future.

Country	Developers	Popularity
Turkey	552	31%
United States	164	9%
Dominican Republic	126	7%
Brazil	106	6%
Vietnam	83	4%
Russia	60	3%
Germany	43	2%
Peru	43	2%
India	43	2%
Israel	39	2%

Table 6: Top 10 login geolocations of malicious developers.

8.1 Lessons Learned

When we first set out to identify malicious extensions our expectation was to find banking trojans and password stealers that duplicated the strategies pioneered by Zeus and SpyEye. In practice, the abusive extension ecosystem is drastically different from malicious binaries. Monetization hinges on direct or indirect relationships with syndicated search partners and ad injection affiliate programs, some of which earn millions of dollars from infected users [37]. Miscreants derive wealth from *traffic* and *user targeting* rather than the computing resources or privileged access mediated via the browser. It may simply be that the authors of malicious binaries have little incentive (or external pressure) to change, leaving extensions to a distinct set of actors. This uncertainty is a strong motivation for exploring the extension ecosystem further.

A second lesson is the importance of equipping an abuse prevention team with the tools necessary to rapidly respond to new, unforeseen threats. As we have shown, even momentary lapses in protection have drastic consequences on Chrome users. This is especially true in the case of social engineering campaigns like those used to distribute malicious Facebook extensions that spread exponentially. We argue that evaluating a detection system purely on precision and recall is not effective when the ultimate goal is to protect users from malware installations. Instead, we must weigh false negatives by their consequences—the number of victims exposed to malware. In this light, our system has continuously improved over the last three years.

In the long term we believe the Chrome Web Store must extricate itself from the current fire-fighting approach to malicious extensions and outright disrupt the malicious actors involved. This reflects a nascent strategy within the research community to pursue criminal relationships such as those underpinning spammed pharmaceuticals [26]. However, to arrive at this point we must first lay a foundation for how to study the extension ecosystem. As the research community develops the necessary understanding this abuse space—and in particular the ad and search relationships involved—there must be a system to both protect users as well as generate longitudinal data on abuse strategies and their support infrastructure. WebEval satisfies both of these requirements.

8.2 Role of Policy

Research primarily considers technical solutions to abuse, but we argue that policy decisions prove equally effective at protecting users. When Chrome first released extensions there was no requirement of developers uploading their code to the Chrome Web Store. This enabled malicious developers to side-load extensions via binaries and left Chrome users with little room for discovering the installation or recourse. The subsequent Chrome lockdown forced all malicious extensions to at least be surfaced to the Chrome Web Store and created a homogeneous enforcement policy for all Chrome users. While binaries can still side-load extensions in the Chrome Web Store, WebEval now incorporates signals to detect organic versus silent installs.

It is worth noting the Chrome lockdown policy has some limitations. Anecdotally, we have observed binaries distributing payloads that overwrite the local content of legitimate extensions previously installed by a user. Because only the legitimate extension is in the store, WebEval cannot offer any protection. Chrome has since responded to this threat by introducing extension content verification, but this is just a single stage in an increasing arms race.

8.3 Limitations

Dynamic analysis and security crawlers consistently run the risk of overlooking malicious behaviors due to cloaking [2, 23, 31]. Extension analysis is equally vulnerable. Potential threats include malware delaying execution until after WebEval's evaluation; supplying benign versions of remotely fetched JavaScript until after evaluation; or malware developers fingerprinting our evaluation environment and IP addresses. A separate issue is code coverage: our behavioral suites are not guaranteed to trigger all of an extension's logic during evaluation. Worse, we face an intractably broad threat surface that we must test as the majority of malware requests access to every page a user visits. While symbolic execution systems exist for Javascript [32], they rely on fuzzing that is not guaranteed to trigger malicious behavior due to the implicit event-driven nature of extensions where activation requires a specific sequence of listeners to fire. Solutions to these challenges remain elusive; we currently rely on human experts and abuse reports to surface false negatives so we can adapt our detection framework.

8.4 Improving Detection

Fundamentally improving WebEval (and by proxy other security scanners) requires we break from evaluating extensions in a sandboxed environment vulnerable to cloaking and instead move to *in situ* monitoring of Chrome users. This strategy, previously considered by researchers to improve drive-by download detection [35], applies equally to malicious extensions. However, such a move creates a new challenge of balancing early infections of clients, user privacy, and anonymous but feature-rich reporting of an extension's behaviors with enough details to detect malice.

Furthermore, while we can retrain our a model of malicious extensions to incorporate client logs, the process would be immensely aided by the cooperation of website developers who label DOM resources as sensitive. We should take these labels as hints, not facts, to account for overzealous developers who label every DOM element as sensitive in an effort to dissuade extension modifications, even when desired by users. We believe this combined approach strikes the best balance between Chrome's current philosophy of allowing users to alter their browsing experience in any way with the necessity of early detection of malicious modifications.

9 Related Work

Security Sandboxes & Malware Detection: WebEval borrows heavily from a history of malware analysis sandboxes that capture system calls and network traffic. Examples include Anubis [5], CWSandbox [40], and GQ [24] among a breadth other architectures [12]. However, malicious extensions pose a unique set of challenges that limit the effectiveness of these sandboxes without modification. Unlike standalone applications, Chrome extensions run in the context of a webpage making it harder for traditional system-wide malware monitoring techniques to isolate malware activity from that of the browser. Our system manages to achieve this isolation by comparing extension activity to baseline activity captured while the extension was not running as well as by tapping natively into Chrome's JavaScript and API modules.

The closest system to our own is Hulk which captures in-browser activity logs [21]. Unlike Hulk, our system goes beyond identifying suspicious behaviors to return a concrete verdict of malice. This is imperative as the signals proposed by Hulk are insufficient at detecting most malicious extensions as we showed in Section 6. Research has also explored competing strategies such as information flow tracking in JavaScript with tainted inputs [11] or tracking common API calls made by Browser Helper Objects installed by adware [22]. These techniques influence our design but only capture a subset of the malicious extensions we identify.

Buggy & Malicious Extensions: Most research into browser extensions has focused on their security and permission model in light of the possible vulnerabilities [3, 4, 9, 19]. Only recently has research shifted towards the threat of outright malicious extensions. This includes re-imagining application-based attacks as man-in-the-browser threats [25]; examining the role of extensions in the ad injection ecosystem [37, 41]; and characterizing malicious extensions found in the Chrome Web Store [21]. Our observations agree with many of these former studies. We expand upon these works by offering a complete perspective of how malicious extension monetization techniques have evolved over the last three years and the techniques malware developers use to distribute extensions.

10 Conclusion

In this work we exposed wide-spread efforts by criminals to abuse the Chrome Web Store as a platform for distributing malicious extensions. As part of our study, we presented the design and implementation of a framework that automatically classifies an extension's behaviors, code base, and author reputation to surface malware. Due to our live deployment, this system cannot run in a fully automated fashion: we required regular inputs from human experts to correct for false negatives surfaced via Chrome user reports and manual investigations. Our unique combination of automated and human systems yielded a framework that identified 96.5% of all known malware submitted to the Chrome Web Store between January 2012–2015.

In total, we detected 9,523 malicious extensions that hijacked social networking sessions to generate synthetic likes, friend requests, and fans; ad injectors and affiliate fraudsters that rewrote DOM content to laden pages with additional advertisements; and information stealers that injected rogue tracking pixels and covertly siphoned search keywords. Despite a short window of operation—we disabled 50% of malware within 25 minutes of creation—a handful of under 100 malicious extensions were able to infect over 50 million users before removal. Our results highlight key challenges of protecting app marketplaces that are broadly applicable beyond the Chrome Web Store.

Meerkat: Detecting Website Defacements through Image-based Object Recognition

Kevin Borgolte, Christopher Kruegel, Giovanni Vigna
University of California, Santa Barbara
{kevinbo,chris,vigna}@cs.ucsb.edu

Abstract

Website defacements and website vandalism can inflict significant harm on the website owner through the loss of sales, the loss in reputation, or because of legal ramifications.

Prior work on website defacements detection focused on detecting unauthorized changes to the web server, e.g., via host-based intrusion detection systems or file-based integrity checks. However, most prior approaches lack the capabilities to detect the most prevailing defacement techniques used today: code and/or data injection attacks, and DNS hijacking. This is because these attacks do not actually modify the code or configuration of the website, but instead they introduce new content or redirect the user to a different website.

In this paper, we approach the problem of defacement detection from a different angle: we use computer vision techniques to recognize if a website was defaced, similarly to how a human analyst decides if a website was defaced when viewing it in a web browser. We introduce MEERKAT, a defacement detection system that requires no prior knowledge about the website's content or its structure, but only its URL. Upon detection of a defacement, the system notifies the website operator that his website is defaced, who can then take appropriate action. To detect defacements, MEERKAT automatically learns high-level features from screenshots of defaced websites by combining recent advances in machine learning, like stacked autoencoders and deep neural networks, with techniques from computer vision. These features are then used to create models that allow for the detection of newly-defaced websites.

We show the practicality of MEERKAT on the largest website defacement dataset to date, comprising of 10,053,772 defacements observed between January 1998 and May 2014, and 2,554,905 legitimate websites. Overall, MEERKAT achieves true positive rates between 97.422% and 98.816%, false positive rates between 0.547% and 1.528%, and Bayesian detection rates[1] between 98.583% and 99.845%, thus significantly outperforming existing approaches.

1 Introduction

The defacement and vandalism of websites is an attack that disrupts the operation of companies and organizations, tarnishes their brand, and plagues websites of all sizes, from those of large corporations to the websites of single individuals [1–3].

In a website defacement, an attacker replaces the content of a legitimate website with some of his/her own content. A website might be defaced for many different reasons and in many different ways: For example, an attacker might deface the website by brute-forcing the administrator's credentials, by leveraging a SQL injection to introduce content or code, or by hijacking the domain name; however, all defaced websites share one characteristic: the defacer leaves a message that is shown to the visitors of the website instead of the legitimate content, changing the visual appearance of the website.

Although nearly all defacers vandalize websites for their "15 minutes of fame," and to get a platform to publicize their message, their messages vary: some embarrass the website's operator, others make a political or religious point, and others again do it simply for "bragging rights." For instance, in the beginning of November 2014, as reported by the BBC [4], attackers defaced the website of the Keighley Cougars, a professional rugby club from England competing in League 1. The defacers modified the website so that visitors were greeted with a message in support of the terrorist organization "Islamic State of Iraq and the Levant/Syria" (ISIL/ISIS). Similarly, in late 2012, defacers close to the Syrian regime defaced the homepage of the prominent Qatari television network Al Jazeera, and instead of being shown news articles, visitors were greeted by a message alleging Al Jazeera of "spreading false fabricated news." Reliably detecting such website defacements is challenging, as there are many ways in which an attacker can tamper with the website's appearance, including re-routing the traffic to a different website, which does not affect the legitimate website's content directly in any way.

In this paper, we introduce MEERKAT, a website monitoring system that automatically detects if a website has been defaced. MEERKAT detects website defacements by rendering the website in a browser, like a normal visitor

[1] The Bayesian detection rate is the likelihood that if we detect a website as defaced, it actually is defaced, i.e., P(true positive|positive).

would, and deciding, based on features learned exclusively from screenshots of defacements and legitimate websites observed in the past, if the website's *look and feel* is that of a defaced or a legitimate website. If the website is detected as being defaced, the system notifies the operator, who, in turn, can, depending on the confidence in MEERKAT's decision, put the website (automatically) in maintenance mode or restore a known good state to reduce the damage.

Our technical contributions in this paper are:

- We introduce MEERKAT, a website defacement detection system that learns a high-level feature set from the visual representation of the website, i.e., it learns a compressed representation of the *look and feel* of website defacements and legitimate websites. Based on the learned features, the system then produces a model to differentiate between defaced and legitimate websites, which it uses to detect website defacements in the wild. In addition, the system notifies the website's operator upon detection (Section 3).
- We evaluate MEERKAT on the largest website defacement dataset to date, comprising of 10,053,772 website defacements observed between January 1998 to May 2014, and 2,554,905 legitimate and (supposedly) not defaced websites from Alexa's, MajesticSEO's, and QuantCast's top 1 million lists (Section 4).

In the remainder of this paper, we make a compelling case for the need of an accurate and lightweight website monitoring system that detects website defacements (Section 2), discuss how MEERKAT works in detail (Section 3), evaluate our system on the largest defacement dataset to date (Section 4), discuss some limitations of website defacement detection systems (Section 5), compare MEERKAT to related work (Section 6), and, finally, we conclude (Section 7).

2 Motivation

Lately, the detection of website defacements as a research topic has not received much attention from the scientific community, while, at the same time, defacements became more prominent than they have ever been. The number of reported defacements has been exceeding the number of reported phishing pages since October 2006 by a factor of 7 on average, and reached up to 33.39 defacements being reported to Zone-H[2] per phishing page reported to PhishTank[3] (see Figure 2). Yet, website vandalism is often played down as a problem instead of being acknowledged and addressed.

The increase in defacements is evident (see Figure 2): while a mere 783 verified defacements were reported on average each day to Zone-H in 2003, the number of reports increased to 3,258 verified defacements per day for the year 2012, to an all-time high of over 4,785 verified defacements being reported each day to Zone-H in 2014. This corresponds to an increase of websites being defaced by 46.87% from 2012 to 2014 [5].

Similarly, according to the Malaysian Computer Emergency Response Team (CERT), 26.04% of all reported incidents in 2013 were website defacements, but only 1.5% of the reported incidents were defacements in 2003, and 10.81% were website defacements in 2007 [7, 8].

Furthermore, in 2014, attackers confirmedly defaced over 53,000 websites ranked on Alexa's, MajesticSEO's, and QuantCast's top 1 million lists. Corroborating that not only websites that are "low-hanging fruit" are being defaced, but that high-profile ones are being attacked alike (see Table 1).

This recent resurgence and the increase in defacements and "cyber-vandalism" is generally attributed to the rise of hacktivist groups, like *anonymous* or *LulzSec* [9, 10], but also gained traction through the escalation of international conflicts [11, 12]. Although the scientific consensus is that the attacks employed to deface a website are usually rather primitive in nature [9], hacktivist groups and other politically- and religiously-motivated defacers have been extremely successful in the past: in February 2015, Google Vietnam was defaced by *Lizard Squad* for several hours [13]; in January 2015, the website of Malaysia Airlines was defaced by *Cyber Caliphate* [3]; in late 2014, the defacer group *Team System Dz* defaced over 1,700 websites to speak out against the actions of the US in the Syrian civil war and to advocate for ISIS/ISIL [2]; in April 2014, over 100 websites be-

[2] Zone-H [5] is an archive containing only defaced websites, all reported defacements are mirrored locally and manually verified [6]. Upon manual inspection, a reported defacement is removed from the archive if it does not constitute a defacement, or it is marked as verified.

[3] PhishTank is the largest public clearinghouse of data about phishing scams, users report potential phishing scams and other users agree or disagree with the submitter, resulting in a user-assigned phishing score. Phishing pages are not being verified by expert analysts.

longing to the government and major companies in Zambia were defaced by Syrian and Saudi Arabian defacers to voice against the Western world's *meddling* in the Syrian civil war [14]; in January 2014, the website of the popular mobile game Angry Birds was defaced in protest of governmental spying by the NSA and GHCQ [15]; and, in October 2013, a Pakistani defacer group gained access to the domain registrars of Suriname, Antigua & Barbados, and Saint Lucia and defaced the regional websites of Audi, AVG, BlackBerry, BMW, Canon, Coca-Cola, Fujitsu, Hitachi, Honda, IBM, Intel, Microsoft, Samsung, Symantec, Rolls-Royce, Vodafone, and other companies simply for "bragging rights" [16].

A prime example that quantifies the impact of defacements is the case of the Telegraph, a major UK daily newspaper, which was defaced in September 2011. The Telegraph is the third most-visited website in the United Kingdom, according to MajesticSEO, and it is the 21st most visited website in the United States, according to Alexa. Each month, the homepage of the Telegraph is visited over 125 million times (48 times per second), and, since reports state that the defacement lasted around three hours, we can estimate that more than 500,000 people saw the defacement instead of the legitimate website.[4]

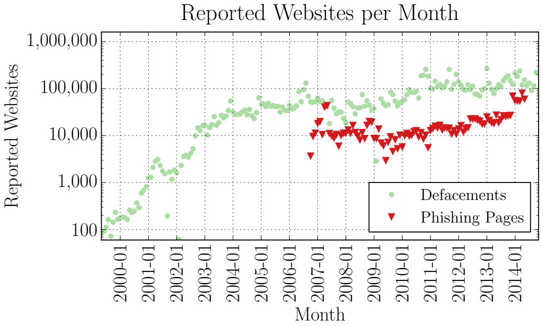

Figure 2: Defacements reported to Zone-H and phishing pages reported to PhishTank, per month from January 2000 to including October 2014. The drops in reported defacements in February 2002, February 2009, and March 2009 are because Zone-H was under maintenance during that time and did not accept any new reports. No data is available from PhishTank earlier than October 2006, when the website was launched. The trend of an increasing number of defacements per month, as well as the gap in the number of defacements to the number of phishing pages of a factor of up to 33x are evident.

While the list of prominent defacements goes on [4, 17–25], it is important to note that most techniques to deface a website, like code and data injection attacks (such as SQL injections), improper access control, or DNS hijacking and poisoning, have been well-studied and protection mechanisms have been proposed by prior

[4] Since the website was defaced on a Sunday afternoon local time in the United Kingdom, the number of visitors is likely much higher.

work [26, 27]. However, it is extremely hard to protect against all defacement attacks simultaneously and at scale.

Even worse, organizations are often responsible for hundreds (or thousands) of different websites, with different levels of security [9]. A single insecure website that is defaced, however, can inflict significant harm on the organization: in qualitative terms because of the loss of reputation, and in quantitative terms because of the cost of having to investigate and remove the defacement.

Although defacements can inflict serious harm on the website operator, a two-month study by Bartoli et al. [28] shows that many website operators still react slowly to defacements with an average response time of over 72 hours. Moreover, their study finds that mere 24% of the defaced websites were restored within one day, about 50% defacements were removed within the first week, while more than 37% of the websites remained defaced for over two weeks. Overall, their findings suggest that prior website defacement protection techniques and detection methods have not been widely adopted.

We argue that the logical first step is to reduce the harm inflicted on the website operator by quickly detecting if his/her website has been defaced, so that the operator can put the website in maintenance mode or restore its content to a known good state. As such, an automatic, accurate, and lightweight defacement detection system that monitors websites, notifies the website's operator, and acts as an early warning system is desired. In this paper, we propose one such system, MEERKAT.

3 Meerkat

The approach MEERKAT takes to detect website defacements is fundamentally different from prior work for three reasons. First, while the system does leverage machine learning for classification, it does not rely on handpicked features that were selected based on prior domain knowledge, i.e., it requires no feature engineering. Instead, MEERKAT relies on recent advances in machine learning, stacked autoencoders, to learn high-level features directly from data. Second, MEERKAT does not require the website operator to supply any information other than the domain name at which his/her website can be accessed. We designed our system in this way because other defacement detection systems that require the operator to define keywords and other metadata, provide a reference version of his/her website, or describe the website's legitimate content, have been rarely adopted in the past. By reducing the effort required from the website operator to actually use a defacement detection system, we hope to improve on this situation. Finally, MEERKAT approaches defacement detection visually: the system analyzes the *look and feel* of the website and how a user would experience it by rendering it in a web browser and analyzing a screenshot of the website, instead of analyzing its source code or content.

Approaching the problem of detecting website defacements visually has several advantages over analyzing the source code or content of a website: some defacements rely heavily on JavaScript and Cascading Style Sheets (CSS) to stylize the defacement, which all must be analyzed in an overarching browser context, and others again rely heavily on images. In fact, similar to spam, phishing, and many scams, defacements often do not contain much textual content, but include images to display text instead [29], thus they trivially evade text-based detection approaches. Furthermore, the source code of two websites can be vastly different, yet they appear the same to the human eye when rendered in a browser. Therefore, leveraging prior work, such as DELTA [30], to analyze the DOM-tree, the website's code, or parts thereof, is unlikely to be successful when trying to detect website defacements accurately, which is why we opted for a perceptual approach that does not suffer from the aforementioned problems.

Following, we describe how MEERKAT learns from defacements and legitimate websites, and how it detects defacements in the wild. Next, we motivate the structure of our deep neural network briefly, then, we discuss the concept and motivation of fine-tuning the network, then, we provide some notes on our implementation, and, last, we briefly recap how MEERKAT can be deployed in practice.

3.1 Training and Detection

Before MEERKAT can be trained, two crucial parameters must be selected that determine how and from what data the system learns the *look and feel* of defacements:

Window Size. MEERKAT is not trained on whole screenshots of websites, but on a window "into" each website (i.e., only a part of the screenshot), thus we must select the size of these *representative windows*. Some important considerations must be made before picking the size of the windows that we extract.

A small window can be more accurate because it might only contain the exact representative part of the defacement but not any noise, like an irrelevant background color. However, if the windows are too small, the system will also have more false positives because the windows are not representative of defacements; instead, they are representative for only parts of the defacements, which might also occur in legitimate websites.

On the other hand, when using larger windows, it will take significantly longer to train the network initially, but the network might learn a more accurate model. However, if the windows are too large, then the system will learn about specific kinds of defacements in-detail and overfit; e.g., the system might learn that two defacements are different, while the two defacements are actually the same but have a slightly different, dynamically-generated background image.

Considering the trade-offs for different window sizes, for our implementation, we decided to extract windows that are 160×160 pixels in size. Our evaluation later shows that this window size works well in practice to detect website defacements (see Section 4). We briefly explored other window sizes, like 30×30, that fared worse.

Window Extraction Strategy. The strategy to extract the representative window from a screenshot is fundamental to learn the *look and feel* of defacements and legitimate websites. If the windows are extracted according to some poorly chosen strategy, then we expect the classification accuracy to be poor as well. For instance, if the strategy always extracts the part of a website that is just a plain background, the system will only detect plain backgrounds. Therefore, it is crucial that the window extraction strategy is chosen well, and we compare some suitable strategies, like extracting the window always from the center or at random, later (see Section 3.1.2).

After selecting these parameters carefully, the system can be trained. This is where most of the complexity of MEERKAT lies. The training phase works as follows:

1. We collect a considerable amount of labeled website defacements and legitimate websites, and we extract their graphic representation (i.e., a screenshot of the browser window; Section 3.1.1)

2. For each sample, we extract the `160×160` representative window from each screenshot according to the selected extraction strategy (Section 3.1.2).

3. The representative windows are first used to learn the features of our approach, and then to learn the model for classification, for which we use a neural network (Section 3.2).

Once the neural network is trained, MEERKAT detects defacements in the wild. Its detection phase consists of only two steps, on which we expand later:

1. The website is visited with a browser to retrieve a representative screenshot (Section 3.1.1).

2. A sliding window approach is used to check if the website is defaced and, if so, an alert is raised (Section 3.1.3).

3.1.1 Screenshot Collection

The first step to detect if a website has been defaced based on its *look and feel* is to collect a screenshot of how the website looks for a normal visitor. MEERKAT visits the website with a browser that renders the website like any other browser would, and takes a screenshot once the browser finished rendering the website. In our implementation, we use PhantomJS to collect the screenshots of the websites. PhantomJS is a headless browser based on the Webkit layout engine that renders websites (nearly) identical to Safari or Google Chrome. PhantomJS also executes included JavaScript code, renders Cascading Style Sheets (CSS), and includes dynamic content, such as advertisements, like a browser that a human would use.

Another important aspect in collecting a representative screenshot of a website with a headless browser is the resolution of the *simulated* screen. The resolution of the display is important when collecting screenshots because many websites render differently for different screen sizes, such as for mobile devices, tablets, small notebooks, or large displays. In our case, we decided to fix the resolution to `1600×900` pixels, which is a display resolution often found in budget and mid-range notebooks.

3.1.2 Window Extraction Techniques

For training the system, after collecting the screenshots, we need to extract a representative window from each screenshot so that we can train the neural network to detect defacements. Various techniques can be used to extract the representative window, which can be grouped into deterministic and non-deterministic techniques. Hereinafter, we discuss the trade-offs for four possible techniques: (i) selecting the center window, (ii) selecting n non-overlapping windows according to some measure (explained later), (iii) uniformly selecting the window at random, and (iv) randomly sampling the window's center from a Gaussian distribution for the x and y dimension separately.

Deterministic Window Extraction

The most straightforward deterministic technique is to always extracts the window from the center of the screenshot of the website. However, this makes evading the system trivial. Generally, if an attacker can accurately predict the window that will be extracted, he can force the system to learn about defacements poorly, and, in turn, deteriorate classification performance drastically. Therefore, such a simple technique is unsuitable for a detection system in an adversarial context.

Alternatively, one can extract the window according to some measure. Identifying the most representative window according to a measure (e.g., the Shannon entropy), however, forces us to compute it for all possible windows and then pick the top ranking one. In turn, for a `1600×900` screenshot and a `160×160` window, we would need to evaluate over 1 million candidate windows for each sample in the dataset. In total, for our dataset, this would require over 13 *trillion* computations of the measure just to extract the representative windows. Clearly, this is impractical.

Nonetheless, a deterministic selection strategy based on a clever measure can increase the accuracy of the system, and it can also be extended trivially to extract multiple top-ranking windows at no additional cost. However, using more than one window per sample increases the dataset size by a factor of n and prolongs training time. Therefore, n would have to be chosen carefully.

Taking into account the trade-offs the different deterministic extraction strategies bear (increased training/detection time, ease of evasion, or computationally impractical) and considering that a comprehensive evaluation of them would require at least an order of magnitude of additional experiments,[5] we decided to select a non-deterministic extraction strategy that follows intuition and is based on user interface and user experience design principles instead. This selection makes our classification performance a lower bound: other window extraction strategies might be more accurate and/or robust, but (at the same time) they also incur significant additional cost at training and/or detection time.

[5] Performing these additional experiments would require at least 6 months just in computational time on our current GPU infrastructure, which is why we decided against performing them.

Non-deterministic Window Extraction

A straightforward non-deterministic strategy to extract a window from a screenshot is to select it uniformly at random. However, one cannot simply take any point from the website's screenshot as the center of the window. Instead, it must be sampled so that the whole window contains only valid data, forcing us to sample its center from the interval $[80, 1520]$ for x and $[80, 820]$ for y (these intervals are specific to the screenshot (`1600×900`) and window size (`160×160`)). Therefore, pixels at the border have a slightly lower probability to occur in a window than those in the center. Although this is an unintended side effect, it has negligible impact in practice because the center of a website is more likely to be descriptive anyways. Alternatively, we could create an "infinite" image by wrapping the screenshot at its borders, which would, however, yield artifacts because we would combine parts of the top of the website with parts of the bottom (and left and right, respectively), resulting in windows that do not occur on the real website, which, in turn, might disturb or confuse detection.

Alternatively to selecting the window's center uniformly at random, one can sample it from any other distribution, discretizing the sampled point. For instance, from a Gaussian distribution to extract windows from mostly the center of the screenshot, but not extracting from it exclusively. A focus on the center of the website is often desirable because it is likely to be more descriptive of the website's *look and feel*. For robustness, however, we also want to the system to not learn exclusively from the center but to also learn about defacements that occur at the border of the website. Therefore, for our implementation, we extract a single window per website with a Gaussian extraction strategy with $\mu_x = 800$ and $\sigma_x = 134.63975$ for x and $\mu_y = 450$ and $\sigma_y = 61.00864$ for y, so that the windows at the border of the screenshot have a lower probability to be sampled but are not ignored completely. If x and y values outside of the screenshot are sampled, we simply resample the value for x or y respectively. We selected the μ and σ values this specifically so that we sample values outside of the screenshot only with likelihood 0.0001%.

3.1.3 Defacement Detection

After MEERKAT has been trained on a set of extracted windows, it can detect if a website has been defaced. Detecting website defacements with MEERKAT is conceptually extremely simple:

1. We visit the website that we want to check with our browser and we take a screenshot of the rendered website (Section 3.1.1).

2. We apply a standard sliding window detection approach on the screenshot we took to check if a part of the screenshot is detected as being defaced, similarly to prior work in image classification [31].

3. If a window is detected to be a defacement by MEERKAT, we raise an alert and inform the website operator that his/her website has been defaced.

Note that MEERKAT does not compare a possibly-defaced website to an older, legitimate version of it, and, thus, does not need to analyze or store an older version. Instead, it detects defacements solely by examining how the current version looks like.

Exclusively to improve performance, instead of starting in a corner of the screenshot, our system starts in the center and moves outward. This behavior is motivated by the fact that the center of the website is likely more descriptive, and our training set was focused on the center region of the screenshots. This does not mean, however, that MEERKAT misses defacements that are at the border of a website, they will be detected when the sliding window reaches the actually-defaced part, the border. The same is also true if a website is only partially defaced: once the sliding window reaches the defaced area, MEERKAT detects that the website is defaced.

Additionally, a special case worth mentioning is that a legitimate website might show a large promotional screen or an advertisement with the same intention of a website defacer: attracting attention. In turn, such a promotional screen might be similar in its *look and feel* to that of a website defacement. While MEERKAT might currently (theoretically) mislabel them as defacements, our evaluation shows that they do not matter much (see Section 4). Furthermore, if they start to matter at one point in the future, it is straightforward to consider them: the defacement engine can make use of an advertisement blocker, and the website operator could whitelist the system to not be shown any promotional screens.

3.2 Neural Network Structure

In this section, we briefly discuss the design of our deep neural network and how the different layers of the network interact with the input image. The structure of our deep neural network was notably inspired by prior work by Le at al. [32], Krizhevsky et al. [33], Sermanet et al. [31], and Girshick et al. [34]. We refer to them for further details.

The main components of our deep neural network are autoencoders, which we stack on top of each other, and a standard feed-forward neural network. Autoencoders are a special type of neural network that are used for unsupervised learning. The goal of an autoencoder is to find a compressed, possibly approximated encoding/representation of the input, which can be used to remove noise from the input, or, when autoencoders are stacked, they can learn high-level features directly from the input, like where edges in an image are, or if cats or human faces are part of an image [32].

Overall, the structure of our deep neural network is based on the following idea: first, we use a stacked autoencoder to denoise the input image and learn a compressed representation of both defaced and legitimate websites, i.e., we leverage the stacked autoencoder to learn high-level features, similar to Le et al. [32]; second, we utilize a feed-forward neural network with dropout for classification, similar to Krizhevsky et al. [33].

The initial layer of our stacked autoencoder is comprised of local receptive fields. This layer is motivated by the need to scale the autoencoders to large images [32, 35–38], this layer groups parts of the image to connect to the next layer

Figure 3: Architecture of our deep neural network.

of the autoencoder, instead of allowing the whole image to be used as input to each node of the following layer. It takes 20,164 (142^2) sub-images of size 18×18 as input, extracted at a stride of 1 from the 160×160 representative window (see Figure 3; note that each pixel in each sub-image has three dimensions for the three colors: red, green, and blue). The second layer of our stacked autoencoder employs L2 pooling to denoise local deformations of the image and to learn invariant features [37, 39–41]. Finally, the last layer of our autoencoder performs local contrast normalization for robustness [42].

The output of the stacked autoencoder is then used as the input to a feed-forward neural network with dropout that provides a 2-way softmax output. The 2-way softmax output corresponds to the two classes that we want to detect: defaced websites and legitimate websites. We use dropout in our deep neural network to prevent overfitting of the network, and to force it to learn more robust features by preventing neurons to rely that other neurons of the network are available (i.e., to prevent the co-adaptation of neurons) [43].

3.3 Fine-Tuning the Network's Parameters

In an adversarial context, such as when trying to detect if an attacker defaced a website, concept drift can be introduced intentionally by the attacker and impede the accuracy of the detection system drastically. Furthermore, concept drift also occurs naturally, such as when the style of defacements evolves over time in such a way that the features cannot distinguish between legitimate and defacement anymore. Therefore, concept drift can be a severe limitation of any detection system, if it is not taken into account and addressed properly (see Section 5.1).

MEERKAT can deal with concept drift in two different, fully-automatic ways: fine-tuning the network's parameters (adjusting feature weights), and retraining the entire network on new data. While the latter is conceptually straightforward and addresses all kinds of concept drift, it is computationally very expensive. The former, on the other hand, allows us to deal with some forms of concept drift gracefully and is computationally much less expensive. However, it requires some further attention: when fine-tuning the neural network, MEERKAT does not learn new features, but adjusts how important the already learned features are. Therefore, fine-tuning cannot address major concept drift for which the already learned features do not model defacements accurately anymore. Instead, when we fine-tune the network's parameters, we adjust the already learned weights of the deeper layers of the neural network so that new observations of defacements and legitimate websites are classified properly. As such, fine-tuning the network to maintain an accurate detection performance requires no additional information about the websites at all, but only defacements and legitimate websites that were not part of the training set before.

Conceptually speaking, when fine-tuning the network given new defacements and legitimate websites, we search for a better and, given the new data, *more optimal* set of weights in the space of all possible weights. To do so more efficiently, instead of initializing the weights at random, we initialize them based on the previously-learned weights.

3.4 Implementation

For this paper, we implemented a prototype of MEERKAT using Python and the "Convolutional Architecture for Fast Feature Embedding" (Caffe) framework by Jia et al. [44]. Caffe was used because of its high-performance and ease of use, however, it does not offer all functionality that our neural network requires and some modifications were made.

Overall, the general architecture of MEERKAT is embarrassingly parallel: the screenshot collection engine is completely separate from the detection engine except for providing its input. For instance, to quickly collect the screenshots of all websites, we utilized 125 machines (with 2 cores and 2 GiB memory each), and collection peaked at about 300 screenshots per second. Similarly, once the neural network has been trained, the learned parameters can be distributed to multiple machines and detection can be scaled out horizontally, and, although the system is trained on a GPU, once trained, the detection engine does not require a GPU and can run on common CPUs instead.

Training the system, on the other hand, is not parallelized to multiple machines yet, but some clever tricks can be used to reduce training time significantly [33], which we leave for future work.

3.5 Real-world Deployment

MEERKAT's main deployment is as a monitoring service, acting as an early warning system for website defacements, to which a website operator subscribes with only the URL at which his website can be reached. For each monitored website, the system regularly checks, such as every few minutes (or even seconds), that the website is not defaced. If it detects it as being defaced, it notifies the website's operator, who, in turn, depending on the confidence in the warning, manually investigates, or automatically puts the website in maintenance mode or restores a known good state. Acting as an early warning system, MEERKAT reduces the reaction time to defacements from hours, days, and even weeks (see Section 2) down to minutes (or even seconds), and, therefore, it reduces the damage inflicted on the website's operator by the defacement significantly.

Furthermore, MEERKAT can also reduce human labor: currently, Zone-H manually vets all submissions for defacements [6], of which nearly two thirds are invalid. MEERKAT automates this significant amount of work.

4 Evaluation

We evaluate our implementation of MEERKAT in various settings. However, first, we provide details on what data our dataset is comprised of, and how we partition it to simulate various defacement scenarios.

Our evaluation scenarios are traditional and simulations of real-world events, such as a new defacer group emerging, or how the system's accuracy changes over time, with and without fine-tuning the neural network.

In our experiments, a true positive is a website defacement being detected as a defacement and a true negative is a legitimate website being detected as legitimate. Correspondingly, a false positive is a legitimate website that is being detected as being defaced, and a false negative is a defacement being detected as being legitimate.

4.1 Dataset

The dataset on which we evaluate MEERKAT contains data from two different sources. First, it includes a comprehensive dataset of 10,053,772 defacements observed from January 1998 to May 9, 2014; we obtained this data through a subscription from Zone-H, but it is also freely available from `http://zone-h.org` under a more restrictive license. From those defacements, 9,258,176 defacements were verified manually by Zone-H [6]; the remaining 795,596 website defacements were pending verification and we do not include them in our dataset. Second, our dataset contains 2,554,905 unique (supposedly) undefaced websites from the top 1 million lists from Alexa, MajesticSEO, and QuantCast.[6] Note that we cannot be certain that the legitimate websites in our dataset are not defaced, and since manual verification is impractical at such a large scale, the true negative rate is actually a lower bound and the false positive rate is an upper bound, correspondingly. In layman's terms: the system might be more accurate than our results suggest.[7]

To accurately evaluate the classification performance of MEERKAT in a real-world deployment, we report its accuracy in three different scenarios:

- Traditional, to compare to prior work, i.e., by performing 10-fold cross-validation by sampling from all data uniformly at random, so that each bin contains 925,817 defacements and 255,490 legitimate websites.
- Reporter, to simulate a new defacer emerging, i.e., by performing 10-fold cross-validation on the reporters of a defacement and including only their defacements in their respective bin; legitimate website are sampled from the legitimate data uniformly at random.
- Time-wise, to evaluate the practicality of our approach in a real-world setting, i.e., we start by training the system on all data from December 2012 to December 2013, and, then, we detect defacements from January to May 2014. We report the system's detection accuracy for each month.

We evaluate our system in these settings to prevent a positive skew of our results that might be the result of the different evaluation method and how the dataset is composed. For instance, a reporter of a defacement might introduce an inherit bias to the distribution of the defacement by only reporting the defacements of one specific defacer (such as themselves), or there might be a bias in how defacements and how the web evolved. Those potential pitfalls might skew the results positively or negatively and must be considered for an accurate comparison to prior work.[8]

Finally, to account for the difference in the number of samples of the legitimate websites (2,554,905) and defaced websites (10,053,772), we report the Bayesian detection rate [45]. The Bayesian detection rate is normalized to the number of samples and corresponds to the likelihood if we detect a website as being defaced, it is actually defaced (the likelihood of a positive prediction being correct, that is a true positive; i.e., P(true positive|positive)).

4.2 Features Learned

The features that MEERKAT learns depend on the data it is being trained on. Although one can treat the system as a black-box and not worry about its internal details, understanding how it comes to its final decision helps one to reason about its robustness and to understand how difficult the system is to evade or to estimate when the system must be retrained to retain its accuracy. In our experiments, MEERKAT learned various features automatically and directly from image data, of which we manually grouped some on a higher, more conceptual level together. We manually identified the learned features by evaluating which representative windows activate the same neuron of the neural network, i.e., which windows trigger the same feature to be recognized by MEERKAT. Note that all the features we discuss hereinafter have been learned *automatically* from data and no domain knowledge whatsoever was required to learn and use these features; yet, the overlap with features that an analyst with domain knowledge would use confirms the prospects of feature/representational learning for website defacement detection. Some of the learned features can be best described as:

Defacement group logos. MEERKAT learned to recognize the individual logos of some of the most prolific defacement groups directly (see Figure 4). Clearly, the

[6] We made a list of all 2,554,905 legitimate websites included in our dataset available at `http://cs.ucsb.edu/~kevinbo/sec15-meerkat/legitimate.txt.bz2`.

[7] Over 191,000 website in our legitimate dataset have been defaced at one point in the past, thus, it is likely that some of them are actually defaced and therefore mislabeled; thus, if classified correctly as a defacement by MEERKAT, they appear as false positives in our results.

[8] We cannot compare prior work on our dataset directly as they do not scale to its size, and we cannot compare on their datasets because they are too small to train MEERKAT accurately (see Section 6.1).

logos of the defacer groups themselves are extremely descriptive of website defacements because they are very unlikely to be included in legitimate websites.

Color combinations. MEERKAT also learned to recognize unique or specific color combinations indicative of legitimate and defaced websites, including but not limited to one of the most prominent combinations: bright red or green text on a black background, which is an often used color combination by defacers, but rarely seen on legitimate websites. On the other hand, small black text on a white or brightly colored background is being consulted as a non-definitive indicator for a legitimate, non-defaced website.

Letter combinations. Interestingly, defacers often not only mix colors, but also mix characters from different alphabets right next to each other, such as Arabic or Cyrillic script being mixed with Latin script, to promote their message in both their native language and also in English as the web's *lingua franca*. Additionally, sometimes the defacement contains characters in a character set encoding specific to the defacer's native language, like ISO-8859-13 for Baltic languages or Windows-1256 for Arabic. As such, characters appear differently or are replaced by special characters if the browser does not support it, or if the website does not specify the character set and if the browser's fallback is different (like in our case, as we fall back to UTF-8), resulting in a *look and feel* that is descriptive of defacements, and, correspondingly, it was automatically learned by MEERKAT.

Leetspeak. Similarly to letter combinations, MEERKAT learned that defacers often use "leetspeak," an English alphabet in which some characters are replaced by numbers or special characters (e.g., "leetspeak" as "1337sp34k") and in which some words are deliberately misspelled ("owned" as "pwned," "the" as "teh," or "hax0red" instead of "hacked"). Defacers often use leetspeak to discern themselves from "common folks," and to show that they are "elite" and special, which, in turn, makes it often a good indicator that a website has indeed been defaced.

Typographical and grammatical errors. While some typographical mistakes are deliberate (as in the case of leetspeak, see above), many defacers make other unintentional typographical and grammatical mistakes, which rarely occurred on the legitimate websites in our dataset. Many defacers make these mistakes most likely because they are not native English speakers (the country of the reporter of the defacement, part of the meta-data in our dataset, suggests that most defacers do not speak English as their first language). MEERKAT learned to detect some of these mistakes at training and values them as a supporting indicator of a website defacement. Some of the examples of (supposedly) unintentional typographical and grammatical errors include "greats to" (instead of "greets to"), "goals is" (instead of "goals are"), or "visit us in our website" ("visit us at our website" or just "visit our website").

Note that, since MEERKAT works on image data, the system is unaware that it analyzes text and the textual features, such as unique letter combinations, leetspeak, or typographical and grammatical errors, are actually being evaluated on rendered text. As such, it seems likely that the textual features are specific to the font, possibly overfitting on the specific font type. However, we manually confirmed that the system actually learned a more robust feature and is not overfitting: it combines slight variances in the font family and size in a single high-level feature. Furthermore, given the sliding window approach MEERKAT employs for detection, the features are also completely independent of the position of the text in the representative window and website.

While some of the learned features can be evaded theoretically, evading them almost always contradicts the defacer's goal: making a name for themselves in the most "stylish" and personalized way possible, thus, it is unlikely that these features will change drastically in the near future. Furthermore, MEERKAT also consults features that were not as easy to discern into high-level feature groups manually, such as artifacts unique to legitimate or defaced websites, or features that are indicative for one group but are not definitive because they might appear more often in defaced websites, but also sometimes legitimately. MEERKAT can also be retrained easily and new features are learned *automatically* once the old features do not model defacements accurately anymore (i.e., if the concept of a defacement drifted significantly). Finally, since MEERKAT uses a non-linear classifier to combine those features, it can learn more complex models about defacements and legitimate websites, and simply evading only some features will not be sufficient to evade detection.

Interestingly, some of the high-level features (letter and color combinations) that MEERKAT learned automatically from data have been leveraged to a smaller degree by prior work [46, 47] (through manual feature engineering), while others (logos, leetspeak, and typographical mistakes) had not been utilized yet. Further suggesting that representation learning and inspection of the learned features can yield important insight into security challenges that were dominated by feature engineering in the past, such as intrusion, malware, or phishing detection.

4.3 Traditional Split

First, for an accurate comparison to prior work, we evaluate MEERKAT on our dataset using 10-fold cross-validation, i.e., we split the dataset into 10 bins that contain 925,817 website defacements and 255,490 legitimate websites each. Note that we discard 6 website defacements and 5 legitimate websites from our dataset at random to have the same number of samples in each bin. Next, for each bin, we train the system on the other 9 bins (training bins) and measure its classification performance on the 10^{th} bin (test bin). Considering the 10 different 90% training and 10% test-set partitions of our dataset separately, MEERKAT achieves true positive rates between 97.422% and 98.375%, and false positive rates ranging from 0.547% to 1.419%. The Bayesian detection rate is between 99.603% and 99.845%.

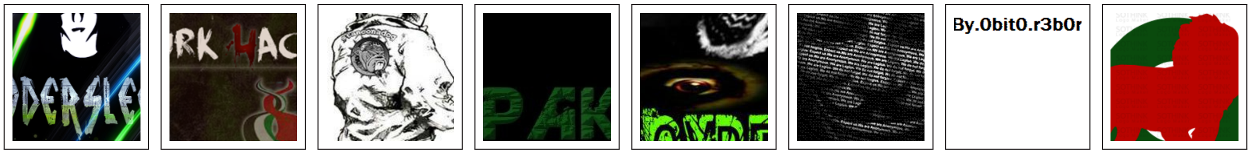

Figure 4: Defacement Group Logos. Example representative windows of logos of defacement groups that MEERKAT learned to recognized to be a significant indicator for defacements. Note that MEERKAT also recognizes variations and that there are many other features used for classification.

More interestingly, as a partition-independent measure of the system's classification performance, the average true positive rate is 97.878%, the average false positive rate is 1.012%, and the average Bayesian detection rate is 99.716%. If MEERKAT detects a defacement and raises an alert, with likelihood 99.716% it is a website defacement. Therefore, MEERKAT is significantly outperforming current state-of-the-art approaches.

4.4 Reporter Split

For the reporter split, we partition our dataset by the reporter of the defaced website. We deliberately designed the experiment this way to show that MEERKAT is not overfitting on specific defacements, which our results verify.

While a partition by reporter might seem counter-intuitive at first, it becomes clear that such a split is meaningful and that it can be used to evaluate that a new defacer group emerges once it is taken into account that these groups often have unique defacement designs and that defaced websites are most often reported by the defacers themselves. Therefore, if we split by reporter, we are practically splitting by defacer group; meaning, we create the most difficult scenario for a defacement detection system: detecting a defacer and his/her defacement style although we have never seen defacements from him/her before.

In the same way as for the traditional split, we employ 10-fold cross-validation. However, we do so slightly differently: first, we separate the reporters of the defacements into 10 bins uniformly at random (each bin containing 7,602 reporters). Second, we construct the corresponding defacement bins, i.e., we construct a defacement bin for each reporter bin so that it contains only the defacements reported by these reporters. For each bin, we then train MEERKAT on the remaining 9 bins and use the 10^{th} bin for testing. Note that the defacement bins contain a different number of samples, simply because the number of reported defacements varies per reporter (see Appendix A). We account for the uneven distribution of defacements by reporting the average true positive and false positive rate weighted by the number of samples.

Overall, when simulating the emergence of a new defacer, MEERKAT achieves a true positive rate of 97.882% and a false positive rate of 1.528% if bins are weighted, and 97.933% and 1.546% if they are not (see Figure 5; the true positive rate is between 97.061% and 98.465%, the false positive rate is between 0.661% and 2.564%). The Bayesian detection rates for the reporter split are 99.567% (unweighted) and 99.571% (weighted) respectively (per split, the Bayesian detection rate is between 99.286% and 99.814%).

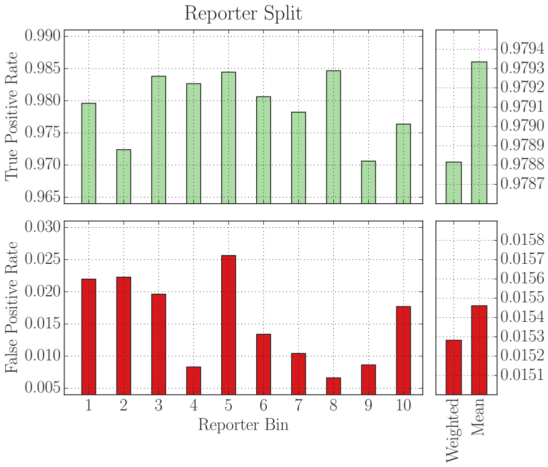

Figure 5: True positive and false positive rates for the reporter split, per bin of the 10-fold cross-validation set. Note that the scales for true positives and false negatives are the same, but that the *y*-axis goes from 0.965 to 0.99 for the true positive rate and 0.005 to 0.03 for the false positive rate. The weighted mean true positive rate is 97.882% and its false positive rate is 1.528% (weighted by samples per bin). The unweighted mean true positive rate is 97.933% and its false positive rate is 1.546%.

4.5 Time-wise Split

The time-wise experiment evaluates how well MEERKAT detects website defacements in the wild, i.e., in a real-world deployment. Here, we train the system on defacements seen in the past, and we detect defacements in the present. Similarly to the reporter split, the time-wise experiment shows that MEERKAT does not overfit on past defacements, and that it successfully detects present defacements.

Our training set selection follows a simple argument: it is extremely unlikely that websites today will be defaced in the same way as they were defaced in 2005 or even 1998. Including those defacements in our training set would then very likely decrease classification performance for defacement detection in 2014. Equivalently, one would not include this data to train the system in practice.

We train MEERKAT on all defacements that were reported between December 2012 and December 2013 (including, i.e., 13 months with 1,778,660 defacements observed in total), and 1,762,966 legitimate websites that we sample from all legitimate websites uniformly at random. We then detect defacements over a five months time frame, from January to May 2014, and we report the classification performance for each month. The test data from January to May 2014 spans a total of 1,538,878 unique samples that are distributed as follows: 421,758 samples from January 2014, 364,168 samples from February 2014, 474,758 samples from March 2014, 241,926 samples from April 2014, and 81,268 samples from the beginning of May 2014.

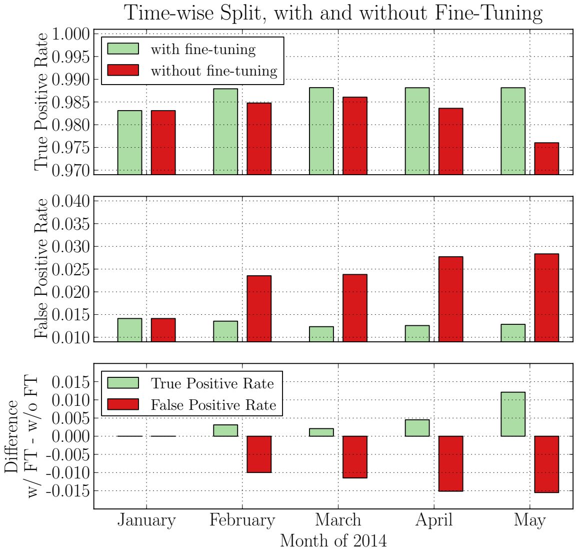

Figure 6: True positive and false positive rates, and the difference with and without fine-tuning, for the time-wise split. Note that the scales for true positives and false negatives are the same, but that the *y*-axis goes from 0.97 to 1 for the true positive rate and 0.01 to 0.04 for the false positive rate. No significant change is visible for the true positive rate in the beginning regardless if the network is fine-tuned regularly or not, however, a non-negligible difference is observable for May 2014. A difference is observable for the false positive rate starting in February 2014, after the network was first fine-tuned.

In detail, MEERKAT achieves a true positive rate between 98.310% and 98.816% when the system is fine-tuned after each month on the data observed in that month, and 97.603% to 98.606% when it is not. Although there is no significant difference in its accuracy from January to March when the neural network is fine-tuned and when it is not (see Figure 6), a non-negligible difference between their accuracy can be observed for April and the beginning of May (increase in 0.452 percentage points (pp) and 1.211 pp for the true positive rate; decrease of 1.513 pp and 1.550 pp for the false positive rate). The Bayesian detection rate if no fine-tuning is used decreases from 98.583% in January 2014 to 97.666% in February (0.917 pp decrease) to 97.177% in May (1.406 pp decrease to January). If fine-tuning is utilized, the Bayesian detection rate increases from 98.583% in January 2014 to 98.717% in May (0.134 pp).

Unsurprisingly, the regularly fine-tuned system performs better over time, probably because some defacers became significantly more active in 2014, like *Team System Dz*, who started to deface websites just in January 2014 and who were not active before at all, and because some defacers changed their defacements to spread a different message as opposed to the one they spread the year before. When the system is not fine-tuned, however, these minor changes to the defacements allow attackers to evade detection without actively trying to evade it, with a minor accuracy deterioration already visible after just four to five months, confirming that detection systems need to be able to tackle even minor concept drift adequately and gracefully to maintain accurate detection capabilities over time, like MEERKAT does with fine-tuning.

5 Limitations

Similar to other systems leveraging machine learning, our system has some limitations that can be used to evade detection. We discuss some of these limitations and show how they can be addressed for a real-world deployment. First, we discuss *concept drift*, a problem all systems leveraging machine learning have to deal with; second, we remark on *browser fingerprinting* and *delayed defacement*, an issue all client-based detection approaches have to address; and, lastly, we introduce the concept of *tiny defacements*, a limitation specific to defacement detection systems.

5.1 Concept Drift

Concept drift is the problem of predictive analysis approaches, such as detection systems, that the statistical properties of the input used to train the models change. In turn, a direct result of concept drift is often a heavy deterioration of the classification performance, up to the point where the system cannot differentiate between good and bad behavior anymore. For instance, prior work [48–55] has shown that concept drift (in the sense of adversarial learning) can actually be leveraged to evade detection systems and classifiers in practice. Therefore, a detection system must address it.

While concept drift is a major issue for all systems using machine learning, it can generally be addressed, due to its nature, by adopting a new feature space or retraining the machine learning model on new data, or with an increased weight on new data. However, often, old instances do not follow the statistical properties of the new feature models, and, therefore, they are classified less accurately than before. This has little impact in practice, because old instances are less likely to occur in the future anyways; yet, it is important to realize that this approach allows attackers to evade the system by oscillating their attack strategy regularly.

For MEERKAT, those shortcomings can be addressed more easily than for traditional systems: for minor concept drift, the system's accuracy can be maintained by fine-tuning the parameters of the network. Here, the system simply needs to learn minor adjustments to the weights of existing features from new data, because some features have become more important and others have become less important (they differ now more from other features than they did previously, relatively speaking; since we start with already-initialized weights, fine-tuning requires much less time than training the whole system again). Here, the features still model the differences between defacements and legitimate websites, however, the weights are not optimal anymore and need to be adjusted. Once the new weights are learned, classification performance is restored. Therefore, to address minor concept drift adequately, we recommend fine-tuning the model regularly, e.g., every month (see Section 4.5).

While fine-tuning the system's parameters can theoretically address major concept drift similar to retraining the system on new data, in practice, we expect prediction accuracy to decrease, since different or more features must be modeled with the same amount of resources. Instead, for major concept drift, increasing the number of hidden nodes of the neural network that learn the compressed representation (the features) and their weights, and then retraining the system

Split	True Positive Rate	False Positive Rate	Bayesian Detection Rate
Traditional	97.878%	1.012%	99.716%
Reporter (weighted)	97.882%	1.528%	99.571%
Reporter (unweighted)	97.933%	1.546%	99.567%
Time-wise with fine-tuning	98.310% - 98.816%	1.233% - 1.413%	98.583% - 98.767%
Time-wise without fine-tuning	97.603% - 98.606%	1.413% - 2.835%	97.177% - 98.583%

Table 2: Average true positive, false positive, and Bayesian detection rates for traditional and reporter split. Lower and upper bound of true positive, false positive, and Bayesian detection rate for time-wise split from January to May 2014.

can maintain the system's accuracy. Simply adding nodes to the hidden layers of the neural network can counteract the issue of major concept drift because we increase the number of features that MEERKAT learns from data directly. Therefore, introducing more hidden units allows the system to learn additional and different internal representations about the *look and feel* of defacements, while, at the same time, maintaining a model of how the old defacements look like. However, it requires computationally-costly retraining of the network (previously, having those additional hidden units in the network would result in overfitting because the system would learn more complex representations than necessary, and each would only differ little from one another; the system would then be prone to missing minor variations of defacements).

It is important to note that in both cases, for minor and major concept drift, MEERKAT requires no additional feature engineering because the features are learned *automatically* from data. In turn, this allows MEERKAT to handle any form of concept drift much more gracefully than approaches introduced by prior approaches, which require manual feature engineering.

5.2 Fingerprinting and Delayed Defacement

A second limitation of detection systems is fingerprinting. Since we are leveraging a web browser to collect the data that we are analyzing, in our case fingerprinting corresponds to IP-based and browser fingerprinting. For IP-based fingerprinting, a set of VPNs and proxies can be used to cloak and regularly change the browser's IP address. In case of browser fingerprinting, the server or some client-side JavaScript code detects what browser is rendering the website, and then displays the website differently for different browsers. In its current form, the screenshot engine from MEERKAT might be detectable (to some degree) by browser fingerprinting. It is theoretically possible to detect it because it is currently built on the headless browser PhantomJS rather than a "headful" browser typically used by a normal user, like Google Chrome. However, since PhantomJS is built from the same components as Google Chrome, fingerprinting the current screenshot engine is not trivial and requires intimate knowledge of the differences between the different versions of the components and their interaction. Therefore, we argue that the evasion through browser fingerprinting is unlikely. If, however, the screenshot engine is evaded this way in the future, only some minor engineering effort is required to utilize a browser extension to retrieve the websites' screenshots instead.[9]

Additionally, the issue of delaying the defacement emerges, also referred to as the snapshot problem [30]. With the increased popularity and use of JavaScript, client-side rendering, and asynchronous requests to backends by websites to provide a seamless and "reload-free" user experience, it is uncertain at what point in time a website is representative of how a user would experience it. This then bears the issue of when a detection system can take a representative snapshot of the website and stop executing client-side scripts. For instance, if a detection system takes a snapshot always after five seconds, to evade detection, defacers could simply inject JavaScript that only defaces the website if a user interacts with it for at least six seconds.

While delayed defacements are currently scarce, it is likely that they will gain some traction once more detection systems have been put in place, in a way similar to mimicry attacks and the evasions of malware detection systems [56, 57]. However, prior work can be leveraged to detect evasions [58] or trigger the functionality [59] to force the defacement to be shown. Both approaches are complementary to MEERKAT and we leave their adoption to defacement detection for future work, once delayed defacements are actually occurring in the wild.

5.3 Tiny Defacements

A third limitation of all current defacement detection systems, including MEERKAT, is the lack of detection capabilities for tiny defacements. Tiny defacements describe a class of defacements in which only a very minor modification is made to part of the content of the defaced website. For instance, a defacer might be dissatisfied by an article published by a newspaper. Instead of defacing the website as a whole, the attacker modifies (or deletes) the news article. It is clear that such defacements are very hard to differentiate from the original content because they might only have minor semantic changes to text or images. Thus, to detect tiny defacements, the detection system must understand the semantics of the website's content, its language, and its general behavior to derive a meaningful model for the website.

However, while those defacements exist, they are extremely scarce in numbers, or they are rarely noticed. In fact, it is seldom the case that a defacer wants to modify a website without embarrassing the operator more publicly. Most often, the goal of the defacer is to expose the insecurity

[9] In fact, we are migrating our screenshot engine to Chrome, eliminating the problem that PhantomJS might be fingerprinted.

of the website, ridicule the operator publicly, show their own "superiority," and place their opinion and beliefs in the most public space possible. Therefore, tiny defacements are currently of little interest to the defacers themselves, and, hence, also of little impact for detection systems. However, we acknowledge that tiny defacements must be addressed once they increase in numbers, possibly leveraging recent work to extract relevant changes from websites [60], and advances in natural language processing.

6 Related Work

Hereinafter, we discuss related work that detects defacement, and image-based detection used in computer security.

6.1 Defacement Detection

Similar to MEERKAT, Davanzo et al. [46] introduce a system that acts a monitoring service for website defacements. Their system utilizes the website's HTML source code for detection, and its features were selected manually based on domain knowledge acquired *a priori*, making the system prone to concept drift. On their, comparatively, very small dataset containing only 300 legitimate websites and 320 defacements, they achieve false positive rates ranging from 3.56% to 100% (depending on the machine learning algorithm used; suggesting extreme under- and over-fitting with some algorithms), and true positive rates between 70.07% to 100% (in the case of simply classifying everything as a defacement; i.e., extremely under-fitting the dataset). Overall, these results are significantly worse than MEERKAT, both in terms of false positives (1.012%) and true positives (97.878%).

Bartoli et al. [47] propose Goldrake, a website defacement monitoring tool that is very similar to the tool proposed by Davanzo et al. and leverages a superset of their features. To learn an accurate model, Goldrake requires knowledge about the monitored website to learn website-specific parameters. However, it is unclear how well Goldrake detects defacements in practice because it is evaluated on a small and (likely) non-diverse dataset comprised of only 11 legitimate websites and 20 defacements, on which it performs poorly with a high false negative rate (27%).

Medvet et al. [61] introduce a defacement detection system based on work by Bartoli et al. and Davanzo et al., but the detection engine is replaced by a set of functions that are learned through genetic programming. The learned functions take the features by Bartoli et al. and Davanzo et al. as input, but classification is more accurate on a dataset comprised of 15 websites (between 0.71% and 23.38% false positives, and about 97.52% true positives). It is, again, unclear how the system would fare in a real-world deployment because of the small and (likely) non-diverse dataset.

Note that all text-based approaches have major shortcomings, similar as those encountered in spam and phishing detection, such as using images to show text to evade detection. MEERKAT does not suffer from these shortcomings.

Lastly, most commercial products that detect website defacements are built upon host-based intrusion detection systems to monitor modifications of the files on the web server, e.g. via file integrity checks (checksums) [62, 63]. Therefore, those approaches bear the major shortcoming that they can only detect the subset of defacements that modify files on disk, and that they cannot detect other defacement attacks, such as through SQL injections; even when the defacements look exactly the same to the website's visitors. MEERKAT does not suffer from this shortcoming.

6.2 Image-based Detection in Security

Since, to the best of our knowledge, no prior work applies image-based methods to detect defacements, we compare prior work to defacement detection that visually detects phishing pages, or leverages image-based techniques as part of a larger system.

Medvet et al. [64] propose a system to detect if a potential phishing page is similar to a legitimate website. The system leverages features such as parts of the visible text, the images embedded in the website, and the overall appearance of the website as rendered by the browser for detection. Similarity is measured by comparing the 2-dimensional Haar wavelet transformations of the screenshots. Their system achieves a 92.6% true positive rate and a 0% false positive rate on a dataset comprised of 41 real-world phishing pages.

Similarly, Liu et al. [65] present an antiphishing solution that is deployed at an email server and detects linked phishing pages by assessing the visual similarity to the legitimate page, but only when analysis is triggered on keyword detection. The system detects phishing pages by comparing the suspicious website to the legitimate website by measuring similarity between text and image properties, like the font size and family used, or source of an image.

While detecting phishing pages by comparing the similarity of two websites makes sense, for defacements the difference between them is more interesting. Instead of creating a visually-similar page to trick users into submitting their credentials, a defacer wants to promote his message. Adopting existing phishing detection systems to detect defacements instead, i.e., by comparing if the website looks different from its usual representation, however, bears two problems: (a) the usual representation must be known and/or stored for comparison, and (b) false positives are much more likely if the website is dynamic or if it shows regularly-changing ads.

Anderson et al. [29] introduce image shingling, a technique similar to w-shingling, to cluster screenshots of scams into campaigns. However, in its current form, image shingling cannot be used to detect defacements as it is trivial to evade the clustering step with only minor modifications that are invisible to the human eye, and, thus, the technique is unsuitable for a detection system in an adversarial context.[10]

Nappa et al. [66] leverage perceptual hashing to group visually similar icons of malicious executables under the assumption that a similar icon suggests that the two executables are part of the same malware distribution campaign. While it is theoretically possible to detect defacements through perceptual hashing-based techniques and comparing the distance of the hashes, it is impractical to do so on a large scale and in an adversarial context. For

[10] The authors acknowledge the shortcomings in an adversarial context in Section 4.2, but they do not discuss any remediation techniques.

once, one must have a ground-truth screenshot that is close enough to the screenshot that one wants to classify; if ground-truth is not available or slightly too different, a system based on perceptual hashing will be unable to detect the defacement. Furthermore, classification is not constant in the number of defacements the system has seen in the past: for each new screenshot we would want to classify, we would need to compute the distance to the hashes of at least some (or all) of the previously-seen defacements.[11]

Grier et al. [67] introduce their own image similarity measure to cluster malicious executables that have similar looking user-interface components after being executed in a dynamic analysis environment. Two images are considered similar if the root mean squared deviation between the images' histograms is below some manually-determined threshold. Clearly, a defacement system based on this technique is not suitable in an adversarial context: an attacker can (and eventually will) simply change the colors slightly or add dynamic content, so that the root mean squared deviation is above the threshold, but remains visually the same to the human eye. Furthermore, exactly as for Nappa et al. [66], one needs to pair-wise compare the histogram of the screenshot one wants to classify to some or all of the already-seen defacements.[11]

MEERKAT does not suffer from these shortcomings: first, it learns high-level features on the defacements' general *look and feel* to detect also previously unseen defacements, and, second, its classification time is constant in the number of already-seen defacements.

7 Conclusions

In this paper, we introduced MEERKAT, a monitoring system to detect website defacements, which utilizes a novel approach based on the *look and feel* of a website to identify if the website has been defaced. To accurately identify website defacements, MEERKAT leverages recent advances in machine learning, like stacked autoencoders and deep neural networks, and combines them with computer vision techniques. Different from prior work, MEERKAT does not rely on additional information supplied by the website's operator, or on manually-engineered features based on domain knowledge acquired *a priori*, such as how defacements look. Instead, MEERKAT automatically learns high-level features from data directly. By deciding if a website has been defaced based on a region of the screenshot of the website instead of the whole screenshot, the system is robust to the normal evolution of websites and defacements and can be used at scale. Additionally, to prevent the evasion of the system through changes to the *look and feel* of defacements and to be robust against defacement variants, MEERKAT employs various techniques, such as dropout and fine-tuning.

We showed the practicality of MEERKAT on the largest website defacement dataset to date, spanning 10,053,772 defacements observed between January 1998 and May 2014, and 2,554,905 legitimate websites. On this dataset, in different scenarios, the system accurately detects defacements with a true positive rate between 97.422% and 98.816%, a false positive rate between 0.547% and 1.528%, and a Bayesian detection rate between 98.583% and 99.845%, thus significantly outperforming existing state-of-the-art approaches.

8 Acknowledgments

We want to express our gratitude toward the reviewers for their helpful feedback, valuable comments and suggestions to improve the quality of the paper.

Appendix

A Reporter Cross-validation Split

In our reporter split experiment (Section 4.4), we split the dataset by reporter to simulate that a new defacer group emerges. Each cross-validation bin contains the same amount of reporters, but because they reported different numbers of defacements, bins do not contain the same amount of samples. We account for the size difference in our experiments by weighting each bin. Table 3 lists the number of samples per bin.

Bin	Defacements	Legitimate Websites
1	1,116,808	308,202
2	992,232	273,823
3	712,270	196,563
4	907,306	250,387
5	696,069	192,092
6	734,208	202,617
7	1,276,764	352,345
8	789,895	217,985
9	979,309	270,257
10	1,053,147	290,634
Total	9,258,008	2,554,905

Table 3: Number of samples per cross-validation bins used for the reporter split. Note that the total number of defacements in the reporter split contains 168 defacements less than available in the whole dataset because otherwise reporters would be distributed unevenly per bin. However, due to the considerable size of the dataset, omitting these defacements has negligible impact.

B Image-based Object Recognition

Much prior work has been carried out in computer vision to classify images and recognize objects in images. Most recently, object recognition underwent a “new spring” with the rise of deep learning. Deep learning gained traction because training them on large datasets became computationally feasible, and they consistently outperformed other algorithms. We discuss our two main inspirations.

Le et al. [32] introduce a feature learning approach that leverages unsupervised learning with a deep networks comprised of stacked sparse autoencoders utilizing pooling and local contrast normalization. The main idea is to learn high-level features from only unlabeled data (10 million pictures from random Youtube videos); high-level features such as if the image contains a cat, or a human face or body part. After training, the network improves relatively to prior state-of-the-art by 70% on the ImageNet dataset.

Krizhevsky et al. [33] employed supervised learning to train a deep convolutional neural network to classify 1.2 million images spanning 1,000 classes from a subset of the ImageNet dataset and they improve considerably on the state-of-the-art with a top-1 error rate of 37.5% (the classifier is correct for 62.5%) and a top-5 error of 17.0% (for 83% images, the correct class is among top 5 classes). To not overfit the dataset and to reduce the network’s training time, they use rectified linear units as the neurons’ output functions.

Recognizing Functions in Binaries with Neural Networks

Eui Chul Richard Shin, Dawn Song, and Reza Moazzezi
University of California, Berkeley
{*ricshin, dawnsong, rezamoazzezi*}*@berkeley.edu*

Abstract

Binary analysis facilitates many important applications like malware detection and automatically fixing vulnerable software. In this paper, we propose to apply artificial neural networks to solve important yet difficult problems in binary analysis. Specifically, we tackle the problem of function identification, a crucial first step in many binary analysis techniques. Although neural networks have undergone a renaissance in the past few years, achieving breakthrough results in multiple application domains such as visual object recognition, language modeling, and speech recognition, no researchers have yet attempted to apply these techniques to problems in binary analysis. Using a dataset from prior work, we show that recurrent neural networks can identify functions in binaries with greater accuracy and efficiency than the state-of-the-art machine-learning-based method. We can train the model an order of magnitude faster and evaluate it on binaries hundreds of times faster. Furthermore, it halves the error rate on six out of eight benchmarks, and performs comparably on the remaining two.

1 Introduction

Binary analysis enables many useful applications in computer security, given the plethora of possible situations in which the original high-level source code is unavailable, has been lost, or is otherwise inconvenient to use. For example, detection of malware, hardening software against common vulnerabilities, and protocol reverse-engineering are most useful when the procedures involved can directly operate on binaries.

The central challenge of binary analysis is perhaps the lack of high-level semantic structure within binaries, as compilers discard it from the source code during the process of compilation. Malware authors often go a step further and obfuscate their output in an attempt to frustrate any possible analysis by researchers.

Functions are a seemingly basic yet fundamental piece of structure in all programs, but most binaries come as an undifferentiated sequence of machine-language instructions without any information about how parts group into functions. Therefore, the many binary analysis techniques which rely on function boundary information must first attempt to recover it through *function identification*. For instance, function identification can assist the addition of control-flow integrity enforcement to binaries, in restricting jumps appropriately. Similarly, decompilers and debuggers need to know the locations of functions to provide useful output to the user [2].

Several previous works have attempted the function identification task, ranging from simple heuristics to approaches using machine learning. The problem might seem simple at first glance, but Bao et al. showed with ByteWeight [2], a recently-proposed machine-learning-based approach, that the simpler techniques used by popular tools like IDA Pro and the CMU Binary Analysis Platform have relatively poor accuracy. By constructing signatures of function starts as weighted prefix trees, ByteWeight greatly improves on the accuracy of function identification results compared to past work. Nevertheless, it leaves much room for improvement, especially in terms of computational efficiency: the authors report that training on their dataset of 2,064 binaries required 587 compute-hours, whereas running the method on the dataset took on the order of several compute-days. Also, while ByteWeight achieves about 98% accuracy on some benchmarks, it performs at just 92-93% on some others.

In this paper, we propose a new approach to function identification leveraging artificial neural networks. First proposed in the 1940s, artificial neural networks arose as a simple approximation of interconnected biological neurons in the central nervous systems of animals, and have remained an active area of of research since then. However, in the past few years, neural networks have experienced a significant surge in popularity (often under the name "deep learning"), largely been driven by new empirical results. The vastly larger amounts of processing power and storage available today enabled researchers to train much larger networks containing many more stages of processing (hence the "deep" appellation) and parameters than before, making full use of the massive labeled datasets available today; these factors have led to repeated breakthroughs in benchmarks of the computer vision and speech recognition communities, among others.

We note some attractive features of neural networks. First, they can learn directly from the original representation with minimal preprocessing (or "feature engineering") needed. As an example, the preprocessing for images might discard information about the precise shading of objects; for binaries, Bao et al. disassembles the code into instructions and removes immediate operands from them. Second, neural networks can learn *end-to-end*, where each of its constituent stages are trained simultaneously in order to best solve the end goal. In contrast, other state-of-the-art approaches to tasks like machine translation or question answering use pipelines of discrete components trained separately at an unrelated task, such as parsers or part-of-speech taggers. Empirical evidence suggests that end-to-end learning enables each stage to directly learn the intermediate representations necessary to solve the task, with less need for preconceived notions (such as syntax trees) about what they should look like.

Given the success that neural networks have shown in other applications, we raise the question of whether they would also prove adept at problems in binary analysis, such as function identification. Our search turned up no other works which attempted using neural networks to solve problems in binary analysis. Nevertheless, our experimental results show that they can successfully solve the function identification task accurately and efficiently. If the experience in other fields can serve as a guide, they may also prove useful for more complicated tasks in program and binary analysis, especially for those which require complicated modeling or analysis difficult to specify by hand. Furthermore, advances with neural networks in other applications might prove directly adaptable and lead to "free" gains in performance; this work certainly relies on general advances within neural networks targeted at entirely different applications.

With our proposed solution, we train a recurrent neural network to take bytes of the binary as input, and predict, for each location, whether a function boundary is present at that location. We found that we did not need to perform any preprocessing, such as disassembly or normalization of immediates, in order to obtain good results. We evaluate our approach using the dataset provided by Bao et al. [2], enabling a direct comparison. We found that recurrent neural networks can learn much more efficiently than ByteWeight, which reported using 587 compute-hours; we can train on the same dataset in 80 compute-hours, while achieving similar or better accuracy. Testing the method on the dataset takes only about 43 minutes of computation, whereas Bao et al. [2] reported needing over 2 weeks.

In the rest of the paper, we first precisely define the problem at hand. We explain the necessary background in neural networks, and describe the particular architecture we chose to use for our method. We give the results of our empirical evaluation, describe some related works in the areas of function identification and neural networks, and then conclude with some discussion.

We make the following contributions in this paper:

- We find that neural networks are a viable approach towards solving some problems in binary analysis.
- In particular, we show that recurrent neural networks can solve the function identification problem more efficiently than the previous state-of-the-art, as shown by empirical evaluation on a dataset consisting of multiple operating systems, architectures, compilers, and compiler options.
- We describe the challenges we faced in correctly applying neural networks to this problem, and how to address them.

2 Problem Definition

We first define notation so that we can precisely define the function identification task that we address in this paper. We then provide a formal definition of function identification.

2.1 Notation

We concern ourselves with the machine code contained within a program binary or library. A typical executable contains many different sections containing various information in addition to the code: for example, dynamically-linked libraries to load, constant strings, and statically-allocated variables, all of which we ignore.

We treat the code C itself as a sequence of bytes $C[0], C[1], \cdots, C[l]$, where $C[i] \in \mathbb{Z}_{256}$ is the i^{th} byte in the sequence. We denote the n functions in the binary as $f_1, \cdots, f_n$. We label the indices of the bytes of code which belong to each function f_i (i.e., the bytes corresponding to instructions which might get executed while running that function) as $f_{i,1}, \cdots, f_{i,l_i}$, where l_i is the total number of bytes in f_i. Without loss of generality, we assume $f_{i,1} < f_{i,2} < \cdots < f_{i,k}$. Each byte may belong to any number of functions, and functions may contain any set of bytes, contiguous or not.

Note that we defined the code and functions as sets of bytes rather than instructions. In the x86 and x86-64 ISAs, a sequence of bytes can have many plausible instruction decodings depending on the offset at which decoding begins; therefore each byte might belong to a handful of possible instructions. Working in terms of bytes allows us to avoid this ambiguity.

2.2 Task definition

Let us assume that we have access the code C of a binary, but no information about the functions $f_1, \cdots, f_n$ within the code. We define the following tasks:

- Function start identification: Given C, find $\{f_{1,1}, \cdots, f_{n,1}\}$. In other words, recover the location of the first byte of each function.
- Function end identification: Given C, find $\{f_{1,l_1}, \cdots, f_{n,l_n}\}$. In other words, find the bytes where each of the n functions in the binary ends. The length of each function is not given.
- Function boundary identification: Given C, find $\{(f_{1,1}, f_{1,l_1}) \cdots, (f_{n,1}, f_{n,l_n})\}$. In other words, discover the location of the first and last byte within each function. This task is more than a simple combination of function start and end identification. If the starts and ends of functions have been identified separately, they need to be paired correctly so that each pair contains the start and end of the same function.
- General function identification: Given C, find $\{(f_{1,1}, f_{1,2}, \cdots, f_{1,l_1}) \cdots, (f_{n,1}, f_{n,2}, \cdots f_{n,l_n})\}$; i.e., determine the number of functions in the file, and all of the bytes which make up each function.

Function boundary identification is a superset of function start and end identification, whereas general function identification is a superset of all other tasks. In this paper, we attempt the first three problems, and leave the fourth to future work.

2.3 Metrics

To evaluate results from the model, we use the precision, recall, and F1 metrics. They have the following definitions:

$$\text{Precision} = \frac{\text{TP}}{\text{TP} + \text{FP}}$$

$$\text{Recall} = \frac{\text{TP}}{\text{TP} + \text{FN}}$$

$$\text{F1} = \frac{2 \cdot \text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}}$$

where TP is the number of true positive predictions, FP is the number of false positive predictions, and FN is the number of false negative predictions. The F1 score is the harmonic mean of precision and recall and allows us to conveniently compare different results using one number.

Since most bytes within a program do not begin or end functions, these metrics can give a better picture of the effectiveness of the model than the simple accuracy metric. For example, predicting that there exists no functions in the code would give greater than 99.9% accuracy, since fewer than 0.1% of the bytes begin or end a function. The accuracy metric does not reveal that these predictions would be mostly useless. In contrast, the 0% recall these predictions would achieve makes it clear.

2.4 Examples

In Figure 1, we show an example of a short C function and its corresponding binary code after compilation at two different optimization levels.

The code in Figure 1b contains very clear markers of function start and end: the function prologue of `push %rbp` and `mov %rsp,%rbp` saves the caller's stack frame, and the function ends with `retq` which occurs nowhere else within the function. In contrast, Figure 1c does not use the stack at all, so the function begins with some accesses to the function arguments passed in `edi` and `esi`; looking for `push %rbp` would fail. Moreover, similar accesses to arguments occur again within the body of the function, making it difficult to solely rely on that as a marker of the function start. Likewise, `retq` occurs twice within the code, and so predicting a function end when we see this instruction would fail.

This example gives an instance of why function identification can pose much difficulty, with simple heuristics unlikely to suffice, contrary to what intuition might suggest.

3 Background

In this section, we describe what neural networks are and how they are trained. In particular, we focus on the various forms of recurrent neural networks, which are the class of model we use for our method.

3.1 Multi-layer perceptrons

A multi-layer perceptron (MLP), also referred to as a feedforward neural network, is a function $L : \mathbb{R}^s \to \mathbb{R}^t$ parameterized in a particular way. As its name implies, a multi-layer perceptron consists of multiple layers L_i,

```
int mul_inv(int a, int b) {
  int b0 = b, t, q;
  int x0 = 0, x1 = 1;
  if (b == 1) return 1;
  while (a > 1) {
    q = a / b;
    t = b, b = a % b, a = t;
    t = x0, x0 = x1 - q * x0, x1 = t;
  }
  if (x1 < 0) x1 += b0;
  return x1;
}
```

(a) A C function which computes the modular multiplicative inverse.

```
00000000004005a1 <mul_inv>:
  4005a1: push   %rbp
  4005a2: mov    %rsp,%rbp
  4005a5: mov    %edi,-0x24(%rbp)
  4005a8: mov    %esi,-0x28(%rbp)
  4005ab: mov    -0x28(%rbp),%eax
...
  400615: jns    40061d <mul_inv+0x7c>
  400617: mov    -0xc(%rbp),%eax
  40061a: add    %eax,-0x8(%rbp)
  40061d: mov    -0x8(%rbp),%eax
  400620: pop    %rbp
  400621: retq
```

(b) Compiled with `gcc -O0`.

```
0000000000400830 <mul_inv>:
  400830: cmp    $0x1,%esi
  400833: mov    %edi,%eax
  400835: je     400878 <mul_inv+0x48>
  400837: cmp    $0x1,%edi
  40083a: jle    400878 <mul_inv+0x48>
  40083c: mov    %esi,%ecx
  40083e: mov    $0x1,%r8d
  400844: xor    %edi,%edi
  400846: jmp    400855 <mul_inv+0x25>
  400848: nopl   0x0(%rax,%rax,1)
  40084f:
...
  400869: jg     400850 <mul_inv+0x20>
  40086b: add    %edi,%esi
  40086d: mov    %edi,%eax
  40086f: test   %edi,%edi
  400871: cmovs  %esi,%eax
  400874: retq
  400875: nopl   (%rax)
  400878: mov    $0x1,%eax
  40087d: retq
  40087e: xchg   %ax,%ax
```

(c) Compiled with `gcc -O3`. Function ends at `40087d`; `40087e` is padding between this function and the next one.

Figure 1: An example function in C (taken from `http://rosettacode.org/wiki/Modular_inverse#C`), and its corresponding machine code (with uninteresting parts omitted for brevity). The function was compiled using GCC 4.9.1 on Linux x86-64. The `-O3` version does not contain a conventional function prologue and epilogue which manipulates the stack or frame pointer.

each of which computes

$$
\begin{aligned}
L_i &: \mathbb{R}^{m_{i-1}} \to \mathbb{R}^{m_i} \\
G &: \mathbb{R} \to \mathbb{R} \\
L_i(x) &= G(W_i x + b_i) \\
W_i &\in \mathbb{R}^{m_i \times m_{i-1}} \\
b_i &\in \mathbb{R}^{m_i}
\end{aligned}
$$

then the entirety (consisting of k layers) is simply these layers composed together:

$$
\begin{aligned}
L(x) &= L_k(L_{k-1}(\cdots(L_1(x)))) \\
m_0 &= s \\
m_k &= t
\end{aligned}
$$

with the dimensions of the output of one layer matching the dimensions of the input of the subsequent layer. The m_i are the dimensionality of the input and the ultimate output of the network, as well as the intermediates produced by each of the layers.

The term “layer” is often used to refer to not the parameters of the functions L_i, but the inputs or outputs of these functions. In turn, each element of the inputs or outputs of the functions are often called “units”, or by analogy, “neurons”.

In this definition, G is referred to as an *activation function* or *nonlinearity*, and computed separately for each element. Without the activation function, L would simply be an affine function which we could write as $Wx + b$, which does not enable the expressivity that we need. Common nonlinearities are the logistic sigmoid function and the hyperbolic tangent function:

$$
\begin{aligned}
\sigma(x) &= \frac{1}{1 + e^{-x}} \\
\tanh(x) &= \frac{e^{2x} - 1}{e^{2x} + 1}
\end{aligned}
$$

which have the ranges of $(0,1)$ and $(-1,1)$, respectively.

Usually, the final layer will have no activation function because we do not wish to bound the output to a limited range, or a softmax function if we want to use the MLP as a multi-class classifier, so that we can interpret the values as a probability distribution. The softmax function is computed as follows:

$$
S(\mathbf{x})_i = \frac{e^{\mathbf{x}_i}}{\sum_{k=1}^{n} e^{\mathbf{x}_k}}
$$

Note that unlike the other activation functions, it does not operate elementwise. Due to the normalization term in the denominator, $S(\mathbf{x})$ sums to 1. A multi-layer perceptron consisting of one layer with a softmax activation function is equivalent to multi-class logistic regression.

3.2 Loss functions

Now that we have defined multi-layer perceptrons as a class of parameterized functions, we need a method to find appropriate parameters so that the neural network does what we want. First, we define a *loss function* in order to quantify how much differently the network behaves from our target. A common loss function is the squared Euclidean distance:

$$d(y, \hat{y}) = \|y - \hat{y}\|_2^2$$

where y is the "true" output and $\hat{y}$ is the one produced by the neural network.

In the multi-class classification case, if y is the correct class and $\pi(x)$ is the probability distribution produced by the neural network, then we can use the negative log probability:

$$d(y, \pi(x)) = -\log \pi(x)_y$$

Usually, we will have a list of correct input-output pairs $(x_1, y_1), \cdots, (x_n, y_n)$ for the purpose of training the network. Then we can seek to minimize the mean of the losses, or $\frac{1}{n} \sum_{i=1}^{n} d(y_i, f(x_i))$. We use this type of loss function throughout this paper.

3.3 Gradient descent and backpropagation

To minimize the loss, and therefore obtain a neural network which performs our desired function, we can consider various standard optimization methods. Specifically, we wish to minimize D defined as such:

$$\begin{aligned} \theta &= (W_1, b_1, \cdots, W_k, b_k) \\ D(\theta) &= \frac{1}{n} \sum_{i=1}^{n} d(y_i, f_\theta(x_i)) \\ \min_\theta \quad & D(\theta) \end{aligned}$$

A typical way to minimize differentiable functions is gradient descent, which works by repeated applications of the following update:

$$\theta' = \theta - \alpha \cdot \frac{\partial D(\theta)}{\partial \theta}$$

where α is generally a small number. Intuitively, the derivative allows us to analytically determine which direction we should move in within each dimension of θ to reduce the value of F. Subtracting a small multiple of the gradient performs this function.

If D is convex, this procedure is guaranteed to converge at the optimal value of θ given appropriate choices of α. Many machine learning models and classifiers involve optimizing a convex function in a similar way. Unfortunately, neural networks are generally non-convex in its parameters, allowing for a richer class of possible functions, but which means that these theoretical guarantees do not hold. Instead, the procedure may lead us to a local optimum or a saddle point where the derivative is zero.

We now need the derivative of D. Estimating the derivative numerically seems a simple and straightforward solution, but it is a highly inefficient one requiring as many evaluations of D as the dimensionality of θ. Instead, we can use a method called *backpropagation* to compute the derivative analytically. We describe the details of backpropagation in Section A.

3.4 Recurrent neural networks

While multi-layer perceptrons can approximate a wide variety of functions, they can only operate on inputs of fixed size and produce an output of fixed size. In principle, given a large input, we could divide it into fixed-size pieces and give them separately to a multi-layer perceptron. However, the output of each piece depends only on that input piece, and we cannot represent any dependencies between parts of the input in one piece and the output for a different piece.

Recurrent neural networks are one paradigm for addressing this conundrum, and map sequences to sequences (recursive neural networks, which have the same initialism, are an alternative developed for computing on trees).

We can formally define them in the following way:

$$\begin{aligned} L &: \mathbb{R}^m \times \mathbb{R}^n \to \mathbb{R}^n \\ G &: \mathbb{R} \to \mathbb{R} \\ L(x, h) &= G(W_{hx}x + W_{hh}h + b) \\ W_{hx} &\in \mathbb{R}^{n \times m} \\ W_{hh} &\in \mathbb{R}^{n \times n} \\ b &\in \mathbb{R}^n \end{aligned}$$

Given an input sequence $(x_1, \cdots, x_T)$ (where $x_i \in R^m$), we compute $(h_1, \cdots, h_T)$ like this:

$$\begin{aligned} h_0 &= 0 \\ h_1 &= L(x_1, h_0) \\ &\vdots \\ h_T &= L(x_T, h_{T-1}) \end{aligned}$$

Note that the operation on each elements uses the same weights. Nevertheless, the use of h enables the network to remember information from past elements to use while processing the current element, and propagate information into the future.

We can use the h_ts as inputs to another recurrent neural network, or apply to them a linear transformation possibly with a softmax activation function (as done in the final layer of a multi-layer perceptron):

$$y_i = S(W_{yh}h_t + b)$$

To define a loss function for a recurrent neural network, we can apply a loss function for a multi-layer perceptron separately to each input-output pair within the sequence and simply sum the losses together:

$$d(y,\hat{y}) = \sum_{i=1}^{T} d(y_t,\hat{y}_t)$$

The input and output sequences of a recurrent neural network need not have the same lengths. For instance, we might allow an arbitrary number of inputs but only one output to summarize the contents of the input in some way. In this case, we can simply adjust the loss function to only compute the loss at the relevant parts of the output sequence. We can also train a recurrent neural network to map an input sequence to an arbitrary number of output symbols, if we run the network to obtain some number of outputs until it produces a special 'stop' output.

As with the multi-layer perceptron, we would like to learn appropriate parameters so that the recurrent neural network parameterized with them computes a desired function, using gradient descent. We can compute the derivative of the RNN with respect to its parameters in the same way as earlier. In particular, we can unroll the RNN so that it becomes a long feedforward neural network which computes on a fixed-length sequence, and compute the gradient for this network using an appropriate loss function with backpropagation. After unrolling, note that the time-dependent layers should share the same weights This procedure is also called *backpropagation through time* [16].

3.5 Limitations of recurrent neural networks

In this section, we point out some limitations of recurrent neural networks which can limit their usefulness.

As specified in this paper, recurrent neural networks cannot compute for an arbitrary number of timesteps before computing the answer. For example, RNNs can easily compute the parity of an arbitrarily long stream of bits [15], as this requires a constant number of operations per input. In contrast, we can reason that a RNN could not multiply numbers of arbitrary size, as multiplication is a $O(n^2)$ operation on the length of the numbers [22].

Also, h has a fixed size which we cannot easily adapt if necessary in order to store more information. For example, previous works have shown success with using RNNs for machine translation, in which the RNN first reads a sentence in the source language and stores its meaning in h before producing the corresponding words in the target language using the information in h. While we can pick a size for h such that it has enough capacity to store information on a typical-length sentence, we can imagine that this scheme would break down for a sentence of sufficient length.

The most-studied limitation revolves around difficulties in training a recurrent neural network, due to what are referred to as the vanishing gradient and exploding gradient problems [16]. Consider that

$$\frac{\partial h_v}{\partial h_t} = \prod_{v \geq i > t} \frac{\partial h_i}{\partial h_{i-1}} = \prod_{v \geq i > t} W_{hh} G'(h_{i-1})$$

The repeated multiplication with W_{hh} ($v-t$ times) can cause $\frac{\partial h_v}{\partial h_t}$ to grow exponentially large ("explodes") or go to 0 ("vanishes") depending on whether the largest eigenvalue of W_{hh} is greater or smaller than 1. Therefore, an input will often have a very large or vanishingly small effect on an output which occurs far in the future, in terms of the gradient computation. For exploding gradients, a simple solution involves rescaling the gradient to a fixed norm if its magnitude is too large. On the other hand, dealing with vanishing gradients can prove more challenging.

3.6 Long Short-Term Memory and Gated Recurrent Units

To avoid the exploding and vanishing gradient problems with recurrent neural networks, previous work has proposed RNN architectures carefully designed to remove the long-range multiplicative characteristics of RNNs which lead to these problems.

Long Short-Term Memory (LSTM), one of these architectures, have enabled impressive empirical results in areas such as speech recognition, machine translation, and image captioning. Within this model, the state which propagates through time has no multiplicative updates at each step; instead, it is stored in a *memory cell* c_t which receives additive updates, combined with a mechanism for erasing irrelevant information from the previous time step. The "input modulation gate" (g) and the "forget gate" (f), respectively, control whether the memory cell receives the additive update or discards (some part of the) previous memory cell contents.

Following the notation in Zaremba et al. [23], we can formally define the LSTM:

$$\begin{aligned}
x_t, h_{t-1}, c_{t-1} &\rightarrow h_t, c_t \\
i &= \sigma(W_{xi}x_t + W_{hi}h_{t-1}) \\
f &= \sigma(W_{xf}x_t + W_{hf}h_{t-1}) \\
o &= \sigma(W_{xo}x_t + W_{ho}h_{t-1}) \\
g &= \tanh(W_{xg}x_t + W_{hg}h_{t-1}) \\
c_t &= f \odot c_{t-1} + i \odot g \\
h_t &= o \odot \tanh(c_t)
\end{aligned}$$

Here, $\odot$ represents element-wise multiplication.

In principle, these gates enable the gradient to propagate across long time scales, since the LSTM can ignore irrelevant inputs through the input modulation gate, remember information only until necessary using the forget gate, and output only relevant information using the output gate. When the forget gate is "open", i.e. close to 1, then the gradient will propagate mostly unchanged. The input and output at each time step only influences the gradient when the corresponding gates are open.

Gated Recurrent Units (GRU) have been proposed more recently as a simpler alternative to LSTMs, while sharing the same goals of avoiding the long-range dependency problems that have plagued RNNs. The main differences lie in that there exists no separate memory state c_t from the hidden state h_t, and the network exposes the entire hidden state at each time step. The forget gate interpolates between the previous hidden state and the new input i, with no separate input modulation gate. Instead, g modulates the amount of influence the previous hidden state has on i.

We define the GRU formally:

$$\begin{aligned} &x_t, h_{t-1} \to h_t \\ &\quad g = \tanh(W_{xg}x_t + W_{hg}h_{t-1}) \\ &\quad i = \tanh(W_{xi}x_t + W_{hi}(g \odot h_{t-1})) \\ &\quad f = \sigma(W_{xf}x_t + W_{hf}h_{t-1}) \\ &\quad h_t = f \odot h_{t-1} + (1-f) \odot i \end{aligned}$$

While the GRU theoretically lacks some of the flexibility provided by the LSTM, it is both simpler to implement and easier to compute, requiring about half as many calculations in each time step compared to the LSTM.

4 Methods

In this section, we describe how we built upon the background in Section 3 to perform the task of function identification.

4.1 Basic architecture

Our simplest architecture uses a recurrent neural network, described in Section 3.4, to process each byte and and output a decision for that byte as to whether it begins a function or not.

Recall that neural networks, as we have defined them, take real-valued vectors $\mathbb{R}^m$ as input, containing m real values. In contrast, a byte is a single 8-bit integer, which can have one of 256 ($= 2^8$) possible values. We cannot input a byte into the neural network directly and need to convert them into a real-valued vector.

Converting the 8-bit integer into a single floating-point number to input into the neural network might seem like a reasonable solution; however, neural networks process their inputs by multiplying them with the weight parameters, which only makes sense when the input values represent intensities (like brightness or loudness).

Instead, we use "one-hot encoding", which converts a byte into a $\mathbb{R}^{256}$ vector (since a byte can have 256 distinct values) where exactly one of the values is 1 and all others are 0. The byte's identity determines the location of the 1 within the vector. For example, a NUL byte (0) would be represented as

$$[1 \quad \underbrace{0 \cdots 0}_{\text{255 elements}}\ ].$$

and a nop in x86 (0x90, or 144) would be

$$[\ \underbrace{0 \cdots 0}_{\text{144 elements}} \ 1 \ \underbrace{0 \cdots 0}_{\text{111 elements}}\ ].$$

Multiplying a matrix A with a one-hot vector x is equivalent to extracting a column from A. In our case, the RNN multiplies a parameter matrix $W_{hx} \in \mathbb{R}^{m\times 256}$ with the one-hot input x, which is equivalent to selecting a column from W_{hx}. Effectively, each byte of input is represented with a h-dimensional vector during computation of the RNN, with the precise representation learned during training of the neural network. Such a mapping is often referred to as an *embedding*. Such embeddings have proved useful in other fields such as natural language processing, with embeddings of words into high-dimensional spaces showing interesting properties.

We could have instead considered encoding the byte as a $\mathbb{R}^8$ vector, with the elements corresponding to the eight bits and having values of 0 or 1. However, this representation imposes the constraint that the embedding of a particular byte is the sum of the embeddings of its constituent bits, even though the bits do not have compositional meaning in typical binary code. We do not further discuss this approach in the paper.

We want our output to serve as a binary classifier at each byte position. We use the softmax function to produce a probability distribution over whether the byte begins (or ends) a function or not. During training, the loss function sums over the error at each position within the sequence. The error at each position is the negative log of the probability that the neural network assigned to the correct answer. We penalize each false positive and false negative equally, without a weighting to discourage one at the expense of the other.

4.2 Optimization with stochastic gradient descent and *rmsprop*

In the beginning, we initialize the weights of the neural network randomly, uniformly drawn from a small range

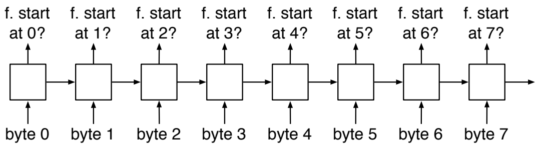

Figure 2: A depiction of the basic architecture of our approach.

near 0. A normal distribution with small variance and mean 0 also sees much use for this purpose. Having the proper initialization can prove crucial to whether we can successfully learn useful parameters for the neural network. We do not initialize the weights to 0, as this leaves the loss function on a saddle point and prevents optimization.

Recall the form of the loss function from Section 3. If we have N different items in the training data, then the loss function for the network requires evaluating the network over all training examples, since it takes the form

$$\frac{1}{N}\sum_{i=1}^{N} d(y_i, \hat{y}_i).$$

Due to how backpropagation works, computing the gradient also requires evaluating the network on all training data. Since we need to compute the gradient a very large number of times during optimization, we would like to avoid performing such an expensive step as a part of it.

Instead of computing the loss over all N items, we can instead compute it over a randomly-selected one at a time. The expectation of the gradient computed in this way equals the gradient averaged over all N examples. Optimization using these gradients is called *stochastic gradient descent*. It is possible to show that given a well-behaved convex function, stochastic gradient descent will find the minimum value. Even in the case of neural networks, where we lack such theoretical guarantees, experience shows that stochastic gradient descent can work quite well; in fact, since computing each gradient takes much less time, results show that stochastic gradient descent allows for much faster convergence in practice.

The most elementary gradient descent methods prescribe changing the parameters in the direction of the gradient each iteration, but optimization of some kinds of functions can benefit from moving in a slightly different direction. Consider a two-dimensional function, which when graphed looks like an elliptical bowl. Then along the axis in which we are closest to the minimum point, the gradient will have the largest magnitude, as the surface of the bowl is steeper in that direction, even though we should move further in the other axis and only a little bit in this one.

In this work, we use a method called *rmsprop* [19]; it involves keeping a running average of the magnitude of each dimension in the gradients seen so far. It then scales each dimension in the gradient, enlarging the dimensions which have a small average and shrinking those which have a large one. This follows the intuition given in the previous paragraph about the elliptical bowl.

We also scale the entire gradient each time by a step size. If the step size is too big, then the optimization might fail as the value of the function does not decrease; if the step size is too small, then optimization will progress slowly or get stuck at a local minimum. Often it makes sense to reduce the learning rate over time, since in the beginning we expect radically-incorrect weights (given their random initialization), whereas after some iterations, the weights should have nearly reached an optimum value. For our experiments, we scaled the learning rate by the inverse square root of the current iteration number (i.e., halved after 4 iterations, quartered after 16 iterations, and so on), which we found to work well.

4.3 Training with mini-batches

In stochastic gradient descent, we compute the gradient of the weights with respect to only one example in each iteration. However, this can cause a large variance in the gradients since each example might significantly differ from one to the next. So instead of computing the gradient over only one example at a time, it can help to average the gradients from a small number of examples, called a *mini-batch*.

While this increases the time needed for each iteration, it does so more modestly than it may initially seem. Evaluating the neural network with a single example involves a large number of matrix-vector multiplications, so we can efficiently and simultaneously evaluate for many examples by replacing these with matrix-matrix multiplications, especially when using highly-optimized linear algebra libraries.

In our application, since each example is a sequence of bytes from a binary, one might vary in length from another. However, to compute with mini-batches efficiently, we need to pack the examples together into a matrix or tensor with padding to extend too-short examples. Then all examples get evaluated for the same number of time steps, so it helps to put examples of similar length together in a mini-batch to avoid wasted computation. Also, we need to take care as to avoid computing the loss over those parts of the mini-batch added as padding.

4.4 Data preparation

For the task of function identification, we can intuitively expect that solving the problem likely does not require

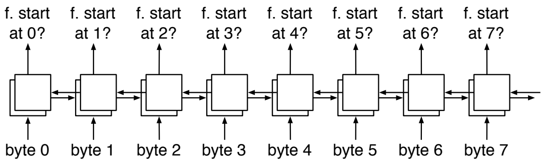

Figure 3: A bi-directional RNN. Note the horizontal arrows pointing in both directions. The forward-propagated and backward-propagated hidden states, represented by the overlapping squares, do not directly interact with each other. However, computing the output uses a concatenation of the two states.

remembering information from hundreds of thousands of bytes in the past or in the future. Code calling other functions can occur far away from the location of that function, and theoretically, we might track such references to help determine where functions occur. In practice, functions typically perform some series of steps at entry and exit, the patterns for which we can learn and should largely suffice for detecting functions.

Therefore, we use fixed-length subsequences taken from binaries instead of entire binaries themselves. Except in rare cases where functions occur near the boundary of the subsequence, there should be enough information to make the determination of the existence of a function or not. Similar to how stochastic gradient descent enables faster convergence by speeding up each update, computing the gradient on truncated sequences takes much less time and enables faster iterations.

We also try reversing the order of bytes in the input before providing it to the neural network, under the intuition that the function prologue, which identifies the beginning of a function and makes it recognizable as such, occurs after the position where we want to predict the beginning of a function. Since the RNN only has access to bytes from before the current position, not after, reversing the order should help the RNN learn.

4.5 Bi-directional RNNs

With the recurrent neural networks discussed in Section 3.4, the output at each time step depends only on the inputs which occur at that time step or before. This model makes sense in some applications where there exists an inherent temporal component to the input; for example, in real-time speech or handwriting recognition. For binary analysis, we have access to the entire binary at once, so there exists no need to confine ourselves in this way.

An extension which allows access to both the past and the future in making a prediction for the present is to combine two recurrent neural networks, one which operates from the beginning of the sequence to the end, and another which operates in the other direction. Figure 3 illustrates the approach.

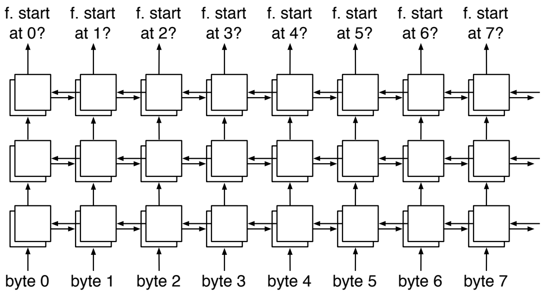

Figure 4: A multi-layer RNN with three bi-directional hidden layers. In the second and third layers, both the forward-propagated and backward-propagated states have access to either state from the previous layer.

In terms of graphical models, we could say that regular (unidirectional) RNNs behave like hidden Markov models, where the hidden state at each time step depends on only the hidden state of the previous time step. Then bidirectional RNNs are analogous to a chain conditional random field, since the hidden state there relates to the hidden states of both the previous and next time steps.

4.6 Multi-layer RNNs

The approaches we have described so far contain only one hidden layer. Depending on the complexity of the pattern we wish to learn, a single hidden layer may prove insufficient due to its limited capacity. If we limit ourselves to one hidden layer, achieving good results may require a very large one, which can significantly increase the amount of processing power required.

In other applications of neural networks like computer vision and speech recognition, using many smaller hidden layers has worked better than using one hidden layer of larger size. During the evaluation, we empirically verify the results of using one versus multiple hidden layers. Figure 4 illustrates an example architecture.

5 Evaluation

In this section, we describe the empirical results we obtained from training a variety of different models on a dataset of binaries. We seek to answer the following questions:

- Can recurrent neural networks successfully solve the problem of function identification in binaries?
- How much computational power do recurrent neural networks require for solving this task?

	ELF x86	ELF x86-64	PE x86	PE x86-64
Number of binaries	1,032	1,032	68	68
Number of bytes	138,547,936	145,544,012	29,093,888	33,351,168
Number of functions	303,238	295,121	93,288	94,548
Average function length	448.84	499.54	292.85	330.03

Table 1: Characteristics of the binary dataset used for evaluation.

	ELF x86			ELF x86-64		
	P	R	F1	P	R	F1
ByteWeight (func. start)	98.41%	97.94%	98.17%	99.14%	98.47%	98.80%
Our models (func. start)	99.56%	99.06%	99.31%	98.80%	97.80%	98.30%
Our models (func. end)	98.69%	97.87%	98.28%	97.45%	95.03%	96.22%
	PE x86			PE x86-64		
	P	R	F1	P	R	F1
ByteWeight (func. start)	93.78%	95.37%	94.57%	97.88%	97.98%	97.93%
Our models (func. start)	99.01%	98.46%	98.74%	99.52%	99.09%	99.31%
Our models (func. end)	99.24%	98.35%	98.79%	99.28%	99.20%	99.24%

Table 2: Function start and end identification: summary of our best results, and comparison with previous work. “P” is precision and “R” is recall. Results of previous work comes from Table 3 of Bao et al. [2]; they did not attempt to identify function ends independently, so we lack those results here.

- How do variations in the model’s design affect the performance?

We ran our experiments on Amazon EC2 using `c4.2xlarge` instances, each of which contains 8 cores of a 2.9 GHz Intel Xeon processor and 15 GB of RAM.

5.1 Dataset

Our dataset comes from Bao et al. [2], consisting of 2200 separate binaries. 2064 of the binaries were for Linux, obtained from the `coreutils`, `binutils`, and `findutils` packages. The remaining 136 for Windows consist of binaries from popular open-source projects. Half of the binaries were for x86, and the other half for x86-64. Half of the Linux binaries were compiled with Intel’s `icc`, while the other half used `gcc`. The binaries for Windows were compiled using Microsoft Visual Studio. Each binary was compiled with one of four different optimization levels. Table 1 summarizes some statistics from the dataset.

Following the procedure in Bao et al. we trained a separate model for each of the four (architecture, OS) configurations. To report comparable results, we also use 10-fold cross-validation as in Bao et al.; we train ten models for each of the four configurations, where each of the ten models uses a different 10% of the binaries as the testing set.

5.2 Implementation

We implemented our models in Python using Theano [4], a linear algebra and automatic differentiation library designed to aid in implementation of machine learning and optimization methods. In Theano, we specify our model as operations on symbolic variables, allowing for construction of a computation graph that describes the operations necessary to compute the result. It can convert this graph into C/C++ code and automatically compute partial derivatives of functions through application of the chain rule.

While Theano can also compile code for use on the GPU, we only used the CPU in our experiments for simpler implementation. Also, while both training and evaluation of RNNs are amenable to parallelization, we also did not use multi-threading for our experiments, and instead ran an independent experiment on each core.

5.3 Summary of results

Tables 2 and 3 summarize our main experimental results. In both tables, we compare to the results as reported by Bao et al. [2], which are marked as “ByteWeight”.

For the function start identification problem, our methods consistently obtain F1 scores in the range of 98-99%. This is in line with the results from Bao et al., except on the PE x86 dataset where we improve by about 4 percentage points in F1 score.

For function boundary identification, we trained two

	ELF x86			ELF x86-64		
	P	R	F1	P	R	F1
ByteWeight	92.78%	92.29%	92.53%	93.22%	92.52%	92.87%
Our models	97.75%	95.34%	96.53%	94.85%	89.91%	92.32%

	PE x86			PE x86-64		
	P	R	F1	P	R	F1
ByteWeight	92.30%	93.91%	93.10%	93.04%	93.13%	93.08%
Our models	97.53%	95.27%	96.39%	98.43%	97.33%	97.88%

Table 3: Function boundary identification: summary of our best results, and comparison with previous work. “P” is precision and “R” is recall.

	ELF x86	ELF x86-64	PE x86	PE x86-64
Our models (func. boundary)	1061.76 s	1017.90 s	236.93 s	264.50 s
ByteWeight (func. start only)	3296.98 s	5718.84 s	10269.19 s	11904.06 s
ByteWeight (func. boundary)	367018.53 s	412223.55 s	54482.30 s	87661.01 s
ByteWeight (func. boundary with RFCR)	457997.09 s	593169.73 s	84602.56 s	97627.44 s

Table 4: Computation time for testing on the data set of 2200 binaries. Numbers for ByteWeight are taken from Bao et al. [2].

models separately for each dataset: one to find function starts, and the other to find function ends. We combine the predictions from each model using a simple heuristic:

- If we predict multiple function ends in sequence after a function start, ignore all but the last.
- If we predict multiple function starts in sequence before a function end, ignore all but the first.
- Otherwise, pair adjacent function starts and ends into a function boundary.

Except on the ELF x86-64 dataset, this allows us to obtain 97-98% in F1 score. In contrast, Bao et al. report 92-93%.

To obtain these results, we used bidirectional models with RNN hidden units (i.e., rather than GRU or LSTM) and one hidden layer of size 16. We trained each model on 100,000 randomly-extracted 1000-byte chunks from the corresponding binaries (or 100 megabytes in total). To clarify, this means that we run two separate recurrent neural networks forward and backward on a 1000-byte sequence from the binary. The forward and backward RNN each computes a $\mathbb{R}^{16}$ hidden representation, which are concatenated together and fed into a linear transformation and the softmax function, producing a probability distribution (a $\mathbb{R}^2$ vector) over whether that byte corresponds to the beginning (or end) of a function or not.

We used *rmsprop* with a step size of 0.1, which was scaled by the inverse square root of the current number of iterations. We used a batch size of 32, which means that in each iteration, we computed the gradients for 32 of the 1000-byte chunks, averaged them together, and applied them to the current weights (per the description in Section 4.3).

These *hyper-parameters* (like the step size, the batch size, and the output size of the RNN), unlike the weights in the neural network, cannot be trained using gradient descent. They have to be selected manually or through an exhaustive search. We selected ours informed by some smaller-scale experiments and our intuition.

5.4 Computation time

Training. In many other applications, neural networks have gained a reputation as requiring a lot of computational power to train. Indeed, it has become standard to train large neural networks using GPUs (graphical processing units), which excel at the large number of linear algebra operations that training a neural network requires. However, the networks we use are relatively small, so training with the CPU seemed to work fine.

In addition, determining the precise number of iterations to train a neural network remains more of an art than a science. Due to noisy gradients in stochastic gradient descent, and the non-convex objective, the accuracy of the neural network does not improve monotonically or predictably as the number of iterations increases. In fact, training for too long can cause the parameters to overfit the training data, and worsen the performance on the test data.

To avoid the issue, we trained our neural networks for the fixed time of two hours each, and report the performance after that. We set the duration of training by

	ELF x86	ELF x86-64	PE x86	PE x86-64
Start	98.95%	98.02%	95.56%	98.37%
End	97.83%	95.51%	94.99%	98.06%
Boundary	95.89%	92.67%	92.45%	95.91%

Table 7: Results with when trained on 10% of the data (F1 scores).

(wall-clock) elapsed time rather than the number of iterations or parameter updates, to avoid biasing in favor of more complicated but powerful architectures which might make more progress per iteration but also take longer to compute each one.

Producing the results in Tables 2 and 3 requires training 40 models, since there are 4 ISA/OS combinations and we used 10-fold cross-validation. Therefore, in total, 80 compute-hours were required. In contrast, Bao et al. [2] report that ByteWeight took 586.44 compute hours to train, over 7× longer.

Furthermore, we needed to train 40 models only for the purposes of matching the 10-fold cross-validation protocol used by Bao et al. We really only need four models to achieve equivalent results, which would take just 8 hours to produce. While abandoning cross-validation for training ByteWeight would presumably also save a significant amount of time, we can expect the factor to be less than 10 since much of the computation (extracting counts of short instruction sequences) occurs before splitting data for cross-validation, further widening the gap between ByteWeight and our method.

Testing. Table 4 summarizes the amount of time needed to run each method on the data set after training completes. Our method is hundreds of times faster than the equivalent complete version ByteWeight which computes function boundaries instead of just function ends.

The disparity mainly arises as our method works without conventional program analysis techniques, such as the static control-flow graph generation used by ByteWeight. We trained the neural network to directly identify both function start and ends, and combine them together using a simple algorithm to recover plausible function boundaries. In addition, the neural network operates directly on bytes rather than instructions, avoiding the need for a disassembly step. In contrast, ByteWeight computes a CFG starting from each identified function start both to identify more functions, and to compute the function boundary. These extra steps require a considerable amount of computation time, and yet our approach gives better results without them.

5.5 Experiments

In this section, we describe some smaller-scale experiments we performed in order to gain insight into how various choices we made in designing our method affects the accuracy of results. We trained each model for two hours, and we did not use cross-validation for these experiments to save on computation time.

Reducing training data. In Table 7, we describe results from training a randomly-selected 10% of the binaries in the dataset and testing on the remainder (normally, the fractions were switched), to simulate common applications of binary analysis where only a small amount of representative training data is available. Despite this, the results dropped by 2-3 points at most.

Unidirectional RNNs. For our main model, we used bidirectional RNNs where the output at each position depends on both previous and future inputs. In Table 5, we compare how bidirectional RNNs fare against the simpler unidirectional ones. As we might expect, the unidirectional RNNs do significantly worse than the bidirectional ones on every benchmark.

In Section 4.4, we speculated that on unidirectional RNNs, reversing the order of the input might provide better results if the bytes which come after, instead of before, a certain location in the binary provide more information about whether that location is the start or end of a function. We found that reversed inputs help with identifying ends of functions, and ordinary inputs with identifying starts. One reason for this may be that with optimization turned on, the compiler will insert no-ops between functions so that function starts occur at an aligned offset; the model can identify these to help find the start or the end.

Variations in model architecture. Table 5 also compares how Gated Recurrent Unit (GRU) and Long Short-term Memory (LSTM) fare against conventional RNNs. As we might expect, GRU and LSTM perform better than RNN in most of the benchmarks. The comparison between GRU and LSTM is more mixed. Since LSTMs take more time to run each iteration, and we trained for a fixed amount of computation time, they may not have converged as much to optimal parameters. Also, while GRU and LSTM are more powerful models than conventional RNNs, this was not enough to beat the bidirectional RNN.

We can also examine what happens when we vary the number of hidden layers or the dimensionality of the hidden layer. Table 6 shows the different results obtained using one hidden layer of size 8, two hidden layers of size 8, or one hidden layer of size 16. The larger models

	Function start identification				Function end identification

$h = 16, l = 1$	98.29%	97.41%	98.42%	99.47%	97.20%	95.51%	98.32%	99.38%

Table 6: Comparison of bidirectional RNNs on the function start and end identification problems. Separate means two models were trained separately for predicting starts and ends; shared means one model does both. h is the size of the hidden layer and l is the number of layers. All percentages are F1 scores.

perform better, but it turns out that increasing the hidden layer size rather than the number of layers provides a slightly greater benefit.

Task sharing. In our prior experiments, we trained two separate neural networks for performing function start and end identification. However, we could instead train one model to recognize both; at each byte, the model would decide among four possibilities instead of two. This could halve the amount of training time required. Also, what the network needs to learn in order to recognize function starts probably overlaps considerably with learning to recognizing function ends, so a network which simultaneously performs both tasks may also learn faster and produce more accurate results.

Table 6 summarizes our experimental results for testing this hypothesis. Overall, the single model which performs both tasks seems to do slightly worse than having separate neural networks for each task. Perhaps the disadvantage incurred from needing to keep track of more information exceeds the advantages mentioned in the previous paragraph.

6 Discussion

Limitations. As with most other machine learning approaches, ours assumes that the same underlying generative process has created both the training set and the test set. If similar patterns from the training data do not exhibit themselves in the test data, our approach will fail to correctly identify the functions.

As a pathological case, consider what would happen if long sequences of instructions which have no effect were inserted at arbitrary locations in the binary, including in the middle of function prologues. Such insertions would cause the internal structure of the binary to differ from what the model saw in the training data, even though it has no affect on the functionality. We might easily remove these instruction sequences if they were simply NOPs (0x90 in x86), but we can imagine the ability to create arbitrarily complicated ones especially if they are allowed to be long. Results from computability theory, such as Rice's theorem, suggest that it could be very difficult (if not impossible) to filter out such sequences from the binary through static analysis.

Table 8: Performance of our function start identification model on different subsets of the dataset. Each percentage value represents the precision, recall, or F1 score on the binaries of a particular architecture, compiler, and optimization level combination.

As for RNNs, since they accumulate and transfer information in a sequential manner, the input from these irrelevant instructions could easily overwrite the parts of the hidden state necessary for making correct predictions about the locations of the function boundaries.

In some cases, we can foresee that our approach will require preprocessing of the data in order to obtain good results. For example, binaries which decompress or decrypt themselves at runtime would not contain recognizable code within the binary stored on disk. Given that such obfuscations affect all static binary analysis techniques, previous works have addressed the problem of detecting and reversing such transformations [10, 21].

Segmented results. In Table 8, we delineate how the accuracy results for function start identification with our model (as described in Section 5.3) differed among different subsets of the binaries as further segmented by compiler and optimization level.

As we might expect, the model does best when run on binaries compiled without any optimizations (labeled as O0 and Od in the table), given that those tend to have very clear indications at the beginnings of functions. Nevertheless, the model's performance remains roughly constant on binaries compiled with more optimizations, with the exception of `gcc` on Linux for the x86-64 architecture where the F1 score decreased by about 2.9 percentage points. Given that the training data contains examples with every optimization level and compiler used for testing, we would hope that the model can learn to recognize functions in all such cases. However, it seems that `gcc` can produce relatively challenging examples with more optimizations enabled. Since the x86-64 ABI passes some function arguments in registers, it is possible to avoid any manipulation of the stack and base pointers upon function entry.

Error analysis. We randomly sampled some of the binaries to manually inspect the errors made by the model in them. Specifically, we selected 5 binaries for each combination of compiler, optimization level, architecture, and OS, then examined the errors to identify some common features between them.

Here are some observations we made:

- Given the bidirectionality of the model, it seems to exploit the appearance of frequently-occurring sequences at the ends of the previous function in addition to typical function prologues. One obvious example are `ret` and its variants, used to return from function execution. The compiler also often inserted padding between functions (such as `nop` (`0x90`) and other no-op instructions with longer encodings, or in Windows binaries, `int3` which triggers an interrupt), the end of which the model would use to recognize the beginnings of functions.

- As a consequence of the above, false positives often occurred after `nop`, `ret`, and other instructions which usually appear at the end of a function. In fact, it would also find false positives within immediate values encoded into the code if they contained `0x90` or `0xc3`, the encodings of those instructions.

- False negatives often occurred when instructions that would typically occur in the middle of functions occurred at the beginning of a function, as we might expect. The first byte of the program was often also falsely not recognized as a function start, presumably due to the lack of context previous to it.

- As documented by Bao et al. [2], `icc` will generate functions with multiple entry points. Many of the false negatives occurred at the second entry points to functions, given that the instructions before it are not the ones which usually end functions.

- The behavior of the model was not easily characterized by simple rules on short sequences of instructions; for example, while many false positives occurred after `nop` and `ret`, this did not mean that the model marked all (or even a large fraction) of such positions as function starts. For relatively difficult cases like these, the precise content of the surrounding bytes might have a complicated effect on the answer produced by the model.

Future work. Although we have seen some experimental evidence about the performance of the RNN under various conditions, we lack a clear explanation of the internal mechanics of the model. One potential approach towards an explanation proceeds through an analysis of the eigenvector structure by linearizing the state of the network as it evolves over time and analyzing which eigenvectors of the linearized systems carry the task-relevant information [12]. This analysis can provide an understanding of how the network ignores irrelevant information while selecting, integrating, and communicating relevant information, and allows identification of which eigenvector(s) of the linearized system are responsible for these tasks performed by the network. However, if the neural network's parameters are available to adversaries interested in disrupting the accuracy of the model, they may be able to use such analyses to more effectively add extra instructions which are not orthogonal to the eigenvectors carrying the task-relevant information, thus preventing its transmission and significantly affecting the RNN's performance.

7 Related Work

Function identification. Given that function identification serves as a basis for many applications within binary analysis, it should not surprise that many past papers have discussed the topic. For example, Kruegel et al. [9] identify functions as a prelude to static disassembly, and Theiling [18] for inferring control-flow graphs. However, these do not focus specifically on function identification as a specific problem, so here we point out some other works that do.

Rosenblum et al. [14] first framed the function identification problem as a task for machine learning. They combine a logistic regression classifier that uses "idioms" (short patterns of instructions) with a conditional random field to impose some structure between predictions for related instructions. Karampatziakis [8] tackles the related problem of accurate static disassembly using similar machine-learning tools, and Jacobson et al. [7] extend the prior work by Rosenblum et al. to fingerprinting library wrappers which appear in binaries. Bao et al. [2] also address function identification using supervised learning, but use weighted prefix trees which require much less computation than Rosenblum et al.'s approach to train, but still seems to give results with high accuracy.

Some tools built for binary analysis provide function identification as part of their functionality, usually using relatively simple heuristics or hand-coded signatures: Dyninst [6] and IDA Pro are some examples.

Neural networks. Much research using neural networks have focused on domains with continuous input data, such as vision and speech. In contrast, binary code contains discrete, multinomial values, where there typically exists no obvious ordering relationship between the possible values (unlike intensities of light or sound, for example).

Natural language processing also involves multinomial values (typically sequences of words), and neural networks have been successfully used for some applications there. Bengio et al. [3] first used neural networks to make a *language model*. Language models give a probability distribution over the next word in a sentence given the words so far, and see usage in machine translation and speech recognition. Mikolov et al. [11] moved to using a RNN. More recently, Sutskever et al. [17], Bahdanau et al. [1], and Cho et al. [5] have used RNNs for machine translation, and Vinyals et al. [20] for parsing.

We could not find any previous works which applied neural networks to binary code, but some use them on source code. Zaremba and Sutskever [22] attempt to train recurrent neural networks to evaluate short Python programs. Mou et al. [13] learn a vector representation from ASTs for supervised classification of programs.

8 Conclusion

In this paper, we proposed a new machine-learning-based approach for function identification in binary code based on recurrent neural networks. To our knowledge, there exists no previous works which apply neural networks to any problems in binary analysis. We address this gap by demonstrating how to use recurrent neural networks for function identification, and empirically show drastic reductions in computation time despite achieving comparable or better accuracy on a prior test suite. We hope that this work can serve as an inspiration for further advancements in binary analysis through neural networks.

Acknowledgements

We would like to thank Philipp Moritz for help with the initial implementation and experiments. We acknowledge Kevin Chen, Warren He, and the anonymous reviewers for their helpful feedback. This work was supported in part by FORCES (Foundations Of Resilient CybEr-Physical Systems), which receives support from the National Science Foundation (NSF award numbers CNS-1238959, CNS-1238962, CNS-1239054, CNS-1239166); by the National Science Foundation under award CCF-0424422; and by DARPA under award HR0011-12-2-005.

A Backpropagation

We can view backpropagation as repeated application of the chain rule. We sketch how it works using the following example of a three-layer network:

$$\begin{aligned} h_1 &= f_1(x; \theta_1) \\ h_2 &= f_2(h_1; \theta_2) \\ \hat{y} &= f_3(h_2; \theta_3) \end{aligned}$$

where $\theta_i = (W_i, b_i)$, and we have named all of the intermediate hidden values for convenience of reference. We wish to minimize the error between the predicted $\hat{y}$ and the true value y. For example:

$$L = d(y, \hat{y}) = ||\hat{y} - y||^2$$

Then we can compute the following partial derivatives using the chain rule:

$$\begin{aligned} \frac{\partial L}{\partial \hat{y}} &= 2(\hat{y} - y) & \frac{\partial L}{\partial \theta_3} &= \frac{\partial L}{\partial \hat{y}} \frac{\partial \hat{y}}{\partial \theta_3} \\ \frac{\partial L}{\partial h_2} &= \frac{\partial L}{\partial \hat{y}} \frac{\partial \hat{y}}{\partial h_2} & \frac{\partial L}{\partial \theta_2} &= \frac{\partial L}{\partial h_2} \frac{\partial h_2}{\partial \theta_2} \\ \frac{\partial L}{\partial h_1} &= \frac{\partial L}{\partial h_2} \frac{\partial h_2}{\partial h_1} & \frac{\partial L}{\partial \theta_1} &= \frac{\partial L}{\partial h_1} \frac{\partial h_1}{\partial \theta_1} \end{aligned}$$

Reassembleable Disassembling

Abstract

Reverse engineering has many important applications in computer security, one of which is retrofitting software for safety and security hardening when source code is not available. By surveying available commercial and academic reverse engineering tools, we surprisingly found that no existing tool is able to disassemble executable binaries into assembly code that can be *correctly assembled back* in a fully automated manner, even for simple programs. Actually in many cases, the resulted disassembled code is far from a state that an assembler accepts, which is hard to fix even by manual effort. This has become a severe obstacle. People have tried to overcome it by patching or duplicating new code sections for retrofitting of executables, which is not only inefficient but also cumbersome and restrictive on what retrofitting techniques can be applied to.

In this paper, we present UROBOROS, a tool that can disassemble executables to the extent that the generated code can be assembled back to working binaries *without manual effort*. By empirically studying 244 binaries, we summarize a set of rules that can make the disassembled code *relocatable*, which is the key to *reassembleable disassembling*. With UROBOROS, the disassembly-reassembly process can be repeated thousands of times. We have implemented a prototype of UROBOROS and tested over the whole set of GNU Coreutils, SPEC2006, and a set of other real-world application and server programs. The experiment results show that our tool is effective with a very modest cost.

1 Introduction

In computer security, many techniques and applications depend on binary reverse engineering, i.e., analyzing and retrofitting software binaries with the source code unavailable. For example, software fault isolation (SFI) [33, 46, 2, 19, 18] rewrites untrusted programs at the instruction level to enforce certain security policies. To ensure program control-flow integrity (CFI, meaning that program execution is dictated to a predetermined control-flow graph) [1, 4, 43, 17, 29, 37] without source code, the original control-flow graph must be recovered from a binary executable and the binary must be retrofitted with the CFI enforcement facility embedded [50, 49]. Symbolic taint analysis [34] on binaries must recover assembly code and data faithfully. The defending techniques against return-oriented programming (ROP) attacks also rely on binary analysis and reconstruction to identify and eliminate ROP gadgets [44, 9, 47, 22, 39].

Despite the fact that many security hardening techniques are highly dependent on reverse engineering, flexible and easy-to-use binary manipulation itself remains an unsolved problem. Current binary decompilation, analysis, and reconstruction techniques still cannot fully fulfill many of the requirements from downstream. To the best of our knowledge, there is no reverse engineering tool that can disassemble an executable into assembly code which can be *reassembled* back in a fully automated manner, especially when the processed objects are commercial-off-the-shelf (COTS) binaries with most symbol and relocation information stripped.

We have investigated many existing tools from both the industry and academia, including IDA Pro [24], Phoenix [42], Dagger [12], MC-Semantics [32], SecondWrite [3], BitBlaze [45], and BAP [8]. Unfortunately, these tools focus more on recovering as much information, such as data and control structures, as possible for analysis purpose mainly, but less on producing assembly code that can be readily assembled back without manual effort. Hence, none of them provide the desired disassembly and reassembly functionality that we consider, even if the processed binary is small and simple.

Due to lack of support from reverse engineering tools, people build high-level security hardening applications based on partial binary retrofitting techniques, including binary rewriting tools such as Alto [35], Vulcan [16], Diablo [13], and binary reuse tools such as BCR [11] and TOP [48]. We consider binary rewriting as a partial retrofitting technique because it can only instrument or patch binaries, thus not suitable for program-wide transformations and reconstructions. As for binary reuse tools, they work by dynamically recording execution traces and combining the traces back to an executable, meaning the new binary is only an incomplete part of the original binary due to the incomplete coverage of dynamic program analysis.

Partial retrofitting has notable drawbacks and limitations:

- Patch-based rewriting could introduce non-negligible runtime overhead. Since the patch usually lives in an area different from the original code of the binary, interactions between the patch and the original code usually require a large amount of control-flow transfers.

- Patch-based rewriting usually relocates instructions at the patch point to somewhere else to make space for the inserted code. As a result, it requires the affected instructions to be relocatable by default.

- Instrumentation-based rewriting expands binary sizes significantly, sometimes generating nearly double-sized products.

- Binary reuse often requires a binary component to be small enough for dynamic analysis to cover; otherwise the correctness cannot be guaranteed.

Having investigated previous research on binary manipulation and reconstruction, we believe that it could be a remarkable improvement if we are able to automatically recover the assembly from binaries and make the assembly code ready for reassembly. When a binary can be reconstructed from assembly code, many high-level and program-wide transformations become feasible, leading to new opportunities for research based on binary retrofitting such as CFI, diversification, and ROP defense.

Our goal is quite different from previous reverse engineering research. Instead of trying to recover high-level data and control structures from program binaries which helps binary code analysis, we aim at a more basic objective, i.e., producing assembly code that can be readily reassembled back without manual effort, which we call the *reassembility* of disassembling. Although the research community has made notable progress on binary reverse engineering, reassembility is still somewhat a blank due to lack of attention. In this sense, our contribution is complementary to existing work.

With that said, we believe that the technical challenge is also a cause for the deficiency in binary reassembly support from existing tools. We have confirmed that the key to reassembility is making the assembly code *relocatable*. Relocation is a linker concept, which is basically for ensuring program elements defined in different source files can correctly refer to each other after linked together. Being relocatable is also a premise for supporting program-wide assembly transformations. In COTS binaries, however, the information necessary for making disassembly results relocatable is mostly unavailable. There has been research trying to address the relocation issue [11, 48, 26], but existing work mostly relies on dynamic analysis which is unlikely to cover the whole program.

In this paper, we present UROBOROS, a disassembler that does reassembleable disassembling. In UROBOROS, we develop a set of methods to precisely recover each part of a binary executable. In particular, we are the first to be capable of not only recovering code, but also data and meta-information from COTS binaries without manual effort. We have implemented a prototype of UROBOROS and tested it on 244 binaries, including the whole set of GNU Coreutils and the C programs in SPEC2006 (including both 32-bit and 64-bit versions). In our experiments, most programs reassembled from UROBOROS's output can pass functionality tests with negligible execution overhead, even after repeated disassembly and reassembly. Our preliminary study shows that UROBOROS can provide support for program-wide transformations on COTS binaries.

In summary, we make the following contributions:

- We initiate a new focus on reverse engineering. Complementary to historical work which mostly focuses on recovering high-level semantic information from binary executables or providing support for binary analysis, our work seeks to deliver *reassembility*, meaning we disassembles binaries in a way that the disassembly results could be directly assembled back into working executables, without manual edits.

- We identify the key challenge is to make the disassembled program *relocatable*, and propose our key technique to recover references among immediate values in the disassembled code, namely "symbolization".

- With reassembility, our research enables direct binary-based transformation without resort to the previously used *patching* method, and can potentially become the foundation of binary-based software retrofitting.

- We implement a prototype of UROBOROS and evaluate its strength on binary reassembly. We applied our technique to 244 binaries, including the whole set of GNU Coreutils and SPEC2006 C binaries. The experiment results show that our tool does correct disassembly and introduces only modest cost.

- Our disassembler produces "normal" assembly code in the sense that binaries reassembled from UROBOROS's output assembly can again be disassembled (and hence the name UROBOROS[1]), or be used to accomplish other reverse engineering tasks. We verify this by repeating the disassemble-reassemble loop for thousands of times on different binaries.

The remainder of the paper is organized as follows. We first discuss the related work and challenges in §2 and §3, respectively. We then present the design and implementation of UROBOROS in §5. The experimental results are presented in §6, followed by some discussions in §7. We conclude the paper in §8.

2 Related Work

This section reviews literature on binary disassembly, binary rewriting, and binary reuse.

2.1 Disassembly

As aforementioned, there is no disassembler known to us that can generate working assembly code from binaries whose symbol and relocation information is stripped. IDA Pro [24] is considered as the best commercial disassembler available on the market. It can decode binaries into assembly and further decompile assembly into C code for program analysis. However, the assembly code produced by IDA Pro cannot be directly used as the input of any assembler. As stated in its manual [21], assembly code produced by IDA Pro is meant for analysis and cannot be directly reassembled or recompiled.

SecondWrite [3] leverages multiple static analysis techniques to lift binaries into LLVM IR. It is reported that the recovered LLVM IR can be converted back into C code given the LLVM's IR-to-C backend. However, it is unclear to us how SecondWrite symbolizes the data sections and recovers the meta-data information of the binaries. The paper does not contain an evaluation on this recompilation functionality. Moreover, the IR-to-C backend has been removed from LLVM release since 3.1, because it is not mature enough to handle non-trivial programs [30].

Dagger [12] is another tool that translates native code into LLVM IR, but the implementation is far from complete. There is a pre-release version available online. We tried to use it to decompile a simple binary (compiled from a C program with only empty main function). The decompiler reported several errors and generated an LLVM IR file which cannot be compiled back into binary due to lack of some symbol definitions.

MC-Semantics [32] is yet another tool for native code to LLVM IR translation. We used MC-Semantics to decompile some quickly written mini programs. Although the code produced by MC-Semantics can be made binaries, the execution results of these binaries are not the same as the originals, which we believe is due to incorrect symbol references. In addition, different from previously reviewed work, MC-Semantics works at the scale of object files rather than executables. Lacking the ability to handle linked binary programs narrows its scope of application.

BAP [8] is a binary analysis platform that comes with a disassembler. It can lift assembly code to a BAP-defined high-level intermediate representation that can be further analyzed statically. Several reverse engineering tools have been built based on BAP, including the C type recovery tool TIE [28] and the C control-flow recovery tool Phoenix [42]. Although BAP provides solid support for binary analysis, the strength of its disassembler is also limited to analysis only.

There could be multiple reasons that existing tools fail on reassembling. One reason is the technical challenges such as separating code and data, symbolizing the data sections, etc. The other reason could be the difference in the design goals. Most existing tools aim to produce more readable code or code that can be analyzed, not for the purpose of translation and reassembly. We emphasize that the ability to reassemble the output from a disassembler can provide an enabling infrastructure, facilitating further research.

2.2 Binary Rewriting

Binary rewriting techniques can be either static or dynamic. Static binary rewriting is widely used in security hardening such as control-flow hijacking mitigation [47], software control-flow integrity enforcement [50, 49], and binary instrumentation [3, 35, 13, 16]. Most static binary rewriting tools make strong assumptions on the input binaries. For example, Vulcan [16], Alto [35, 13], and Diablo [13] require binaries to be compiled from specific compilers or require symbol information not stripped. SecondWrite [3] can patch binaries with new code and data, but the original content in the binary shall remain unmodified.

As aforementioned, typical static binary rewriting has to relocate instructions at the patch point to make room for newly inserted code. In order to make sure that the rearranged instructions can be relocated while still pre-

[1] Uroboros is a symbol depicting a serpent eating its own tail.

serving program semantics, a stub-based idea is adopted to redirect control flow from the original location to the relocated new place at run time [14, 50, 47]. Control transfer instructions, i.e., stubs, are inserted at memory addresses that are pointed to by some code pointers. This strategy broadens the application scope of binary rewriting tools. However, there could be a large amount of stubs inserted, thus incurring notable execution overhead and size expansion on the rewritten binaries.

Dynamic binary rewriting tools, such as Pin [31] and DynamoRIO [7], can trace the execution of a binary and instrument or patch the program on the fly. Dynamic rewriters are able to handle COTS binaries, whereas with the cost of considerable performance penalty. Also, dynamic binary rewriting requires the rewriter itself to be shipped with or embedded into the target binaries.

Dyninst [10, 20] is a tool that features both static and dynamic binary rewriting. It supports performance measurement and computational steering. It can disassemble the stripped binaries and instrument them statically or dynamically, but does not deliver reassembleable disassembling either.

2.3 Binary Reuse

Binary reuse is mostly based on dynamic analysis. One of the representative binary reuse tools is BCR [11]. BCR extracts and reuses functions from binaries with a hybrid approach. BCR first executes binaries in a monitored environment and records execution traces and memory dumps. Binaries are then statically disassembled starting from the entry point. In the disassembly process, the dynamically collected information is used to resolve the destinations of indirect branches. In the end BCR manages to extract a “closure” of code reachable from the entry point which can be reused by other programs. Clearly, the correctness of the reused code cannot be guaranteed if BCR does not cover all feasible execution paths.

In addition to BCR, there are other binary reuse tools that employs similar basic ideas, such as Inspector Gadget [26] and TOP [48]. While these tools have made improvements in different aspects, the fact that they all rely on dynamic analysis leads to the incompleteness issue, more or less. In general, these tools can only do partial binary retrofitting.

3 Challenges

We have briefly discussed the technical challenges for developing a disassembler which can deliver *reassembility*. In this section, we discuss these difficulties in more details. In this research, we assume that the binaries to disassemble are stripped COTS binaries, namely binaries without any relocation information or symbols, except those necessary for dynamic linking. We also assume that the binaries are compiled from unobfuscated C programs, without self-modifying features. The target hardware architectures of the binaries are x86 and x64. The binary executable format is the Executable and Linkable Format (ELF).

3.1 Raw Disassembly

In this paper, raw disassembly is referred to as the process of parsing the binary form of a program to its raw textual representation. The difficulty of raw disassembly can vary a lot in different situations. In the most general case, this problem is undecidable. One of the reasons is that the problem of statically determining the addresses of indirect jumps is undecidable [23]. Furthermore, the existence of advanced program features such as self-modifying code makes the problem harder. Another issue is that current computer architectures do not distinguish code and data, and there is no easy way for a raw disassembler to distinguish them either. This problem is further worsened by the variable-length instruction encoding used by, for example, the x86 instruction set architecture.

However, with years of intensive effort on improving related techniques, the state of the art can already reach a very high success rate when disassembling binaries compiled from practical legitimate C source code by mainstream compilers. A recent paper by Zhang et al. [50] proposed a novel raw disassembly method which combines two existing disassembly algorithms together. We reimplemented this algorithm and applied it to our evaluation set which includes 244 binaries. No errors were reported by the raw disassembler and subsequent evaluation also verified the correctness of this algorithm on our evaluation set. As a result, we do not consider raw disassembly, or binary decoding, as a major challenge to address in this research.

3.2 Reassembly

Successfully decoding the binaries is only the first step to the goal of this research. Ideally, binary reverse engineering tools should be able to support at least the following process:

- The reverse engineering tool disassembles the original binary into assembly code.
- Users can perform static analysis on the disassembled program.
- Users can perform transformations on the disassembled program.

- The transformed program can be assembled back into an usable binary executable, with all transformation effects retained.

Although it may not be obvious, the feasibility of the first three steps does not naturally imply the feasibility of the last step. There have been reverse engineering tools or platforms that can (partially) enable the first three steps [8, 45], but support for reassembly is still a blank.

As mentioned in the introduction, making the assembly code relocatable is the crux of reassembility. Figure 1 is an artificial example comparing relocatable and unrelocatable assembly code. In COTS binaries, information required for making disassembly results relocatable is unavailable. Most program transformations inevitably change binary layouts, but a reverse engineering tool has only very limited control over how the linkers assign memory addresses of the program elements, leading to situations illustrated by Figure 1. Note the memory cell located at address `0xc0` in the original memory, which is possibly a global variable. The raw disassembly process does not recognize the concrete value `0xc0` in the code as a reference. Thus when this unrelocatable assembly code is reassembled, the resulting binary will very likely be defected because the content of the memory cell at `0xc0` in the original binary may not be placed the same address in the new binary. In the relocatable assembly, however, the data originally living at `0xc0` is given a symbolic name, and the concrete address `0xc0` is replaced by a reference to this name. This is why relocatable assembly can be reassembled into a working executable.

As suggested by the example, if a reverse engineering tool seeks to reassemble the transformed assembly code into a working executable, it has to identify program elements whose addresses could possibly change in the new binary, and lift concrete memory addresses referring to them to abstract symbolic references. Obtaining relocatable assembly from a COTS binary is non-trivial because very little auxiliary information in the binary can be utilized to help identify references among concrete values. Essentially, the problem can be generalized as the following: given an immediate value in the assembly code (either in a code section or data section), is it an memory address or a constant? Although this looks like a typical type analysis problem, in the context of binary reassembly it becomes much more challenging. From a static point of view, since most machine assembly languages are untyped, type inference is difficult in the first place. Compared to high-level programming languages, assembly languages lack explicit syntax for denoting procedure boundaries and basic control-flow logic, making static analysis even more difficult. What is worse, many references live in the data sections, some of which are indirectly referred to by the code via numerous reference hops. At present, most proposed program analysis techniques, either static or dynamic, are code oriented, lacking the capability of analyzing the property of a given data chunk. Finally, reassembly has almost zero tolerance for type inference errors, because a single false positive or false negative can place the reassembled binary in a non-functional state.

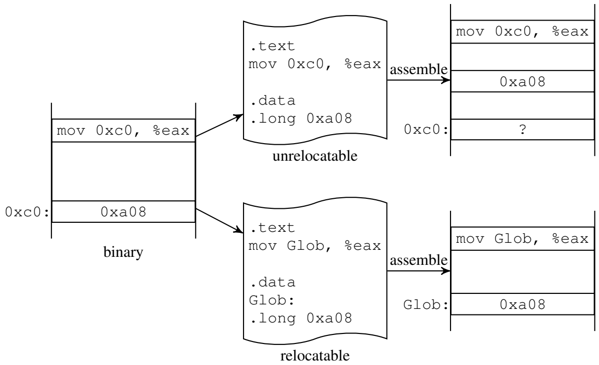

Figure 1: Relocatable and unrelocatable assembly code

Solving the relocatable problem in binary disassembly is the main purpose and contribution of this paper. In the rest of the paper, we call the process of identifying references among immediate values in the raw assembly the process of "symbolization". To distinguish the concept from the traditional meaning of disassembling, we call our work *reassembleable disassembling* that generates relocatable assembly code.

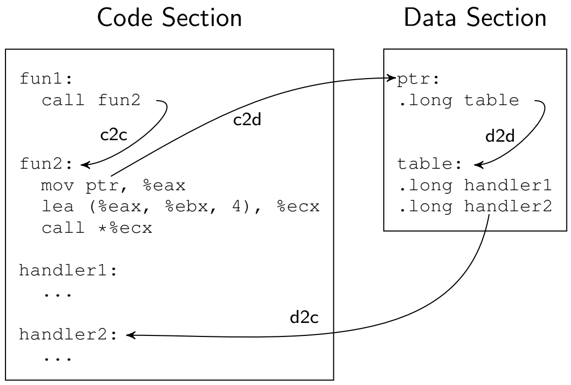
In addition to relocation information, a full-fledged disassembler also needs to recover some meta information to make the reassembly feasible. Meta-data sections in a binary executable provide information to direct some link-time and runtime behavior of the program. They should also be recovered properly in order to ensure the reassembled binaries are semantic-equivalent to the originals.

4 Symbolization

This section describes the symbolization problem in detail and presents our solution.

4.1 Classification

There are four types of symbol references that we need to identify for reassembility. The classification is based on two criteria—where a reference lives and where a reference points. Basically, we divide the binary into two parts, i.e., the code sections and the data sections, whose contents are as suggested by their names. For ELF binaries on Unix-like platforms, typical code sections include



```
fun1:
  call fun2

fun2:
  mov ptr, %eax
  lea (%eax, %ebx, 4), %ecx
  call *%ecx

handler1:
  ...

handler2:
  ...
```

```
ptr:
.long table

table:
.long handler1
.long handler2
```

Figure 2: Different types of symbol references in assembly code

.text and .init etc. Typical data sections include .data, .rodata, .bss, etc. A symbol reference can live in either code sections or data sections, and can point to either code sections or data sections as well, leading to a total of four types. Figure 2 is an example showing all four types of symbol references. We give each of them a short name, i.e., c2c, c2d, d2c, and d2d references.

4.2 Method

When it comes to solving the symbolization problem, we have considered various potential solutions. Due to the reasons listed in §3.2, we conclude that no existing program analysis technique can handle the symbolization problem in our special context. Hence, we decide to turn to another direction. In this work, we identify the immediate values which are actually symbol references by applying several matching rules inferred from our study on a large amount of binaries. Although some of these strategies may not seem exciting at the first sight, they work surprisingly well in our evaluation on 244 binaries compiled from C code.

Since we are solving the symbolization problem in an empirical way, the matching strategies are all based on certain assumptions. Depending on whether an assumption is accepted or not, different rules are applied for symbolization. We now introduce the assumptions and the corresponding symbolization strategies.

At the point of symbolization, we assume that we have already obtained the raw assembly decoded from binaries using the algorithm by Zhang et al. [50], so we can get all immediate values that appear in a binary. There are two kinds of immediate values—constants used as instruction operands and the byte stream living in data sections. Among all these immediate values, some can be excluded from being considered for symbolization at the first place. Unless a program intentionally causes memory access errors, which is rarely the case, an immediate value can be a reference to symbols *only if* this value falls in the address space allocated for the binary. For a binary of reasonable size, the utilization of address space is usually sparse, so there is a wide range of address space which is actually invalid.

Assuming all immediate values are potential symbol references, we can filter out obviously invalid references based on their target addresses. According to our symbol reference classification in §4.1, a reference can only point to code sections or data sections; especially, if a reference points to code sections, the destination must be the starting address of some instruction. Our study on 244 binaries shows that this simple filter is sufficient to identify c2c and c2d symbol references with full correctness.

The really challenging part is data section symbolization, i.e., identifying d2c and d2d references. The first step of data section symbolization is to slice the data sections, which are continuous areas of binary bytes, into individual values of different lengths. Since the raw disassembly process does not assign the data sections any semantics, there is no ready-made guidance on how they should be sliced. Regarding this problem, we introduce the first assumption which is about binary layout:

> (A1) *All symbol references stored in data sections are n-byte aligned, where n is 4 for 32-bit binaries and 8 for 64-bit binaries.*

Since unaligned memory accesses cause considerable performance penalty, compilers tend to keep data aligned by its size. For data alignment, compilers can even sacrifice memory efficiency by inserting padding into data sections. With that said, A1 stays as an assumption because occasionally programmers do want non-aligned data layout. For example, the "packed" attribute supported by GCC allows programmers to override the default alignment settings.

If we accept assumption A1, only *n*-byte long values which are also *n*-byte aligned in data sections are considered for symbolization. Alternatively with A1 rejected, all *n*-byte long memory content in data sections are considered for symbolization. This is implemented as an *n*-byte sliding window which starts from the beginning of a data section and scans through the entire section in a *first-fit* manner. Each time the sliding window moves forward 1 byte and check the value of the covered bytes. If the value fulfills the basic requirements for being a d2d or d2c reference, it will be considered for symbolization and the sliding window advances *n* bytes forward. In case that the value does not meet the requirements, the sliding window moves forward 1 byte only.

In addition to assuming the characteristics of binaries, making assumptions on user requirements for our tool also helps improve its performance. As stated earlier, the goal of symbolization is to make assembly code relocatable so that users can perform program-wide transformations on the assembly and then assemble it back to a working executable. From our experience, most transformations on assembly only touch the instructions without modifying the original data. If we make the following assumption

> (A2) *Users do not need to perform transformation on the original binary data.*

then we can keep the starting addresses of data sections the same as their old addresses when performing reassembly, by providing a directive script to the linker. In this way, we can ignore d2d references during symbolization simply because we do not need them to be relocatable anymore. Thus, with A2 accepted, only the immediate values that fall within code sections (d2c references) are considered for symbolization. Contrarily, without deterministically fixing the starting addresses of data sections in the new binary, the immediate values that fall within either code sections or data sections are considered for symbolization.

We want to avoid symbolizing d2d references because they are used in a very flexible manner. On the other hand, there are more common patterns in d2c references which can be exploited by our symbolization method. We summarize the patterns with the following assumption:

> (A3) *d2c symbol references are only used as function pointers or jump table entries.*

By accepting A3, an *n*-byte value in data sections is lifted to a d2c reference if it is the starting address of some function, or it forms a jump table together with other *n*-byte values adjacent to it. Otherwise with A3 rejected, an *n*-byte data section value is symbolized whenever it is within the address space of code sections.

When A3 is taken, we will need to know whether a code section address is the start of a function. We also need to clarify what a jump table would be in the binary form. Identifying function beginnings in a binary is not a new research topic. Based on machine learning techniques, recent research [6] can reportedly identify function starting addresses with over 98% precision and recall. To avoid reinventing the wheel, we assume we have already known all the function start addresses. Since the binaries used in our research are all compiled from source code, we are able to get the ground truth by controlling the compilation and linking process.

Regarding the identification of jump tables, our algorithm is as follows:

- *Jump table start.* We traverse the data sections from the beginning to the end. If the address of an *n*-byte value is referred to by an instruction as the operand, it is considered as the first entry of a new jump table.
- *Jump table entry.* If an *n*-byte value follows an already identified jump table entry, this value is also considered as an entry as long as it refers to instructions within the same function that previous entries point to.

The three assumptions A1, A2, and A3 are the basics of our symbolization method. With different choices of an assumption being applied or not, we can derive different strategies when processing a binary. §6 has a detailed evaluation on the correctness of reasonable combinations of these assumptions.

5 Design and Implementation

5.1 Overview

The architecture of UROBOROS is shown in Figure 3. UROBOROS consists of two main modules—the disassembly module and the analysis module. The disassembly module decodes instructions with raw disassembling (§5.2) and dumps the data sections. The analysis module symbolizes memory references in both code and data sections (§4) and recovers the meta-information from the dumped content (§5.4). UROBOROS also recovers part of the control-flow structures from direct transfers so that it provides basic support for program-wide transformation (§5.3).

The disassembly module employs an interactive process to validate disassembled code from a linear disassembler. The linear disassembler decodes the code sections and dumps out all data and meta information sections. A validator is then invoked to correct disassembly errors due to "data gaps" embedded inside code sections. The details are presented in §5.2.

After the raw disassembly is over, the dumped code, data, and meta-data are sent to the analysis module. This module identifies symbol references among immediate values in the code and data. As elaborated in §4, we propose three assumptions for reassembleable disassembling. The corresponding strategies are implemented in UROBOROS to guide the symbolization process. UROBOROS can be configured to utilize different combinations of assumptions for symbolization. We give a detailed evaluation on the correctness of different strategies in §6.1.

Given the symbolized instructions, the analysis module also partially recovers the control flows based on direct control-flow transfers. With the relocatable assembly and the basic control-flow structures, users of UROBOROS can easily perform advanced program anal-

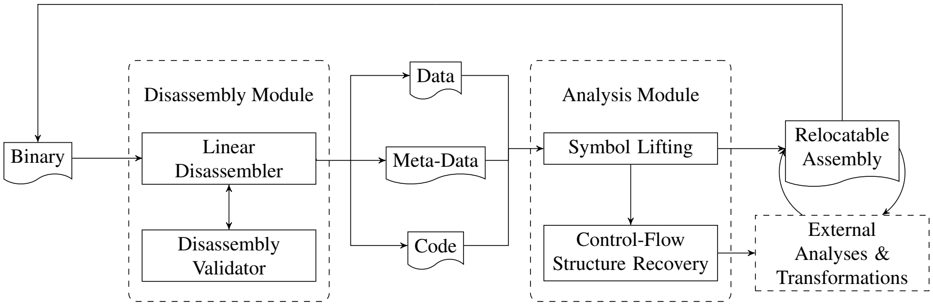


Figure 3: The architecture of UROBOROS

ysis and program-wide transformations before they assemble the code back to binaries.

Finally, we emphasize that the assembly code generated and transformed by UROBOROS can be directly assembled back as a working binary by normal assemblers. In particular, the binary output is indeed a *normal* executable file without any abnormal characteristics such as patched or duplicated sections. Therefore, the reassembled binary can be disassembled again by UROBOROS or be processed by other reverse engineering tools.

We have implemented a prototype of UROBOROS in OCaml and Python, with a total of 13,209 lines of code. Our prototype works for both x86 and x64 ELF binaries.

5.2 Disassembly

In our prototypical implementation, the linear disassembler employed by UROBOROS's disassembly module is `objdump` from GNU Binutils. We implement an interactive disassembly process originally proposed in BinCFI [50].[2] In this process, the disassembler communicates with a validator which corrects disassembly errors due to "data gaps" between adjacent code blocks. The interactive procedure is as follows:

- `objdump` tries to decode the input binary for the first time.
- The validator examines the output and check if there are explicit errors reported by `objdump`. In case there are no errors, the raw disassembly process terminates. Otherwise, the validator assumes the errors are caused by data embedded in code and computes the upper and lower bounds of identified "data gaps".
- With the computed range of identified "gaps", the validator guides `objdump` to decode the binary again, with those "gaps" skipped.
- Repeat this decode-validate process until no error occurs or the running time of the whole process reaches a time limit specified by users.

We leverage three rules proposed in BinCFI to validate the disassembly results and locate the data "gaps", i.e., "invalid opcode", "direct control transfers outside the current module", and "direct control transfer to the middle of an instruction". Since identifying bounds of each data gap can rely on the control-flow information of decoded instructions, the validator occasionally leverages UROBOROS's analysis module to retrieve the control-flow information.

5.3 Support for Program Transformation

UROBOROS provides basic support for program-wide transformations by partially recovering control-flow structures of the decoded instructions. We collect all the control transfer instructions to divide each function into multiple basic blocks. Control-flow graphs are rebuilt on top of these basic blocks. As a prototype, UROBOROS currently only processes direct control transfers. Regarding the intractable indirect transfers, a potential solution is to use value set analysis (VSA) [5] for destination computation. We leave including indirect control transfers in the CFG as future work.

5.4 Meta-Information Recovery

UROBOROS recovers the program-linkage table (PLT) and the export table in ELF binaries. The PLT table supports dynamic linkage by redirecting intra-module transfers on its stubs to external functions. As the base address of the PLT table can change after reassembling, we translate the memory references to PLT stubs to their corresponding external function names, and let the linker to rebuild the PLT table with correct memory references during link time. In particular, this table is dumped out from the input binary and parsed into multiple entries, each containing the memory address of a PLT stub with

[2] The BinCFI tool is available open source. We choose to reimplement the algorithm to make the codebase of UROBOROS more consistent such that it is fully automated and easy to extend. We refer readers to BinCFI [50] for the details of the disassembly process.

its corresponding function name. Next, we scan the program and identify the addresses that match to a table entry. These addresses are then replaced by the corresponding function name.

Symbols need to be "exported" so that other compilation units can refer to them. The exported symbols together with their memory addresses are recorded in the export table. As ELF binaries do not keep a standalone export table, we construct this table by searching for all global objects in the symbol table. The symbol name of each entry and its memory address are then kept in a map. The export table can help identify functions and variables that are only referred to by other compilation units. We iterate each entry of the export table to insert symbols and `.globl` macros to the corresponding addresses.

For typical ELF binaries compiled from C code, `.eh_frame` and `.eh_frame_hdr` sections are used by compilers to store information for some rarely-used compiler-specific features, such as the "cleanup" attribute supported by GCC. For these sections, we dump the content out and directly write them back to the output. These sections are also used to store exception information for C++ programs. Regarding this, we have a related discussion in §7.

5.5 Position Independent Code

Position independent code (PIC) typically employs a particular routine to obtain its memory address at run time. This address is then added by a fixed memory offset to access static data and code. According to our observation, the routine below is utilized by PIC code in 32-bit binaries to achieve relative addressing.

```
804C452: mov (%esp),%ebx
804C456: ret
```

PIC code invokes this routine by a `call` instruction, and register `ebx` is then assigned the value on top of the stack, which equals the return address. Uroboros identifies this instruction pattern, traces the usage of `ebx`, and rewrites the instructions that add `ebx` with memory offsets to a relocatable format.

An example is shown in Figure 4. Once we identify a `call` instruction targeting the above sequence, we calculate the absolute address by adding `0x804c466` with offset `0x2b8e`, which equals `0x804eff4`. By querying the section information from ELF headers, `0x804eff4` equals the starting address of `.got.plt` table, and we rewrite offset `0x2b8e` to the corresponding symbol, which is `_GLOBAL_OFFSET_TABLE` in this case.

Theoretically PIC could use other patterns besides the above sequence to obtain its own memory address; the above instruction sequence is, however, the only PIC pattern we encountered after testing a broad range of real world applications (compiler and platform information is disclosed in § 6).

```
804c460: push %ebx
804c461: call 804c452
804c466: add $0x2b8e,%ebx
804c46c: sub $0x18,%esp

804c460: push %ebx
804c461: call S_0x804C452
804c466: add $_GLOBAL_OFFSET_TABLE_,%ebx
804c46c: sub $0x18,%esp
```

Figure 4: PIC code reuse

As for x64 architectures, RIP-relative [25] memory references allow assembly code to access data and code relative to the current instruction by leveraging the `rip` register and memory offsets, which makes the implementation of PIC more flexible. In the raw disassembly output, instructions utilizing this mode are commented by `objdump` with the absolute addresses they refer to. We identify the comments, symbolize the memory offsets, and insert labels to the corresponding absolute addresses.

5.6 Redundancy Trim

When a binary is dynamically linked to libc, the prologue and epilogue functions of the library are automatically added to the final product. Uroboros attempts to support multiple iterations of the disassemble-reassemble process. Each time the binary is assembled, a new copy of the prologue and epilogue functions are inserted, which unnecessarily expands binary size. Some tentative experiments show that binary size can grow 5 to 6 times larger with respect to the original, if we perform the disassemble-reassemble iteration for 1,000 times.

We cannot identify the prologue and epilogue functions in COTS binaries as the symbol information has been stripped. However, after the first disassemble-reassemble attempt, we get an unstripped binary with sufficient information indicating which functions are added by the linker. If we are to do another disassemble-reassemble round, Uroboros can skip these functions in the disassembly phase.

Another source of redundancy is the padding bytes in data sections. In ELF binaries,there are three data sections (`.data`, `.rodata`, and `.bss`) that have padding bytes at the beginning. As these padding bytes are not used, we remove them from the recovered program before reassembling.

With the code and data redundancy trimmed, binary size expansion is reduced to almost zero, no matter how many times a binary is disassembled and reassembled.

5.7 Main Function Identification

In a compiler-produced object file, the symbol information of the main function is exported so that it can be accessed by the libc prologue functions in the linking process. However, as this symbol information in executable file is stripped in COTS binaries after linking, we need to recover and export it before reassembling.

Through our investigation, we found that the code sequence shown below is typically used to pass the starting address of main to libc prologue function libc_start_main.

```
push $0x80483b4
call 80482f0 <__libc_start_main@plt>
hlt
```

The first argument of libc_start_main, which is 0x80483b4 in this example, is recognized as the starting address of the main function. We insert a label named main and the type macro .globl main in the output at this address.

5.8 Interface to External Transformation

As briefly discussed in §1, existing binary software security applications mainly rely on patch-based or instrumentation-based binary manipulations. We argue that given the assembly program and support for program-wide transformation from UROBOROS, we can bridge external instrumentation and analysis techniques with binary retrofitting application development. The program-wide security instrumentation such as CFI, ROP attack mitigation, randomization and software diversification could be ported on the basis of UROBOROS to legacy binaries, without the inefficiency, cumbersomeness and restriction brought by previous binary manipulation methods.

In order to demonstrate that UROBOROS is an enabling tool that makes analysis and transformations applicable to legacy binaries in general, we implement a diversification transformation based on basic block reordering. After disassembly, we walk through each function and randomly select two basic blocks from its CFG as the reordering targets. Control-flow transfer instructions and labels are inserted in the selected blocks, their predecessors, and successors to guarantee semantic equivalence. We perform this reordering *iteratively*, namely the output of each iteration becomes the input of the next round. We conducted a quick experiment on gzip. The disassembly-transformation-reassembly process was iterated 1,000 times. The effectiveness of the diversification transformation is evaluated by the elimination rate of ROP gadgets measured by the ROP gadget detector ROPGadget [40]. From this preliminary study, we find that it is much easier than binary rewriting to perform binary-based software retrofitting based on UROBOROS. As the ROP defense is not the focus of this research, we omit the detailed results in this paper.

Table 1: Programs used in UROBOROS evaluation

Collection	Size	Content
COREUTILS	103	GNU Core Utilities
REAL	7	bc, ctags, gzip, mongoose, nweb, oftpd, thttpd
SPEC	12	C programs in SPEC2006

6 Evaluation

We evaluate UROBOROS with respect to correctness, cost, and its ability to support program-wide transformation. The correctness verification examines whether UROBOROS's reassembly is semantic preserving. Evaluation on the cost of UROBOROS reveals its reassembly's impact on binary size and execution speed, and also the running time of UROBOROS itself. As presented in §5.8, we study UROBOROS's support for binary-based software retrofitting, by implementing a basic block reordering algorithm to diversify disassembled binaries and eliminate ROP gadgets. As we have emphasized, UROBOROS is an enabling tool for other security hardening techniques. However, as goal-driven software security hardening is out of the scope of this paper, we do not present the detailed experiment results here.

We use three collections of binaries compiled from C code to evaluate UROBOROS. The first set, referred to as COREUTILS, is the entire GNU core utilities including 103 utility programs for file, shell, and text manipulation. The second set, called REAL, consists of 7 real-world programs picked by us, covering multiple categories such as floating-point and network programs. The last set subsumes all the C programs in the SPEC2006 benchmark suit, thus will be denoted by SPEC. Details of each collection are listed in Table 1. In the evaluation we compile all programs for both 32-bit and 64-bit targets. Since there are 122 programs, the number of tested binaries is 244 in total. The compiler is GCC 4.6.3, using the default configuration and optimization level of each program. All experiments are undertaken on Ubuntu 12.04. For each test case, we use the strip tool from GNU Binutils to strip off the symbol information and debug information before testing.

Table 2: Functionality test input for REAL

Program	Test Input
bc	Test cases shipped with the program
gzip	Test cases shipped with the program
ctags	Parse a C source file of 152,270 lines
oftpd	Login and fetch a large file
thttpd	Request some web pages & a large file
mongoose	Request some web pages & a large file
nweb	Request some web pages & a large file

6.1 Correctness

We verify the correctness of UROBOROS's reassembility in two steps. First, we execute binaries assembled from UROBOROS's output with test input shipped with the software. Both COREUTILS and SPEC have test cases shipped with the software by default. As for the REAL programs, most of them do not have test cases, so we develop input by ourselves to verify the major functionality. The input we use for testing the REAL collection is listed in Table 2.

Second, we examine the false positives and false negatives of our symbolization process for all the binaries of the three collections. In our context, a false positive is an immediate value that we mistakenly symbolize, while a false negative is a symbol reference that we fail to identify.

As described in §4, we have different assumptions to guide the symbolization process, so the correctness of different assumption combinations are verified. Since the three assumptions are orthogonal, there are eight different combinations with the choices of the three assumptions. With limited resources, it is difficult to test all 244 programs on all assumption sets. With some tentative experiments, we found that A1 is an assumption which greatly improves the overall performance of our disassembly and reassembly method. Therefore, we reduce the eight candidates to five by always including A1 except in the empty assumption set. In detail, the five assumption sets applied are {} (empty set), {A1}, {A1, A2}, {A1, A3}, and {A1, A2, A3}.

For all tested assumption sets, all reassembled binaries from COREUTILS and REAL pass the functionality tests. Some binaries from SPEC, however, fail to pass the tests, which are listed in Table 3. With the assumption set {A1, A2, A3}, only the 32-bit version of `gobmk` from SPEC (out of 244 cases in total) fails the functionality test. By inspecting this defected binary, we successfully locate the cause of failure. Some 4-byte sequences in the data sections happen to contain the same value as the starting address of a function, but they are not code pointers. UROBOROS incorrectly symbolizes them, leading to false positives. After we correct these errors, `gobmk` successfully passes the test.

For symbol-level correctness verification, we provide the statistics on false positives and false negatives of symbolization. A false positive is an immediate value that should not have been symbolized. A false negative is an immediate value which should be symbolized but failed to be after our symbolization process. We obtain the ground truth by parsing the relocation information provided by the linker.

We have verified all binaries in this step. Due to limited space, we only list the results for non-trivial cases, namely programs with at least one symbolization false positive or false negative with any assumption combination. Table 4 and 5 show the false positive and false negative analysis for 32-bit binaries, and Table 6 reports false positive analysis for 64-bit binaries. There are no false negatives on any of the 64-bit binaries. We emphasize in particular that, *with {A1, A2, A3} applied, among all the 244 binaries, only `gobmk` has a few false positives, and none has false negatives.*

The results of symbol-level verification are highly synchronized with the results from the first stage—binaries reassembled with no false positives or false negatives can pass all test cases. The results show that symbolization errors are found in `gobmk` no matter which assumption set we apply. In particular, we have verified that symbolization errors found in `gobmk` when applying {A1, A2, A3} are all caused by program data colliding with some function starting addresses. These collisions cause a functionality test failure for 32-bit `gobmk`, but the 64-bit version can pass the test due to the incompleteness of test input. In summary, the two stages of verification together imply that all three assumptions proposed for symbolization are reasonable.

Although the symbolization errors occurring in the case of `gobmk` seem conceptually "general", our study shows that the collisions are actually rare in practice, unless the disassembled binary has very large data sections like `gobmk` does. See Appendix A for the symbolization errors in `gobmk`. On the other hand, UROBOROS can successfully disassemble large and complicated binaries like `gcc` and `perlbench`. Overall, the results from two stages of correctness verification suggest that UROBOROS is a promising tool with remarkable practical value.

6.2 Cost

The cost of UROBOROS manifests from three aspects: size expansion of reassembled binaries, execution overhead of reassembled binaries, and the processing time of UROBOROS itself.Due to space restrictions, we only report the evaluation results on 32-bit binaries in this paper.

Table 3: Dynamic test results on reassembled binaries

Assumption Set	Binaries Failing Functionality Tests	
	32-bit	64-bit
{}	h264ref, gcc, gobmk, hmmer	perlbench, gcc, gobmk, hmmer, sjeng, h264ref, lbm, sphinx3

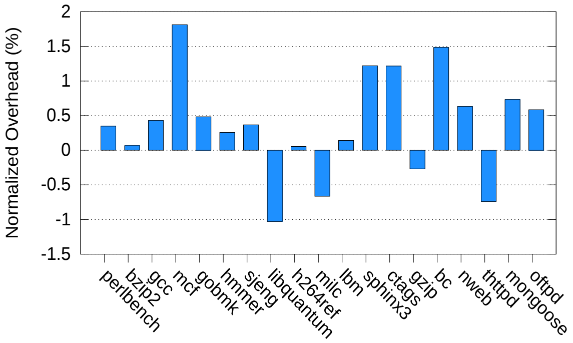

Figure 5: Execution overhead for REAL and SPEC programs relative to the original versions

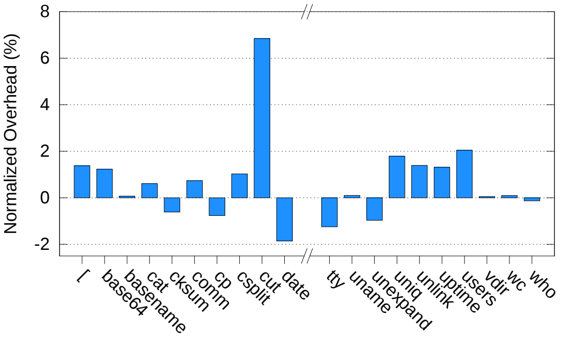

Figure 6: Execution overhead for COREUTILS programs relative to the original versions

6.2.1 Execution Overhead

Some programs in COREUTILS are not suitable for performance benchmarking, including `su`, `nohup`, and `timeout`, etc. After excluding these programs, we have 90 left to inspect in COREUTILS. The experiments are conducted on a machine with Intel Core i7-3770 3.40GHz and 8GB memory running Ubuntu 12.04.

We present the execution slowdown of reassembled binaries in Figure 5 and Figure 6. Since it is hard to present the data of all 90 binaries from COREUTILS, we sort COREUTILS programs by their names in alphabet order and plot the data for the first and last 10 programs in Figure 6. We report that the average slowdown for is 0.44% for COREUTILS, 0.29% for SPEC and 0.52% for REAL. The data suggests that UROBOROS does not have any significant impact on the execution speed of reassembled binaries.

6.2.2 Size Expansion

We use the `stat` program from GNU Coreutils to calculate file size expansion of the reassembled binaries compared to the originals. As the increase is generally negligible, we only report the average data here. The average expansion for COREUTILS is 0.83%, 0.00% for SPEC and -0.02% for REAL. Data shows that UROBOROS has almost zero impact on binary size when delivering reassembility. As aforementioned in §5.6, subsequent disassembly-reassembly iterations have zero expansion.

6.2.3 Processing Time

We measure how long it takes UROBOROS to disassemble binaries. Figure 7 presents the processing time for SPEC and REAL binaries. Figure 8 presents processing time for COREUTILS binaries selected using a same al-

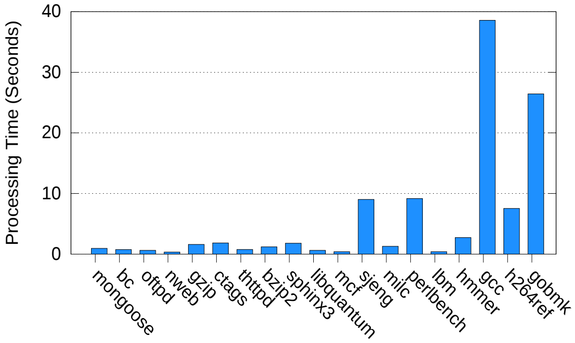

Figure 7: Processing time for SPEC and REAL binaries

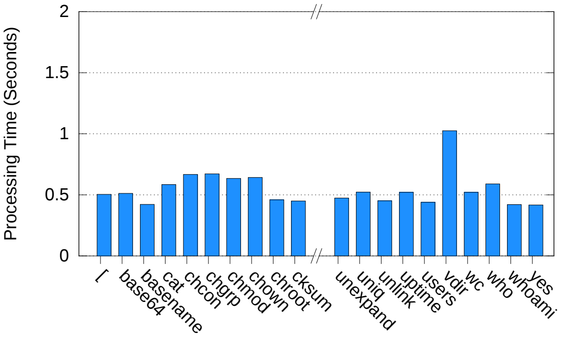

Figure 8: Processing time for COREUTILS binaries

phabet order strategy. As expected, larger binaries take more time to process. On average, UROBOROS spends 8.27 seconds on binaries from SPEC, 0.98 seconds on binaries from REAL, and 0.57 seconds on binaries from COREUTILS. We interpret this as a promising result, and the efficiency of UROBOROS makes it a tool totally practical for production deployment.

7 Discussions and Limitations

Compiler Compatibility. Sometimes binary reverse engineering is compiler dependent, but UROBOROS does not explicitly depend on any compiler-specific features as far as we know. To roughly investigate UROBOROS's compatibility with other compilers, we try to disassemble and reassemble some binaries compiled by Clang, another widely used compiler different from GCC. We only briefly present the results here due to limited space. We repeat the same functionality verification described in §6.1 on the 32-bit binaries in REAL, which are compiled by Clang this time. The applied assumption set in this experiment is the empty assumption set, and all reassembled binaries can pass the functionality tests. We plan to test UROBOROS's compatibility in more depth in the future.

C++ Binary Disassembly. The C++ programming language has more specific features compared with C. Binaries compiled from C++ programs often contain more sections to store meta-information. At this point UROBOROS still cannot fully support C++ disassembly, but we have already worked out a blueprint on how to recover these sections. There are two kinds of meta-information sections specific to C++. We now briefly discuss how to recover them.

- The `.ctors` and `.init_array` sections contain the addresses of constructor functions—functions that need to be executed at start up before the `main` function takes control. These sections can be directly dumped out and symbolized by treating them as data sections.
- The `.eh_frame` and `.gcc_except_table` sections store the information used for stack unwinding and exception handling for C++ programs in the DWARF format [15]. There have been some reverse engineering tools, e.g., Katana [38] and IDA Pro, that can parse the DWARF data. By understanding the semantics of a DWARF entry, we can adjust its content and make the reassembly flawless.

We leave fully supporting C++ binary disassembly as part of our future work.

Availability of function starting addresses. We assume the availability of the function starting addresses in the input binary, as in this research we would like to assess the assumptions and techniques we develop for the symbolization problem. Identifying function starting addresses is an orthogonal research issue which has been the focus of recent work [6, 41]. UROBOROS can leverage existing techniques to make the tool more practical. Nevertheless, this is currently a limitation of UROBOROS and we plan to investigate further in the future.

Data Section Relocation. By accepting the assumption A2 (see §4), we fix the starting address of data sections, which leads to certain limitations related to the relocation of data sections. However, data can still be manipulated as long as the starting addresses stay the same. Besides, `.bss` section can be extended with new elements, as it is at the end of typical ELF binaries and the increase of its size does not need to relocate other sections. In the future, it would be interesting to see whether some more sophisticated heuristics or analysis can be developed to symbolize d2d references.

Extensions. We believe that we have built an enabling technology that could be employed as the basis of many important research and applications, such as software fault isolation (SFI), control-flow integrity (CFI), ROP defense, and in general software retrofitting for binary code, which is extremely important for legacy code systems. Nevertheless, this is a first step in the toolchain development. We plan to build and maintain a sustainable ecosystem, and also link to the existing ecosystems such as LLVM [27] and CIL [36] by lifting assembly to LLVM and CIL IR.

8 Conclusion

We have presented UROBOROS, a tool that can disassemble stripped binaries and produce *reassembleable* assembly code in a fully automated manner. We call this technique *reassembleable disassembling* and have developed a prototype called UROBOROS. Our experiments show that reassembled programs incur negligible execution overhead, and thus UROBOROS can be potentially used as a foundation for binary-based software retrofitting.

A Symbolization Errors in gobmk

Among the 244 binaries from the Coreutils, Real, and Spec collections, we found 5 d2c reference symbolization errors in `gobmk`, one of the largest Spec programs, 4 of which are in the 32-bit version and 1 of which is in the 64-bit version, all false positives.

The software `gobmk` is GNU Go (http://www.gnu.org/software/gnugo/), a program for playing the board game of Go. The program contains a fairly large database of board configuration patterns. In order to speed up pattern matching, it builds Deterministic Finite Automata (DFA) from the pattern database.

The five reference symbolization errors are shown in Table 7 and Figure 9. In Figure 9, the two arrays `state_owl_attackpat` and `state_owl_defendpat` encode two DFAs with 24,701 and 34,044 entries, respectively. Each entry represents a state in the corresponding DFA. Each state has 5 numbers of the C short datatype, the current state and its four neighbors, as Go games are played on 2-dimensional grid boards.

We found two consecutive states in DFA `state_owl_attackpat` of the 64-bit `gobmk` are `{66,{0,0,0,0}},{70,{0,0,0,0}}`. The two C short int numbers 0 and 70 in the middle forms 0x460000 (little-endian), which happens to be the starting address of function `gtp_trymove`. Similar patterns exist in the 32-bit `gobmk`. States in array `state_owl_defendpat` forms value 0x080c0000 from two C short int numbers 0 and 2060 next to each other (little-endian), which collides with the starting address of function `autohelperpat1029`.

Table 7: Source code locations of symbolization errors

Program	Location (file and line no.)
32-bit gobmk	`owl_defendpat.c: 9688`
	`owl_defendpat.c: 9702`
	`owl_defendpat.c: 9703`
	`owl_defendpat.c: 9704`
	`owl_defendpat.c: 9761`
64-bit gobmk	`owl_attackpat.c: 5828`

```
static const state_rt_t

Abstract

Throughout the last few decades, computer software has experienced an arms race between exploitation techniques leveraging memory corruption and detection/protection mechanisms. Effective mitigation techniques, such as Address Space Layout Randomization, have significantly increased the difficulty of successfully exploiting a vulnerability. A modern exploit is often two-stage: a first information disclosure step to identify the memory layout, and a second step with the actual exploit. However, because of the wide range of conditions under which memory corruption occurs, retrieving memory layout information from the program is not always possible.

In this paper, we present a technique that uses the dynamic loader's ability to *identify* the locations of critical functions directly and call them, without requiring an information leak. We identified several fundamental weak points in the design of ELF standard and dynamic loader implementations that can be exploited to resolve and execute arbitrary library functions. Through these, we are able to bypass specific security mitigation techniques, including partial and full RELRO, which are specifically designed to protect ELF data-structures from being coopted by attackers. We implemented a prototype tool, Leakless, and evaluated it against different dynamic loader implementations, previous attack techniques, and real-life case studies to determine the impact of our findings. Among other implications, Leakless provides attackers with reliable and non-invasive attacks, less likely to trigger intrusion detection systems.

1 Introduction

Since the first widely-exploited buffer overflow used by the 1998 Morris worm [27], the prevention, exploitation, and mitigation of memory corruption vulnerabilities have occupied the time of security researchers and cybercriminals alike. Even though the prevalence of memory corruption vulnerabilities has finally begun to decrease in recent years, classic buffer overflows remain the third most common form of software vulnerability, and four other memory corruption vulnerabilities pad out the top 25 [13].

One reason behind the decreased prevalence of memory corruption vulnerabilities is the heavy investment in research on their prevention and mitigation. Specifically, many mitigation techniques have been adopted in two main areas: system-level hardening (such as CGroups [23], AppArmor [4], Capsicum [41], and GRSecurity [18]) and application-level hardening (such as stack canaries [3], Address Space Layout Randomization (ASLR), and the *No-eXecute* (NX) bit [8]).

In particular, *Address Space Layout Randomization* (ASLR), by placing the dynamic libraries in a random location in memory (unknown to the attacker), lead attackers to perform exploits in two stages. In the first stage, the attacker must use an *information disclosure* vulnerability, in which information about the memory layout of the application (and its libraries) is revealed, to identify the address of code that represents security-critical functionality (such as the `system()` library function). In the second stage, the attacker uses a *control flow redirection* vulnerability to redirect the program's control flow to this functionality.

However, because of the wide range of conditions under which memory corruptions occur, retrieving this information from the program is not always possible. For example, memory corruption vulnerabilities in parsing code (e.g., decoding images and video) often take place without a direct line of communication to an attacker, precluding the possibility of an information disclosure. Without this information, performing an exploit against ASLR-protected binaries using current techniques is often infeasible or unreliable.

As noted in [36], despite the race to harden applications and systems, the security of some little-known aspects of application binary formats and the system components using them, have not received much scrutiny. In particular we focus on the *dynamic loader*, a userspace component of the operating system, responsible for loading binaries, and the libraries they depend upon, into memory. Binaries use the dynamic loader to support the *resolution* of imported symbols. Interestingly, this is the exact behavior that an attacker of a hardened application attempts to reinvent by leaking a library's address and contents.

Our insight is that a technique to eliminate the need for an information disclosure vulnerability could be developed by abusing the functionality of the dynamic loader. Our technique leverages weaknesses in the dynamic loader and in the general design of the ELF format to resolve and execute arbitrary library functions, allowing us to successfully exploit hardened applications without the need for an information disclosure vulnerability. Any library function can be executed with this technique, even if it is not otherwise used by the exploited binary, as long as the library that it resides in is loaded. Since almost every binary depends on the C Library, this means our technique allows us to execute security-critical functions such as `system()` and `execve()`, allowing arbitrary command execution. We will also show application-specific library functions can be re-used to perform sophisticated and stealthy attacks. The presented technique is reliable, architecture-agnostic, and does not require the attacker to know the version, layout, content, or any other unavailable information about the library and library function in question.

We implemented our ideas in a prototype tool, called Leakless[1]. To use Leakless, the attacker must possess the target application, and have the ability to exploit the vulnerability (i.e., hijack control flow). Given this information, Leakless can automatically construct an exploit that, without the requirement of an information disclosure, invokes one or more critical library functions of interest.

To evaluate our technique's impact, we performed a survey of several different distributions of Linux (and FreeBSD) and identified that the vast majority of binaries in the default installation of these distributions are susceptible to the attack carried out by Leakless, if a memory corruption vulnerability is present in the target binary. We also investigated the dynamic loader implementations of various C Libraries, and found that most of them are susceptible to Leakless' techniques. Additionally, we showed that a popular mitigation technique, RELocation Read-Only (RELRO), which protects library function calls from being redirected by an attacker, is completely bypassable by Leakless. Finally, we compared the length of Leakless' ROP chains against ROP compilers implementing similar functionality. Leakless produces significantly shorter ROP chains than existing techniques, which, as we show, allows it to be used along with a wider variety of exploits than similar attacks created by traditional ROP compilers.

In summary, we make the following contributions:

- We develop a new, architecture- and platform-agnostic attack, using functionality inherent in ELF-based system that supports dynamic loading, to enable an attacker to execute arbitrary library functions without an information disclosure vulnerability.
- We detail, and overcome, the challenges of implementing our system for different dynamic loader implementations and in the presence of multiple mitigation techniques (including RELRO).
- Finally, we perform an in-depth evaluation, including a case study of previously complicated exploits that are made more manageable with our technique, an assessment of the security of several different dynamic loader implementations, a survey of the applicability of our technique to different operating system configurations, and a measurement of the improvement in the length of ROP chains produced by Leakless.

2 Related Work: The Memory Corruption Arms Race

The memory corruption arms race (i.e., the process of defenders developing countermeasures against known exploit techniques, and attackers coming up with new exploitation techniques to bypass these countermeasures) has been ongoing for several decades. While the history of this race has been documented elsewhere [37], this section focuses on the sequence of events that has required many modern exploits to be *two-stage*, that is, needing an *information disclosure* step before an attacker can achieve arbitrary code execution.

Early buffer overflow exploits relied on the ability to inject binary code (termed *shellcode*) into a buffer, and overwrite a return address on the stack to point into this buffer. Subsequently, when the program would return from its current function, execution would be redirected to the attacker's shellcode, and the attacker would gain control of the program.

As a result, security researchers introduced another mitigation technique: the *NX* bit. The NX bit has the effect of preventing memory areas not supposed to contain code (typically, the stack) from being executed.

The *NX bit* has pushed attackers to adapt the concept of *code reuse*: using functionality already in the program (such as system calls and security-critical library functions) to accomplish their goals. In return-into-libc exploits [30, 39], an attacker redirects the control flow directly to a sensitive libc function (such as `system()`) with the proper arguments to perform malicious behavior, instead of using injected shellcode.

To combat this technique, a system-level hardening technique named *Address Space Layout Randomization*

[1] The source code is available at: `https://github.com/ucsb-seclab/leakless`

(ASLR) was developed. When ASLR is in place, the attacker does not know the location of libraries, in fact, the program's memory layout (the locations of libraries, the stack, and the heap) is randomized at each execution. Because of this, the attacker does not know *where* in the library to redirect the control flow in order to execute specific functions. Worse, even if the attacker is able to determine this information, he is still unable to identify the location of specific functions inside the library unless he is in possession of a copy of the library. As a result, an attacker usually has to leak the contents of the library itself and parse the code to identify the location of critical functions. To leak these libraries, attackers often reuse small chunks of code (called *gadgets*) in the program's code segment to disclose memory locations. These gadgets are usually combined by writing their addresses onto the stack and consecutively returning to them. Thus, this technique is named *Return Oriented Programming* (ROP) [35].

ROP is a powerful tool for attackers. In fact, it has been shown that a "Turing-complete" set of ROP gadgets can be found in many binaries and can be employed, with the help of a *ROP compiler*, to carry out exploitation tasks [34]. However, because of their generality, ROP compilers tend to produce long ROP chains that, depending on the specific details of a vulnerability, are "too big to be useful" [22]. Later, we will show that Leakless produces relatively short ROP chains, and, depending on present mitigations, requires very few gadgets. Additionally, Leakless is able to function without a Turing-complete gadget set.

In real-world exploits, an attacker usually uses an *information disclosure* attack to leak the address or contents of a library, then uses this information to calculate the correct address of a security-critical library function (such as `system()`), and finally sends a second payload to the vulnerable application that redirects the control flow to call the desired function.

In fact, we observed that that the goal of finding the address of a specific library function is actually already implemented by the *dynamic loader*, an OS component that facilitates the resolution of dynamic symbols (i.e., determining the addresses of library functions). Thus, we realized that we could leverage the dynamic loader to remove the information disclosure step, and craft exploits, which would work without the need of an information disclosure attack. Since our attack does not require an information leak step, we call it *Leakless*.

The concept of using the dynamic loader as part of the exploitation process was briefly explored in the context of return-into-libc attacks [15,21,30]. However, existing techniques are extremely situational [30], platform-dependent, require two stages [21], or are susceptible to current mitigation techniques such as RELRO [30], which we will discuss in future sections. Leakless, on the other hand, is a single-stage, platform-independent, general technique, and is able to function in the presence of such mitigations.

In the next section, we will describe how the dynamic loader works, and afterwards will show how we abuse this functionality to perform our attack.

3 The Dynamic Loader

The dynamic loader is a component of the userspace execution environment that facilitates loading the libraries required by an application at start time and resolving the dynamic symbols (functions or global variables) that are exported by libraries and used by the application. In this section, we will describe how dynamic symbol resolution works on systems based on the ELF binary object specification [33].

ELF is a standard format common to several Unix-like platforms, including GNU/Linux and FreeBSD, and is defined independently from any particular dynamic loader implementation. Since Leakless mostly relies on standard ELF features, it is easily applicable to a wide range of systems.

3.1 The ELF Object

An application comprises a main binary ELF file (the executable) and several dynamic libraries, also in ELF format. Each ELF object is composed of *segments*, and each segment holds one or more *sections*.

Each section has a conventional meaning. For instance, the `.text` section contains the code of the program, the `.data` section contains its writeable data (such as global variables), and the `.rodata` section contains the read-only data (such as constants and strings). The list of sections is stored in the ELF file as an array of `Elf_Shdr` structures.

Note that there are two versions of each ELF structure: one version for 32-bit ELF binaries (e.g., `Elf32_Rel`) and one for 64-bit (e.g., `Elf64_Rel`). We ignore this detail for the sake of simplicity, except in specific cases where it is relevant to our discussion.

3.2 Dynamic Symbols and Relocations

In this section, we will give a summary of the data structures involved in ELF symbol resolution. Figure 1 gives an overview of these data structures and their mutual relationships.

An ELF object can export symbols to and import symbols from other ELF objects. A symbol represents a function or a global variable and is identified by a name.

Each symbol is described by a corresponding `Elf_Sym` structure. This structure, instances of which comprise the `.dynsym` ELF section, contains the following fields relevant to our work:

`st_name`. An offset, relative to the start of the `.dynstr` section, where the string containing the name of the symbol is located.

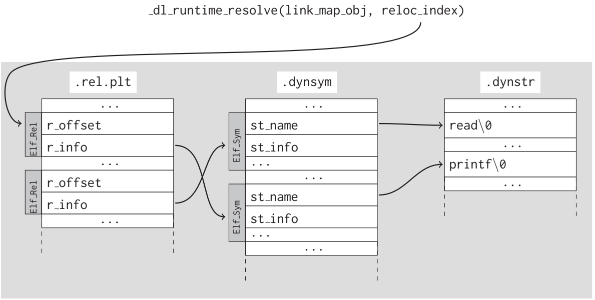

Figure 1: The relationship between data structures involved in symbol resolution (without symbol versioning). Shaded background means read only memory.

st_value. If the symbol is exported, the virtual address of the exported function, NULL otherwise.

These structures are referenced to resolve imported symbols. The resolution of imported symbols is supported by relocations, described by the Elf_Rel structure. Instances of this structure populate the .rel.plt section (for imported functions) and the .rel.dyn section (for imported global variables). In our discussion we are only interested to the former section. The Elf_Rel structure has the following fields:

r_info. The three least significant bytes of this field are used as an unsigned index into the .dynsym section to reference a symbol.

r_offset. The location (as an absolute address) in memory where the address of the resolved symbol should be written to.

When a program imports a certain function, the linker will include a string with the function's name in the .dynstr section, a symbol (Elf_Sym) that refers to it in the .dynsym section, and a relocation (Elf_Rel) pointing to that symbol in the .rel.plt section.

The target of the relocation (the r_offset field of the Elf_Rel struct) will be the address of an entry in a dedicated table: the Global Offset Table (GOT). This table, which is stored in the .got.plt section, is populated by the dynamic loader as it resolves the relocations in the .rel.plt section.

3.3 Lazy Symbol Resolution

Since resolving every imported symbol and applying all relocations at application startup can be a costly operation, symbols are resolved *lazily*. In lazy symbol resolution, the address of a function (which corresponds to an entry in the GOT) is only resolved when necessary (i.e., the first time the imported function is called).

When a program wants to calls an imported function, it instead calls a dedicated stub of code, located in the Procedure Linkage Table (the .plt section). As shown in Listing 1, each imported function has a stub in the PLT that performs an unconditional indirect jump to the associated entry in the GOT.

After symbol resolution, this GOT entry contains the address of the actual function, in the imported library, and execution continues seamlessly into this function. When the function returns, control flow returns to the *caller* of the PLT stub, and the rest of the PLT stub is not executed. However, at program startup, GOT entries are initialized with an address pointing to the *second* instruction of the associated PLT stub. This part of the stub will push onto the stack an identifier of the imported function (in the form of an offset to an Elf_Rel instance in the .rel.plt section) and jump to the PLT0 stub, a piece of code at the beginning of the .plt section. In turn, the PLT0 stub, pushes the value of GOT[1] onto the stack and performs an indirect jump to the address of GOT[2]. These two entries in the GOT have a special meaning and the dynamic loader populates them at application startup:

GOT[1]. A pointer to an internal data structure, of type link_map, which is used internally by the dynamic loader and contains information about the current ELF object needed to carry out symbol resolution.

GOT[2]. A pointer to a function of the dynamic loader, called _dl_runtime_resolve.

In summary, PLT entries basically perform the following function call:

```
_dl_runtime_resolve(link_map_obj, reloc_index)
```

This function uses the link_map_obj parameter to access the information it needs to resolve the desired imported function (identified by the reloc_index argument) and writes the result into the appropriate GOT entry. After _dl_runtime_resolve resolves the imported function, control flow is passed to that function, making the resolution process completely transparent to the caller. The next time the PLT stub for the specified function is invoked execution will be diverted directly to the target function.

Listing 1: Example PLT and GOT.

```
100 PLT0:                    196 ; .plt.got start
100     push *0x200          196 ; Empty entry
106     jmp *0x204           196 0
110 printf@plt:              200 ; link_map object
110     jmp *0x208           200 &link_map_obj
116     push #0              204 ; Resolver function
11B     jmp PLT0             204 &_dl_runtime_resolve
120 read@plt:                208 ; printf entry
120     jmp *0x20C           208 0x116
126     push #1              20C ; read entry
12B     jmp PLT0             20C 0x126
```

The link_map structure contains all the information that the dynamic loader needs about a loaded ELF object. Each link_map instance is an entry in a doubly-linked list containing the information about all loaded ELF objects.

3.4 Symbol Versioning

The ELF standard provides a mechanism to import a symbol with a specific version associated with it. This feature is used to require a function to be imported from a

Table 1: Entries of the .dynamic section. d_tag is the key, while d_value is the value.

d_tag	d_value	d_tag	d_value
DT_SYMTAB	.dynsym	DT_PLTGOT	.got.plt
DT_STRTAB	.dynstr	DT_VERNEED	.gnu.version
DT_JMPREL	.rel.plt	DT_VERSYM	.gnu.version_r

specific version of a library. For instance, it is possible to require the fopen C Standard Library function, as implemented in version 2.2.5 of the GNU C Standard Library, using the version identifier GLIBC_2.2.5. The .gnu.version_r section contains version definitions in the form of Elf_Verdef structures.

The association between a dynamic symbol and the Elf_Verdef structure that it refers to is kept in the .gnu.version section, as an array of Elf_Verneed structures, one for each entry in the dynamic symbol table. These structures have a single field: a 16-bit integer that represents an index into the .gnu.version_r section.

Due to this layout, the index in the r_info field of the Elf_Rel structure is used by the dynamic loader as an index into both the .dynsym and .gnu.version sections. This is important to understand, as Leakless will later leverage this fact.

3.5 The .dynamic section and RELRO

The dynamic loader collects all the information that it needs about the ELF object from the .dynamic section, which is composed of Elf_Dyn structures. An Elf_Dyn is a key-value pair that stores different types of information. The relevant entries of this section, shown in Table 1, hold the absolute addresses of specific sections. One exception is the DT_DEBUG entry, which holds a pointer to an internal data structure of the dynamic loader. This is initialized by the dynamic loader and is used for debugging purposes.

An attacker able to tamper with these values can pose a security risk. For this reason, a protection mechanism known as RELRO (RELocation Read Only) has been introduced in dynamic loaders. RELRO comes in two flavors: partial and full.

Partial RELRO In this mode, some sections, including .dynamic, are marked as read-only after they have been initialized by the dynamic loader.

Full RELRO In addition to partial RELRO, lazy resolution is disabled: all import symbols are resolved at startup time, and the .got.plt section is completely initialized with the final addresses of the target functions and marked read-only. Moreover, since lazy resolution is not enabled, the GOT[1] and GOT[2] entries are not initialized with the values we mentioned in Section 3.3.

As we will see, RELRO poses significant complications that Leakless must (and does) address in order to operate in the presence of these countermeasures.

Note that the previously mentioned link_map structure stores in the l_info field an array of pointers to most of entries in the .dynamic section for internal usage. Since the dynamic loader trusts the content of this field implicitly, Leakless will later be able to misuse this to its own ends.

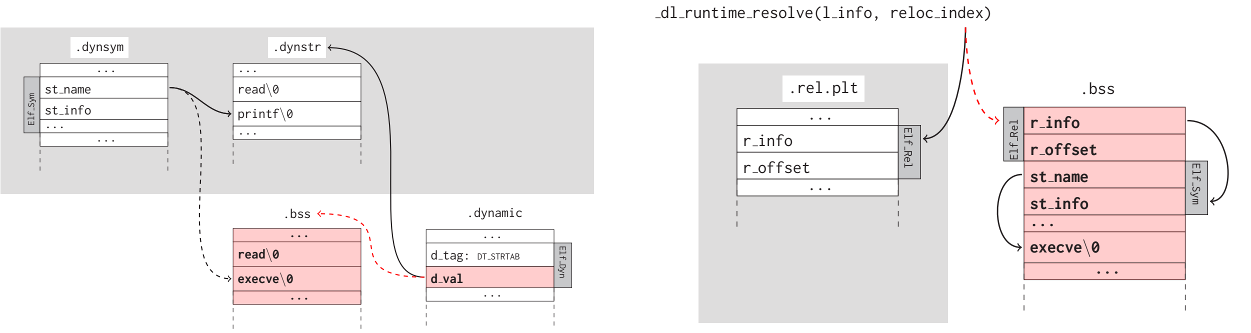
4 The Attack

Leakless enables an attacker to call arbitrary library functions, using only their name, without any information about the memory layout of the vulnerable program's libraries. To achieve this, Leakless abuses the dynamic loader, forcing it to resolve and call the requested function. This is possible for the same reason that memory corruption vulnerabilities are so damaging: the mixing of control data and non-control data in memory. In the case of a stack overflow, the control data in question is a stored return address. For the dynamic loader, the control data is comprised of the various data structures that the dynamic loader uses for symbol resolution. Specifically, the *name* of the function, stored in the .dynstr section, is analogous to a return address: it specifies a specific target to execute when the function is invoked.

The dynamic loader makes the assumption that the parameters it receives and its internal structures are trustworthy because it assumes that they are provided directly by the ELF file or by itself during initialization. However, when an attacker is able to modify this data, the assumption is broken. Some dynamic loaders (FreeBSD) validate the input they receive. However, they still implicitly trust the control structures, which will be readily corrupted by Leakless.

Leakless is designed to be used by an attacker who is attempting to exploit an existing vulnerability. The input to Leakless is comprised of the executable ELF file, a set of ROP gadgets of the binary (we detail what gadgets an attacker needs in Section 5.1), and the name of a library function that the attacker wishes to call (typically, but not necessarily, execve()). Given this information, Leakless outputs a ROP payload that executes the needed library function, bypassing various hardening techniques applied to the binary in question. This ROP chain is generally very short: depending on the mitigations present in the binary, the chain is 3 to 12 write operations. Some examples of the output produced by Leakless are available in the documentation of the Leakless code repository [17].

Leakless does *not* require any information about the addresses or contents of the libraries; we assume that ASLR is enabled for all dynamic libraries and that no knowledge about them is available. However we also assume that the executable is not position-independent, and, thus, is always loaded in a specific location in memory. We discuss this limitation in detail in Section 7.2, and show



(a) Example of the attack presented in Section 4.1. The attacker is able to overwrite the value of the DT_STRTAB dynamic entry, tricking the dynamic loader into thinking that the .dynstr section is in .bss, where he crafted a fake string table. When the dynamic loader will try to resolve the symbol for printf it will use a different base to reach the name of the function and will actually resolve (and call) execve.

(b) Example of the attack presented in Section 4.2. The reloc_index passed to _dl_runtime_resolve overflows the .rel.plt section and ends up in .bss, where the attacker crafted an Elf_Rel structure. The relocation points to an Elf_Sym located right afterwards overflowing the .dynsym section. In turn the symbol will contain an offset relative to .dynstr large enough to reach the memory area after the symbol, which contains the name of the function to invoke.

Figure 2: Illustration of some of the presented attacks. Shaded background means read only memory, white background means writeable memory and bold or red means data crafted by the attacker.

how infrequently Position Independent Executables (PIE) binaries occur in modern OS distributions in Section 6.2.

While in most cases, Leakless works independently of the dynamic loader implementation and version that the target system is running, some of our attacks require minor modifications to accommodate different dynamic loaders.

Note that Leakless's aim, obtaining the address of a library function and call it, is similar to what the dlsym function of libdl does. However, in practice this function is rarely used by applications and, therefore, its address is not generally known to the attacker.

4.1 The Base Case

As explained in Section 3 and illustrated in Figure 1, the dynamic loader starts its work from a Elf_Rel structure in the .rel.plt, then follows the index into the .dynsym section to locate the Elf_Sym structure, and finally uses that to identify the name (a string in the .dynstr section) of the symbol to resolve. The simplest way to call an arbitrary function would be to overwrite the string table entry of an existing symbol with the name of the desired function, and then invoke the dynamic loader, but this is not possible, as the section containing the string table for dynamic symbols, i.e., .dynstr, is not writeable.

However, the dynamic loader obtains the address of the .dynstr section from the DT_STRTAB entry of the .dynamic section, which is at a known location and, by default, writeable. Therefore, as shown in Figure 2a, it is possible to overwrite the d_val field of this dynamic entry with a pointer to a memory area under the control of the attacker (typically the .bss or .data section). This memory area would then include a single string, for example execve. At this point, the attacker needs to choose an existing symbol pointing to the correct offset in the fake string table and invoke the resolution of relocation corresponding to that symbol. This can be done by pushing the offset of this relocation on the stack and then jumping to PLT0.

This approach is simple, but it is only effective against binaries in which the .dynamic section is writeable. More sophisticated attacks must be used against binary compiled with partial or full RELRO.

4.2 Bypassing Partial RELRO

As we explained in Section 3.3, the second parameter of the _dl_runtime_resolve function is the offset of an Elf_Rel entry in the relocation table (.rel.plt section) that corresponds to the requested function. The dynamic loader takes this value and adds it to the base address of the .rel.plt to obtain the absolute address of the target Elf_Rel structure. However most dynamic loader implementations do not check the boundaries of the relocation table. This means that if a value larger than the size of the .rel.plt is passed to _dl_runtime_resolve, the loader will use the Elf_Rel at the specified location, despite being outside the .rel.plt section.

As shown in Figure 2b, Leakless computes an index that will lead _dl_runtime_resolve to look into a memory area under the control of the attacker. It then crafts an Elf_Rel structure that contains, in its r_offset field, the address of the writeable memory location where the address of the function will be written. The r_info field will, in turn, contain an index that causes the dynamic loader to look into the attacker-controlled memory. Leakless stores a crafted Elf_Sym object at this location, which, likewise, holds a st_name field value large enough to point into attacker-controlled memory. Finally, this location is where Leakless stores the name of the desired function to call.

In sum, Leakless crafts the full chain of structures involved in symbol resolution, co-opting the process to invoke the function whose name Leakless has written into attacker-controlled memory. After this, Leakless pushes the computed offset to the fake Elf_Rel structure onto the stack and invokes PLT0.

However, this approach is subject to several constraints. First, the symbol index in Elf_Rel has to be positive, since the r_info field is defined by the ELF standard as an unsigned integer. In practice, this means that the writable memory area (e.g., the .bss section) must be located *after* the .dynsym section. In our evaluation, this has always been the case.

Another constraint arises when the ELF makes use of the symbol versioning system described in Section 3.4. In this case, the Elf_Rel.r_info field is not just used as an index into the dynamic symbol table, but also as an index in the symbol version table (the .gnu.version section). In general, Leakless is able to automatically satisfy these constraints, except for x86-64 small binaries using huge pages [32]. We detail the additional constraints introduced by symbol versioning in Appendix A. When the constraints cannot be satisfied, an alternate approach must be adopted. This involves abusing the dynamic loader by corrupting its internal data structures to alter the dynamic resolution process.

4.3 Corrupting Dynamic Loader Data

We recall that the first parameter to _dl_runtime_resolve is a pointer to a data structure of type link_map. This structure contains information about the ELF executable, and the contents of this structure are implicitly trusted by the dynamic loader. Furthermore, Leakless can obtain the address of this structure from the second entry of the GOT of the vulnerable binary, whose location is deterministically known.

Recall from Section 3.5 that the link_map structure, in the l_info field, contains an array of pointers to the entries of the .dynamic section. These are the pointers that the dynamic loader uses to locate the objects that are used during symbol resolution. As shown in Figure 3, by overwriting part of this data structure, Leakless can make the DT_STRTAB entry of the l_info field point to a specially-crafted dynamic entry which, in turn, points to a fake dynamic string table. Hence, the attacker can reduce the situation back to the base case presented in Section 4.1.

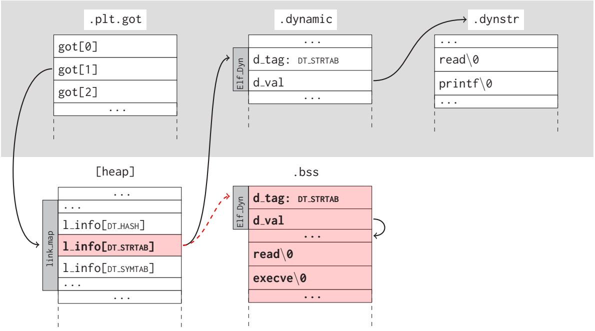


Figure 3: Example of the attack presented in Section 4.3. The attacker dereferences the second entry of the GOT and reaches the link_map structure. In this structure he corrupts the entry of the l_info field holding a pointer to the DT_STRTAB entry in the dynamic table. Its value is set to the address of a fake dynamic entry which, in turn, points to a fake dynamic string table in the .bss section.

This technique has wider applicability than the one presented in the previous section, since there are no specific constraints, and, in particular, it is applicable also against small 64 bit ELF binaries using huge pages. However, while in the previous attacks we were relying exclusively on standard ELF features, in this case (and in the one presented in the next section) we assume the layout of a glibc-specific structure (link_map) to be known. Each dynamic loader implements this structure in its own way, so minor modifications might be required when targeting a different dynamic loader. Note that link_map's layout might change among versions of the same dynamic loader. However, they tend to be quite stable, and, in particular, in glibc no changes relevant to our attack have taken place since 2004.

4.4 The Full RELRO Situation

Leakless is able to bypass full RELRO protection.

When full RELRO is applied, all the relocations are resolved at load-time, no lazy resolving takes place, and the addresses of the link_map structure and of _dl_runtime_resolve in the GOT are never initialized. Thus, it is not directly possible to know their addresses, which is what the general technique to bypass partial RELRO relies upon.

However, it is possible to indirectly recover these two values through the DT_DEBUG entry in the dynamic table. The value of the DT_DEBUG entry is set by the dynamic loader at load-time to point to a data structure of type r_debug. This data structure contains information used by debuggers to identify the base address of the dynamic loader and to intercept certain events related to dynamic loading. In addition, the r_map field of this structure holds a pointer to the head of the linked list of link_map structures.

Leakless corrupts the first entry of the list describing the ELF executable so that the l_info entry for DT_STRTAB points to a fake dynamic string table. This is presented in

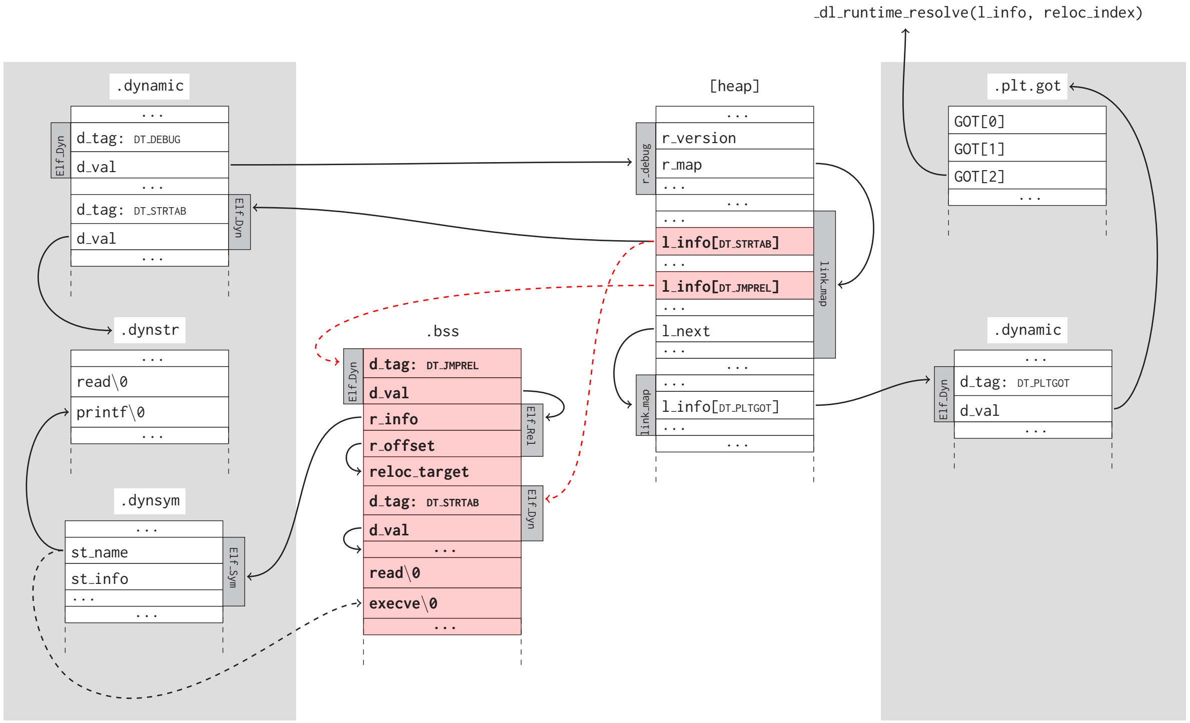

Figure 4: Example of the attack presented in Section 4.4. Shaded background means read only memory, white background means writeable memory and bold or red means data crafted by the attacker. The attacker goes through the DT_DEBUG dynamic entry to reach the r_debug structure, then, dereferencing the r_map field, he gets to the link_map structure of the main executable, and corrupts l_info[DT_STRTAB] as already seen in Section 3.
Since the .got.plt section is read-only due to full RELRO, the attacker also have to forge a relocation. To do so, he corrupts l_info[DT_JMPREL] making it point to a fake dynamic entry in turn pointing to a relocation. This relocation refers to the existing printf symbol, but has an r_offset pointing to a writeable memory area.
Then the attacker also needs to recover the pointer to the _dl_runtime_resolve function, which is not available in the GOT of the main executable due to full RELRO, therefore he dereferences the l_info field of the first link_map structure and gets to the one describing the first shared library, which is not protected by full RELRO. The attacker accesses the l_info[DT_PLTGOT] field and gets to the corresponding dynamic entry (the .dynamic on the right), and then to the .plt.got section (always on the right), at the second entry of which he can find the address of _dl_runtime_resolve.

Figure 4.

After this, Leakless must invoke _dl_runtime_resolve, passing the link_map structure that it just corrupted as the first argument and an offset into the new .dynsym as the second parameter. However, as previously mentioned, _dl_runtime_resolve is not available in the GOT due to full RELRO. Therefore, Leakless must look for its address in the GOT of *another* ELF object, namely, a library loaded by the application that is not protected by full RELRO. In most cases, only ELF executables are compiled with full RELRO, and libraries are not. This is due to the fact that RELRO is designed to harden, at the cost of performance, specific applications that are deemed “risky”. Applying full RELRO to a shared library would impact the performance of all applications making use of this library, and thus, libraries are generally left unprotected. Since the order of libraries in the linked list is deterministic, Leakless can dereference the l_next entry in link_map to reach the entry describing a library that is not protected by full RELRO, dereference the entry in l_info corresponding to the DT_PLTGOT dynamic entry, dereference its value (i.e., the base address of that library’s GOT), and read the address of _dl_runtime_resolve from this GOT.

Leakless must then overcome a final issue: _dl_runtime_resolve will not only call the target function, but will also try to write its address to the appropriate GOT entry. If this happens, the program will crash, as the GOT is read-only when full RELRO is applied. We can circumvent this issue by faking the DT_JMPREL dynamic entry in the link_map structure that points to the .rel.dyn section. Leakless points it to an attacker-controlled memory area and writes an

Elf_Rel structure, with a target (r_offset field) pointing to a writeable memory area, referring to the symbol we are targeting. Therefore, when the library is resolved, the address will be written to a writeable location, the program will not crash, and the requested function will be executed.

5 Implementation

Leakless analyzes a provided binary to identify which of its techniques is applicable, crafts the necessary data structures, and generates a ROP chain that implements the chosen technique. The discovery of the initial vulnerability itself, and the automatic extraction of usable gadgets from a binary are orthogonal to the scope of our work, and have been well-studied in the literature and implemented in the real world [6, 16, 19, 20, 34, 38]. We designed Leakless to be compatible with a number of gadget finding techniques, and have implemented a manual backend (where gadgets are provided by the user) and a backend that utilizes ROPC [22], an automated ROP compiler prototype built on the approach proposed by Q [34].

We also developed a small test suite, composed of a small C program with a stack-based buffer overflow compiled, alternatively, with no protections, partial RELRO, and full RELRO. The test suite runs on GNU/Linux with the x86, x86-64 and ARM architectures and with FreeBSD x86-64.

5.1 Required Gadgets

Leakless comprises four different techniques that are used depending on the hardening techniques applied to the binary. These different techniques require different gadgets to be provided to Leakless. A summary of the types of gadgets is presented in Table 2. The write_memory gadget is mainly used to craft data structures at known memory locations, while the deref_write gadget to traverse and corrupt data structures (in particular link_map). The deref_save and copy_to_stack gadgets are used only in the full RELRO case. The aim of the former is to save at a known location the address of link_map and _dl_runtime_resolve, while the latter is used to copy link_map and the relocation index on the stack before calling _dl_runtime_resolve, since using PLT0 is not a viable solution.

For the interested reader, we provide in-depth examples of executions of Leakless in the presence of two different sets of mitigation techniques in the documentation of the Leakless code repository [17].

6 Evaluation

We evaluated Leakless in four ways. First, we determined the applicability of our technique against different dynamic loader implementations. We then analyzed the binaries distributed by several popular GNU/Linux and BSD distributions (specifically, Ubuntu, Debian, Fedora, and FreeBSD) to determine the percentage of binaries that would be susceptible to our attack. Then we applied Leakless in two real-world exploits against a vulnerable version of Wireshark and in a more sophisticated attack against Pidgin. Finally we used a Turing-complete ROP compiler to implement the approach used in Leakless and two other previously used techniques, and compared the size of the resulting chains.

6.1 Dynamic Loaders

To show Leakless' generality, especially across different ELF-based platforms, we surveyed several implementations of dynamic loaders. In particular, we found that the dynamic loader part of the *GNU C Standard Library* (also known as glibc and widely used in GNU/Linux distributions), several other Linux implementations such as *dietlibc*, *uClibc* and *newlib* (widespread in embedded systems) and the *OpenBSD* and *NetBSD* implementations are vulnerable to Leakless. Another embedded library, *musl*, instead, is not susceptible to our approach since it does not support lazy loading. *Bionic*, the C Standard Library used in Android, is also not vulnerable since it only supports PIE binaries. The most interesting case, out of all the loaders we analyzed, is *FreeBSD*'s implementation. In fact, it is the only one which performs boundary checks on arguments passed to _dl_runtime_resolve. All other loaders implicitly trust input arguments argument. Furthermore, *all* analyzed loaders implicitly trust the control structures that Leakless corrupts in the course of most of its attacks.

In summary, out of all of the loaders we analyzed, only two are immune to Leakless by design: musl, which does not support lazy symbol resolution, and bionic, which only supports PIE executables. Additionally, because the FreeBSD dynamic loader performs bounds checking, the technique explained in Section 4.2 is not applicable. However, the other techniques still work.

6.2 Operating System Survey

To understand Leakless' impact on real-world systems, we performed a survey of all binaries installed in default installations of several different Linux and BSD distributions. Specifically, we checked all binaries in /sbin, /bin, /usr/sbin, and /usr/bin on these systems and classified the binaries by the applicability of the techniques used by Leakless. The distributions that we considered were Ubuntu 14.10, Debian Wheezy, Fedora 20, and FreeBSD 10. We used both x86 and x86-64 versions of these systems. On Ubuntu and Debian, we additionally installed the LAMP (Linux, Apache, MySQL, PHP) stack as an attempt to simulate a typical server deployment configuration.

The five categories that we based our ratings on are as

Table 2: Gadgets required for the various approaches. The "Signature" column represents the name of the gadget and the parameters it accepts, while "Implementation" presents the behavior of the gadget in C-like pseudo code. The last four columns indicate whether a certain gadget is required for the corresponding approach presented in Section 4. Under RELRO, "N" indicates RELRO is disabled, "P" means partial RELRO is used, "H" stands for the partial RELRO and small 64 bit binaries using huge pages, and "F" denotes that full RELRO is enabled.

		RELRO			
Signature	Implementation	N	P	H	F
write_memory $(destination, value)$	$*(destination) = value$	✓	✓	✓	✓
deref_write$(pointer, offset, value)$	$*(*(pointer) + offset) = value$			✓	✓
deref_save $(destination, pointer, offset)$	$*(destination) = *(*(pointer) + offset)$				✓
copy_to_stack $(offset, source)$	$*(stack\_pointer + offset) = *(source)$				✓

follows:

Unprotected. This category includes binaries that have no RELRO or PIE. For these binaries, Leakless can apply its base case technique, explained in Section 4.1.

Partial RELRO. Binaries that have partial RELRO, but lack PIE, fall into this category. In this case, Leakless would apply the technique described in Section 4.2.

Partial RELRO (huge pages). Binaries in this category have partial RELRO, use huge pages, and are very small, therefore, they require Leakless to use the technique described in Section 4.3. They are included in this category.

Full RELRO. To attack binaries that use full RELRO, which comprise this category, Leakless must apply the technique presented in Section 4.4.

Not susceptible. Finally, we consider binaries that use PIE to be insusceptible to Leakless (further discussion on this in Section 7.2).

The results of the survey, normalized to the total number of binaries in an installation, are presented in Figure 5. We determined that, on Ubuntu, 84% of the binaries were susceptible to at least one of our techniques and 16% were protected with PIE. On Debian, Leakless can be used on 86% of the binaries. Fedora has 76% of susceptible binaries. Interestingly, FreeBSD ships no binaries with RELRO or PIE, and is thus 100% susceptible to Leakless.

Additionally, we performed a survey on the shared libraries of the systems we considered. We found that, on average, only 11% of the libraries had full RELRO protection. This has some interesting implications for Leakless: for a given binary, the likelihood of finding a loaded library without full RELRO is extremely high and, even if a vulnerable binary employs RELRO, Leakless can still apply its full RELRO attack to bypass this. This has the effect of making RELRO basically useless as a mitigation technique, unless it is applied system-wide.

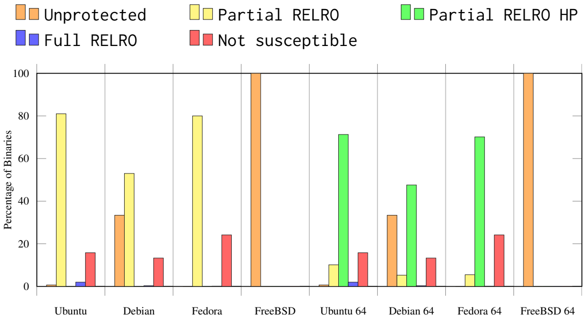

Figure 5: Classification of the binaries in default installations of target distributions. Binaries marked as `Unprotected`, `Partial RELRO`, `Partial RELRO HP` and `Full RELRO` require, respectively, to the attacks detailed in Sections 4.1, 4.2, 4.3 and 4.4, while for `Not susceptible` binaries, the Leakless approach is not applicable

6.3 Case Study: Wireshark

We carried out a case study in applying Leakless to a vulnerability in a program that does not present a direct line of communication to the attacker. In other words, the exploit must be done in one-shot, with no knowledge of the layout of the address space or the contents of libraries.

We picked a recent (April 2014) vulnerability [7], which is a stack-based buffer overflow in *Wireshark*'s MPEG protocol parser in versions 1.8.0 through 1.8.13 and 1.10.0 through 1.10.6. We carried out our experiments against a Wireshark 1.8.2 binary compiled with partial RELRO and one compiled with full RELRO. Both were compiled for x86-64 on Debian Wheezy and used the GNU C Library, without other protections such as PIE and stack canaries.

We used the manual Leakless backend to identify the required gadgets to construct the four necessary primitives (described in Section 5.1): *write_memory*, *deref_write*, *deref_save* and *copy_to_stack*. In the case of Wireshark, it was trivial to find gadgets to satisfy all of these primitives.

Leakless was able to construct a one-shot exploit using the attacks presented in Section 4.2 and Section 4.4. In both cases, the exploit leverages the dynamic loader in order to call the execve function from glibc to launch an executable of our choice.

6.4 Case Study: Pidgin

We also applied Leakless to Pidgin, a popular multi-protocol instant-messaging client, to build a more sophisticated exploit. Specifically, we wanted to perform a malicious operation without calling any anomalous system call (e.g. execve("/bin/sh")) which could trigger intrusion detection systems. We used Pidgin 2.10.7, building it from the official sources with RELRO enabled and targeting the x86 architecture.

To this end, we crafted an exploit designed to masquerade itself in legitimate functionality present in the application logic: tunneling connections through a proxy. The idea of the attack is that an IM service provider exploits a vulnerability such as CVE-2013-6487 [14] to gain code execution, and, using Pidgin's global proxy settings, redirects all IM traffic through a third-party server to enable chat interception.

Once we identified the necessary gadgets to use Leakless with full RELRO protection, it was easy to invoke functions contained in libpurple.so (where the core of the application logic resides) to perform the equivalent of the C code shown in Listing 2.

Listing 2: The Pidgin attack.

```
void *p, *a;
p = purple_proxy_get_setup(0);
purple_proxy_info_set_host(p, "legit.com");
purple_proxy_info_set_port(p, 8080);
purple_proxy_info_set_type(p, PURPLE_PROXY_HTTP);

a = purple_accounts_find("usr@xmpp", "prpl-xmpp");
purple_account_disconnect(a);
purple_account_connect(a);
```

Interestingly, some of this library-provided functionality is not imported into the Pidgin executable itself, and would be very challenging to accomplish in a single-stage payload, without Leakless.

6.5 ROP chain size comparison

To prove the effectiveness of the Leakless approach, we compared it with two existing techniques that allow an attacker to call arbitrary library functions. The first consists in scanning a library backwards, starting from an address in the .plt.got section, until the ELF header is found, and then scan forward to find a fingerprint of the function the attacker wants to invoke. This approach is feasible, but not very reliable, since different versions (or implementations) of a library might not be uniquely identified with a single fingerprint. The second technique is more reliable, since it implements the full symbol resolution process, as it is carried out by the dynamic loader.

Table 3: Size of the ROP chains generated by ROPC for each technique presented in Section 6.5, and by Leakless' manual backend (*). The second column represents the size in bytes for the setup and the first call, while the third column shows the additional cost (in bytes) for each subsequent call. Finally, the fourth column indicates the percentage of vulnerabilities used in Metasploit that would be feasible to exploit with a ROP chain of the *First call* size.

Technique	First call	Subsequent	Feasibility
ROPC - scan library	3468 bytes	+340 bytes	16.38%
ROPC - symbol resolution	7964 bytes	+580 bytes	8.67%
Leakless partial RELRO	648 bytes	+84 bytes	73.78%
Leakless full RELRO	2876 bytes	+84 bytes	17.44%
Leakless* partial RELRO	292 bytes	+48 bytes	95.24%
Leakless* full RELRO	448 bytes	+48 bytes	88.9%

We implemented these two approaches using a Turing-complete ROP compiler for x86, based on Q [34], called ROPC [22]. We compare these approaches against that of Leakless' ROPC backend, in partial RELRO and full RELRO modes. For completeness, we also include the Leakless' manual backend, with gadgets specified by the user.

In fact, the size of a ROP payload is critical, vulnerabilities often involve an implicit limit on the size of the payload that can be injected into a program. To measure the impact of Leakless' ROP chain size, we collected the size limits imposed on payloads of all the vulnerability descriptions included in the *Metasploit Framework* [31], a turn-key solution for launching exploits against known vulnerabilities in various software. We found that 946 of the 1,303 vulnerability specifications included a maximum payload size, with an average specified maximum payload size of 1332 bytes. To demonstrate the increase in the feasibility of automatically generating complex exploits, we include, for each evaluated technique, the percentage of Metasploit vulnerabilities for which the technique can automatically produce short enough ROP chains.

The results, in terms of length of the ROP chain generated for ROPC's test binaries and feasibility against the vulnerabilities used in Metasploit, are shown in Table 3. Leakless outperforms existing techniques, not only in the absolute size of the ROP chain to perform the initial call, but also in the cost of performing each additional call, which is useful in a sophisticated attack such as the one demonstrated in Section 6.4.

7 Discussion

In this section, we will discuss several aspects relating to Leakless: why the capabilities that it provides to attackers are valuable, when it is most applicable, what its limitations are, and what can be done to mitigate against them.

7.1 Leakless Applications

Leakless represents a powerful tool in the arsenal of exploit developers, aiding them in three main areas: functionality reuse, one-shot exploitation, and ROP chains shortening.

One-shot exploitation. While almost any exploit can be simplified by Leakless, we have designed it with the goal of enabling exploits that, without it, require an information disclosure vulnerability, but for which an information disclosure is not feasible or desirable. A large class of programs that fall under this category are file format parsers.

Code that parses file formats is extremely complex and, due to the complex, untrusted input that is involved, this code is prone to memory corruption vulnerabilities. There are many examples of this: the image parsing library `libpng` had 27 CVE entries over the last decade [10], and `libtiff` had 53 [11]. Parsers of complex formats suffer even more: the multimedia library `ffmpeg` has accumulated 170 CVE entries over the last five years alone [9]. This class of libraries is not limited to multimedia. Wireshark, a network packet analyzer, has 285 CVE entries, most of which are vulnerabilities in network protocol analysis plugins [12].

These libraries, and others like them, are often used *offline*. The user might first download a media or PCAP file, and *then* parse it with the library. At the point where the vulnerability triggers, an attacker cannot count on having a direct connection to the victim to receive an information disclosure and send additional payloads. Furthermore, most of these formats are *passive*, meaning that (unlike, say, PDF), they cannot include scripts that the attacker can use to simulate a two-step exploitation. As a result, even though these libraries might be vulnerable, exploits for them are either extremely complex, unreliable, or completely infeasible. By avoiding the information disclosure step, Leakless makes these exploits simpler, reliable, and feasible.

Functionality reuse. Leakless empowers attackers to call arbitrary functions from libraries loaded by the vulnerable application. In fact, the vulnerable application does not have to actually *import* this function; it just needs to link against the library (i.e., call any other function in the library). This is brings several benefits.

To begin with, the C Standard Library, which is linked against by most applications, includes functions that wrap almost every system call (e.g., `read()`, `execve()`, and so on). This means that Leakless can be used to perform any system call, in a short ROP chain, even without a system call gadget.

Moreover, as demonstrated in Section 6.4, Leakless enables easy reuse of existing functionality present in the application logic. This is important for two reasons.

First, this helps an attacker perform stealthy attacks by making it easier to masquerade an exploit as something the application might normally do. This can be crucial when a standard exploitation path is made infeasible by the presence of protection mechanisms such as seccomp [2], AppArmor [1], or SELinux [25].

Second, depending on the goals of the attacker, reusing program functionality may be better than simply executing arbitrary commands. Aside from the attack discussed in our Pidgin case study, an attacker can, for example, silently enable insecure cipher-suites, or versions of SSL, in the Firefox web browser with a single function call to `SSL_CipherPrefSetDefault` [24].

Shorter ROP chains. As demonstrated in Section 6.5, Leakless produces shorter ROP chains than existing techniques. In fact, in many cases, Leakless is able to produce ROP chains less than one kilobyte that lead to the execution of arbitrary functions. As many vulnerabilities have a limit as to the maximum size of the input that they will accept, this is an important result. For example, the vulnerability that we exploited in our Pidgin case study allowed a maximum ROP chain of one kilobyte. Whereas normal ROP compilation techniques would be unable to create automatic payloads for this vulnerability, Leakless was able to call arbitrary functions via an automatically-produced ROP chain that remained within the length limit.

7.2 Limitations

Leakless' biggest limitation is the inability to handle Position Independent Executables (PIEs) without a prior information disclosure. This is a general problem to any technique that uses ROP, as the absolute addresses of gadgets must be provided in the ROP chain. Additionally, without the base address of the binary, Leakless would be unable to locate the dynamic loader structures that it needs to corrupt.

When presented with a PIE executable, Leakless requires the attacker to provide the application's base address, which is presumably acquired via an information disclosure vulnerability (or, for example, by applying the technique presented in BROP [5]). While this breaks Leakless' ability to operate without an information disclosure, Leakless is likely still the most convenient way to achieve exploitation, as no library locations or library contents have to be leaked. Additionally, depending on the situation, the disclosure of just the address of the binary might be more feasible than the disclosure of the *contents* of an entire library. Unlike other techniques, which may need the latter, Leakless only requires the former.

In practice, PIEs are uncommon due to the associated cost in terms of performance. Specifically, measurements have shown that PIE overhead on x86 processors averages at 10%, while the overhead on x86-64 processors, thanks to instruction-pointer-relative addressing, averages at 3.6% [28].

Because of the overhead associated with PIE, most distributions ship with PIE enabled only for those applications deemed "risky". For example, according to their documentation, Ubuntu ships only 27 of their officially supported packages (i.e., packages in the "main" repository) with PIE enabled, out of over 27,000 packages [40]. As shown in Section 6.1, PIE executables comprise a minority of the executables on all of the systems that we surveyed.

7.3 Countermeasures

There are several measures that can be taken against Leakless, but they all have drawbacks. In this sections we analyze the most relevant ones.

Position Independent Executables. A quick countermeasure is to make every executable on the system position independent. While this would block Leakless's automatic operation (as discussed in Section 7.2), it would still allow the application of the Leakless technique when any information disclosure does occur. For that reason, and the performance overhead associated with PIE, we consider the other countermeasures described in this section to be better solutions to the problem.

Disabling lazy loading. When the `LD_BIND_NOW` environment variable is set, the dynamic loader will completely disable *lazy loading*. That is, all imports, for the program binary and any library it depends on, are resolved upon program startup. As a side-effect of this, the address of `_dl_runtime_resolve` does not get loaded into the GOT of any library, and Leakless cannot function. This is equivalent to enable full RELRO on the whole system, and consequently, it incurs in the same, non-negligible, performance overhead.

Disabling DT_DEBUG. Finally, Leakless also uses the `DT_DEBUG` dynamic entry, used by debuggers for intercepting loading-related events, to bypass full RELRO. Currently, this field is always initialized, opening the doors for Leakless' full RELRO bypass. To close this hole, the dynamic loader could be modified to only initialize this value when a debugger is present or in the presence of an explicitly-set environment variable.

Better protection of loader control structures. Leakless heavily relies on the fact that dynamic loader control structures are easily accessible in memory, and their locations are well-known. It would be beneficial for these structures to be better protected, or hidden in memory, instead of being loaded at a known location. For example, as shown in [29], these structures, along with any sections that provide control data for symbol resolution, could be marked as read-only after initialization. Such a development would eliminate Leakless' ability to corrupt these structures and would prevent the attack from redirecting the control flow to sensitive functions.

Additionally, modifying the loading procedure to use a table of `link_map` structure, and letting `_dl_runtime_resolve` take an index in this table, instead of a direct pointer, will break Leakless' bypass of full RELRO. However, this change would also break compatibility with any binaries compiled before the change is implemented.

Isolation of the dynamic loader. Isolating the dynamic loader from the address space of the target program could be an effective countermeasure. For instance, on Nokia's *Symbian OS*, which has a micro-kernel, the dynamic loader is implemented in a separate process as a *system server* which interfaces with the kernel [26]. This guarantees that the control structures of the dynamic loader cannot be corrupted by the program, and, therefore, this makes Leakless virtually ineffective. However, such a countermeasure would have a considerable impact on the overall performance of applications due to the overhead of IPC (Inter-Process Communication).

In general, the mitigations either represent a runtime performance overhead (PIE or loader isolation), a load-time performance overhead (non-lazy loading and system-wide RELRO), or a modification of the loading process (`DT_DEBUG` disabling or loader control structure hiding). In the long run, we believe that a redesign of the dynamic loader, with security in mind, would be extremely beneficial to the community. In the short term, there are options available to protect against Leakless, but they all come with a performance cost.

8 Conclusion

In this paper, we presented Leakless, a new technique that leverages functionality provided by the dynamic loader to enable attackers to use arbitrary, security-critical library functions in their exploits, without having to know where in the application's memory these functions are located. This capability allows exploits that, previously, required an information disclosure step to function.

Since Leakless leverages features mandated in the ELF binary format specification, the attacks it implements are applicable across architectures, operating systems, and dynamic loader implementations. Additionally, we showed how our technique can be used to bypass hardening schemes such as RELRO, which are designed to protect important control structures used in the dynamic resolution process. Finally, we proposed several countermeasures against Leakless, discussing the advantages and disadvantages of each one.

A Symbol versioning challenges

In Section 3.4 we introduced the concept of symbol versioning, and in Section 4.2 we mentioned that its usage introduces additional constraints in the value that `Elf_Rel.r_info` can assume. In this Appendix we illustrate these constraints, and how Leakless can automatically verify and satisfy them.

A.1 Constraints due to symbol versioning

In presence of symbol versioning, the `Elf_Rel.r_info` field is used both as an index into the dynamic symbol table and as an index in the symbol version table (the `.gnu.version` section), which is composed by `Elf_Verneed` values. An `Elf_Verneed` value of zero or one has a special meaning, and stops the processing of the symbol version, which is a desirable situation for the attacker.

To understand the constraints posed by this, we introduce some definitions and naming conventions. *idx* is the index in `Elf_Rel.r_info` that Leakless has computed, baseof(x) is the function returning the base address of section x, sizeof(y) is the function returning the size in bytes of structure y, and $*$ is the pointer dereference operator. We define the following variables:

$$\begin{aligned} sym &= \text{baseof}(\texttt{.dynsym}) + idx \cdot \text{sizeof}(\texttt{Elf\_Sym}) \\ ver &= \text{baseof}(\texttt{.gnu.version}) + \\ &\quad + idx \cdot \text{sizeof}(\texttt{Elf\_Verneed}) \\ verdef &= \text{baseof}(\texttt{.gnu.version\_r}) + \\ &\quad + *(ver) \cdot \text{sizeof}(\texttt{Elf\_Verdef}) \end{aligned}$$

To be able to carry on the attack, the following conditions must hold:

1. *sym* points to a memory area controlled by the attacker, and
2. one of the following holds:
   (a) *ver* points to a memory area containing a zero or a one, or
   (b) *ver* points to a memory area controlled by the attacker, which will write a zero value there, or
   (c) *verdef* points to a memory area controlled by the attacker, which will place there an appropriately crafted `Elf_Verdef` structure.

All the other options result in an access to an unmapped memory area or the failure of the symbol resolution process, both of which result in program termination.

Leakless is able to satisfy these constraints automatically in most cases. The typical successful situation results in an *idx* value that points to a version index with value zero or one in the `.text` section (which usually comes after `.gnu.version`) and to a symbol in the `.data` or `.bss` section. A notable exception, where this is impossible to achieve, is in the case of small x86-64 ELF binaries compiled with the support of huge pages [32]. Using huge pages means that memory pages are aligned to boundaries of 2 MiB and, therefore, the segment containing the read-only sections (in particular, `.gnu.version` and `.text`) is quite far from the writeable segment (containing `.bss` and `.data`). This makes it hard to find a good value for *idx*.

A.2 The huge page issue

The effect of huge pages can be seen in the following examples:

```
$ readelf --wide -l elf-without-huge-pages

Program Headers:
  Type VirtAddr   MemSiz   Flg Align
  ...
  LOAD 0x00400000 0x006468 R E 0x1000
  LOAD 0x00407480 0x0005d0 RW  0x1000
  ...

$ readelf --wide -l elf-with-huge-pages

Program Headers:
  Type VirtAddr   MemSiz   Flg Align
  ...
  LOAD 0x00400000 0x00610c R E 0x200000
  LOAD 0x00606e10 0x0005d0 RW  0x200000
  ...
```

While in the first case the distance between the beginning of the executable and the writeable segments is in the order of the kilobytes, with huge pages is more than 2 MiB, and a valid value for *idx* cannot be found.

There are two ways to resolve the problems posed to Leakless by small 64-bit binaries.

The first option is to find a zero value for `Elf_Verneed` in the read-only segment (usually `.text`). Given *ro_start*, *ro_end* and *ro_size*, as the start and end virtual addresses and the size of the read-only segment respectively, and *rw_start*, *rw_end* and *rw_size* as the respective values for the writeable segment, the following must hold:

$$\begin{aligned} ro\_start \leq\ ver\ &< ro\_end \\ rw\_start \leq sym &< rw\_end \end{aligned}$$

Here, the most difficult case to satisfy is if `.dynsym` or `.gnu.version` start at *ro_start*. If we assume that *both* hold true, we can write the following:

$$\begin{aligned} idx \cdot \text{sizeof}(\texttt{Elf\_Verneed}) &< ro\_end - ro\_start \\ idx \cdot \text{sizeof}(\texttt{Elf\_Sym}) &\geq rw\_start - ro\_start \end{aligned}$$

Or, alternatively:

$$\begin{aligned} idx \cdot \text{sizeof}(\texttt{Elf\_Verneed}) &< ro\_size \\ idx \cdot \text{sizeof}(\texttt{Elf\_Sym}) &\geq 2 \text{ MiB} \end{aligned}$$

Knowing that `Elf_Verneed` and `Elf_Sym` have, respectively, a size of 2 and 24 bytes for 64 bit ELFs, we can compute the minimum value of `ro_size` to make this system of inequalities satisfiable. The result is 170.7 KiB. If the `.rodata` section is smaller than this size, an alternative method must be used.

The second option is to position `Elf_Verneed` in the writeable segment. In this case, the attack requirements can be described by the following system of inequalities:

$$\begin{aligned} rw\_start \leq\ ver\ &< rw\_end \\ rw\_start \leq sym &< rw\_end \end{aligned}$$

If we, once again, consider the most stringent constraints and apply the previously mentioned assumptions, we get the following:

$$\begin{aligned} idx \cdot \text{sizeof}(\texttt{Elf\_Verneed}) &\geq rw\_start - ro\_start \\ idx \cdot \text{sizeof}(\texttt{Elf\_Sym}) &< rw\_start - ro\_start + \\ &\quad + rw\_size \end{aligned}$$

Or, alternatively:

$$\begin{aligned} idx \cdot \text{sizeof}(\texttt{Elf\_Verneed}) &\geq 2 \text{ MiB} \\ idx \cdot \text{sizeof}(\texttt{Elf\_Sym}) &< 2 \text{ MiB} + rw\_size \end{aligned}$$

We can now put a lower bound on the size of the writeable segment (*rw_size*) to make the system satisfiable: 22 MiB. However, this is unreasonably large, and leads us to the conclusion that this approach is not viable with small 64 bit ELF binaries that use huge pages.

Finding Unknown Malice in 10 Seconds: Mass Vetting for New Threats at the Google-Play Scale

Abstract

An app market's vetting process is expected to be scalable and effective. However, today's vetting mechanisms are slow and less capable of catching new threats. In our research, we found that a more powerful solution can be found by exploiting the way Android malware is constructed and disseminated, which is typically through repackaging legitimate apps with similar malicious components. As a result, such attack payloads often stand out from those of the same repackaging origin and also show up in the apps not supposed to relate to each other.

Based upon this observation, we developed a new technique, called *MassVet*, for vetting apps at a massive scale, without knowing what malware looks like and how it behaves. Unlike existing detection mechanisms, which often utilize heavyweight program analysis techniques, our approach simply compares a submitted app with all those already on a market, focusing on the difference between those sharing a similar UI structure (indicating a possible repackaging relation), and the commonality among those seemingly unrelated. Once public libraries and other legitimate code reuse are removed, such diff/common program components become highly suspicious. In our research, we built this "DiffCom" analysis on top of an efficient similarity comparison algorithm, which maps the salient features of an app's UI structure or a method's control-flow graph to a value for a fast comparison. We implemented MassVet over a stream processing engine and evaluated it nearly 1.2 million apps from 33 app markets around the world, the scale of Google Play. Our study shows that the technique can vet an app within 10 seconds at a low false detection rate. Also, it outperformed all 54 scanners in VirusTotal (NOD32, Symantec, McAfee, etc.) in terms of detection coverage, capturing over a hundred thousand malicious apps, including over 20 likely zero-day malware and those installed millions of times. A close look at these apps brings to light intriguing new observations: e.g., Google's detection strategy and malware authors' countermoves that cause the mysterious disappearance and reappearance of some Google Play apps.

1 Introduction

The phenomenal growth of Android devices brings in a vibrant application ecosystem. Millions of applications (*app* for short) have been installed by Android users around the world from various *app markets*. Prominent examples include Google Play, Amazon Appstore, Samsung Galaxy Apps, and tens of smaller third-party markets. With this prosperity, the ecosystem is tainted by the rampancy of Android malware, which masquerades as a useful program, often through repackaging a legitimate app, to wreak havoc, e.g., intercepting one's messages, stealing personal data, sending premium SMS messages, etc. Countering this menace primarily relies on the effort from the app markets, since they are at a unique position to stop the spread of malware in the first place. Accomplishing this mission, however, is by no means trivial, as highlighted by a recent report [8] that 99% of mobile malware runs on Android devices.

Challenges in app vetting. More specifically, the protection today's app market puts in place is a *vetting process*, which screens uploaded apps by analyzing their code and operations for suspicious activities. Particularly, Google Play operates *Bouncer* [24], a security service that statically scans an app for known malicious code and then executes it within a simulated environment on Google's cloud to detect hidden malicious behavior. The problem here is that the static approach does not work on new threats (i.e., *zero-day* malware), while the dynamic one can be circumvented by an app capable of fingerprinting the testing environment, as discovered by a prior study [30]. Also the dynamic analysis can be heavyweight, which makes it hard to explore all execution paths of an app.

New designs of vetting techniques have recently been proposed by the research community [57, 28] for capturing new apps associated with known suspicious behavior, such as dynamic loading of binary code from a remote untrusted website [57], operations related to component hijacking [28], Intent injection [12], etc. All these approaches involve a heavyweight information-flow analysis and require a set of heuristics that characterize the known threats. They often need a dynamic analysis in addition to the static inspection performed on app code [57] and further human interventions to annotate the code or even participate in the analysis [14]. Moreover, emulators that most dynamic analysis tools employ can be detected and evaded by malware [23]. Also importantly, none of them has been put to a market-scale test to understand their effectiveness, nor has their performance been clearly measured.

Catching unknown malice. Actually, a vast majority of Android malware are repackaged apps [56], whose authors typically attach the same attack payload to different legitimate apps. In this way, not only do they hide their malicious program logic behind the useful functionalities of these apps, but they can also automate the repackaging process to quickly produce and distribute a large number of Trojans[1]. On the other hand, this practice makes such malware stand out from other repackaged apps, which typically incorporate nothing but advertising libraries [2]. Also as a result of the approach, similar code (typically in terms of Java methods) shows up in unrelated apps that are not supposed to share anything except popular libraries.

These observations present a new opportunity to catch malicious repackaged apps, the mainstay of Android malware, without using any heuristics to model their behavior. What we can do is to simply compare the code of related apps (an app and its repackaged versions, or those repackaged from the same app) to check their *different* part, and unrelated apps (those of different origins, signed by different parties) to inspect their *common* part to identify suspicious code segments (at the method level). These segments, once found to be inexplicable (e.g., not common libraries), are almost certain to be malicious, as discovered in our study (Section 4.2). This *DiffCom* analysis is well suited for finding previously unknown malicious behavior and also can be done efficiently, without resorting to any heavyweight information-flow technique.

Mass vetting at scale. Based on this simple idea, we developed a novel, highly-scalable vetting mechanism for detecting repackaged Android malware on one market or cross markets. We call the approach *mass vetting* or simply *MassVet*, as it does not use malware signatures and any models of expected malicious operations, and instead, solely relies on the features of existing apps on a market to vet new ones uploaded there. More specifically, to inspect a new app, MassVet runs a highly efficient DiffCom analysis on it against the whole market. Any existing app related to the new one (i.e., sharing the same repackaging origin) is quickly identified from the structural similarity of their user interfaces (aka., *views*), which are known to be largely preserved during repackaging (Section 2). Then, a *differential analysis* happens to those sharing the similar view structure (indicating a repackaging relation between them) when a match has been found. Also, an *intersection analysis* is performed to compare the new app against those with different view structures and signed by different certificates. The code components of interest discovered in this way, either the common (or similar) methods (through the intersection analysis) or different ones (by the differential analysis), are further inspected to remove common code reuses (libraries, sample code, etc.) and collect evidence for their security risks (dependence on other code, resource-access API calls, etc.), before a red flag is raised.

Supporting this mass vetting mechanism are a suite of techniques for high-performance view/code comparisons. Particularly, innovations are made to achieve a scalable analysis of different apps' user interfaces (Section 3.2). The idea is to project a set of salient features of an app's view graph (i.e., the interconnections between its user interfaces), such as types of widgets and events, to a single dimension, using a unique index to represent the app's location within the dimension and the similarity of its interface structure to those of others. In our research, we calculated this index as a geometric center of a view graph, called *v-core*. The v-cores of all the apps on the market are sorted to enable a binary search during the vetting of a new app, which makes this step highly scalable. The high-level idea here was applied to application clone detection [7], a technique that has been utilized in our research (mapping the features of a Java method to an index, called *m-core* in our research) for finding common methods across different apps (Section 3.3). It is important to note that for the view-graph comparison, new tricks need to be played to handle the structural changes caused by repackaging, e.g., when advertisement interfaces are added (Section 3.2).

Our findings. We implemented MassVet on a cloud platform, nearly 1.2 million real-world apps collected from 33 app markets around the world. Our experimental study demonstrates that MassVet vetted apps within ten seconds, with a low false positive rate. Most importantly, from the 1.2 million apps, our approach discovered 127,429 malware: among them at least 20 are likely zero-day and 34,026 were missed by the majority of the malware scanners run by *VirusTotal*, a website that syn-

[1] Those Trojans are typically signed by different keys to avoid blocking of a specific signer.

dicates 54 different antivirus products [43]. Our study further shows that MassVet achieved a better detection coverage than *any* individual scanner within VirusTotal, such as Kaspersky, Symantec, McAfee, etc. Other highlights of our findings include the discovery of malicious apps in leading app markets (30,552 from Google Play), and Google's strategies to remove malware and malware authors' countermoves, which cause mysterious disappearance and reappearance of apps on the Play Store.

Contributions. The contributions of the paper are summarized as follows:

- *New techniques*. We developed a novel mass vetting approach that detects new threats using nothing but the code of the apps already on a market. An innovative differential-intersection analysis (i.e., DiffCom) is designed to exploit the unique features of repackaging malware, catching the malicious apps even when their behavior has not been profiled *a priori*. This analysis is made scalable by its simple, static nature and the feature projection techniques that enable a cloud-based, fast search for view/code differences and similarities. Note that when the v-core and m-core datasets (only 100 GB for 1.2 million apps) are shared among multiple markets, MassVet can help one market to detect malicious submissions using the apps hosted by all these markets.
- *New discoveries*. We implemented MassVet and evaluated it using nearly 1.2 million apps, a scale unparalleled in any prior study on Android malware detection, up to our knowledge, and on a par with that of Google Play, the largest app market in the world with 1.3 million apps [39]. Our system captured tens of thousands of malware, including those slipping under the radar of most or all existing scanners, achieved a higher detection coverage than all popular malware scanners within VirusTotal and vetted new apps within ten seconds. Some malware have over millions of installs. 5,000 malware were installed over 10,000 times each, impacting hundreds of millions of mobile devices. A measurement study further sheds light on such important issues as how effective Google Play is in screening submissions, how malware authors hide and distribute their attack payloads, etc.

2 Background

Android App markets. Publishing an app on a market needs to go through an approval process. A submission will be inspected for purposes such as quality control, censorship, and also security protection. Since 2012, Google Play has been under the protection of Bouncer. This mechanism apparently contributes to the reduction of malware on the Play store, about 0.1% of all apps there as discovered by F-Secure [15]. On the other hand, this security vetting mechanism was successfully circumvented by an app that fingerprints its simulator and strategically adjusts its behavior [33]. Compared with the Android official market, how third-party markets review submitted apps is less clear. The picture painted by F-Secure, however, is quite dark: notable markets like Mumayi, AnZhi, Baidu, etc. were all found riddled with malware infiltrations [16].

Attempts to enhance the current secure vetting mechanisms mainly resort to conventional malware detection techniques. Most of these approaches, such as VetDroid [52], rely on tracking information flows within an app and the malicious behavior modeling for detecting malware. In the case that what the malware will do is less clear to the market, these approaches no longer help. Further, analyzing information flows requires semantically interpreting each instruction and carefully-designed techniques to avoid false positives, which are often heavyweight. This casts doubt on the feasibility of applying these techniques to a large-scale app vetting.

Repackaging. App repackaging is a process that modifies an app developed by another party and already released on markets to add in some new functionalities before redistributing the new app to the Android users. According to Trend Micro (July 15, 2014), nearly 80% of the top 50 free apps on Google Play have repackaged versions [49]. Even the Play store itself is reported to host 1.2% repackaged apps [58]. This ratio becomes 5% to 13% for third-party markets, according to a prior study [55]. These bogus apps are built for two purposes: either for getting advertisement revenues or for distributing malware [7]. For example, one can wrap AngryBird with ad libraries, including his own adverting ID to benefit from its advertising revenue. Malware authors also found that leveraging those popular legitimate apps is the most effective and convenient avenue to distribute their attack payloads: repackaging saves them a lot of effort to build the useful functionalities of a Trojan and the process can also be automated using the tools like smali/baksmali [36]; more importantly, they can free-ride the popularity of these apps to quickly infect a large number of victims. Indeed, research shows that the vast majority of Android malware is repackaged apps, about 86% according to a study [56]. A prominent feature shared by all these repackaged apps, malicious or not, is that they tend to keep the original user interfaces intact, so as to impersonate popular legitimate apps.

Scope and assumptions. MassVet is designed to detect repackaged Android malware. We do not consider the situation that the malware author makes his malicious payload an inseparable part of the repackaged app, which needs much more effort to understand the legitimate app than he does today. Also, MassVet can handle typical code obfuscation used in most Android apps (Section 3). However, we assume that the code has not been

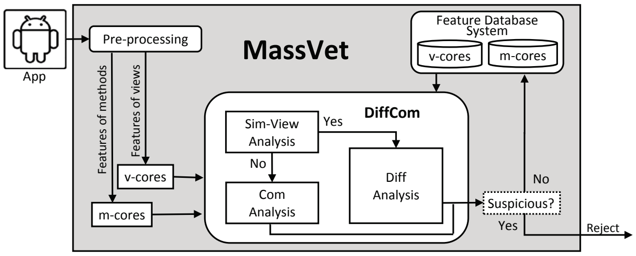

Figure 1: The Architecture of MassVet.

obfuscated to the extent that even disassembly cannot go through. When this happens, not only our approach but also most of other static analyses will fail. Finally, we assume that the app market under protection accommodates a large number of highly-diverse apps, so that for the malicious repackaged app uploaded, on the market there will be either another app sharing its repackaging origin or the one incorporating the same attack payload. To make this more likely to happen, different markets can share the feature datasets of their apps (i.e., v-cores and m-cores) with each other. Note that such datasets are very compact, only 100 GB for 1.2 million apps.

3 MassVet: Design and Implementation

3.1 Overview

Design and architecture. To detect unknown malware at a large scale, we come up with a design illustrated in Figure 1. It includes three key components: a preprocessing module, a feature database system and a DiffCom module. The preprocessing module automatically analyzes a submitted app, which includes extracting the features of its view structure and methods, and then summarizing them into the app's v-cores and m-cores respectively. The DiffCom component then works on these features, searching for them within the app market's v-core and m-core databases. Matches found there are used to identify suspicious different or common methods, which are further screened to remove false positives.

How it works. Here we use an example to walk through the work flow of the system. MassVet first processes all the apps on a market to create a v-core database for view structures and an m-core database for Java methods (Section 3.4). Both databases are sorted to support a binary search and are used for vetting new apps submitted to the market. Consider a repackaged AngryBird. Once uploaded to the market, it is first automatically disassembled at the preprocessing stage into a `smali` representation, from which its interface structures and methods are identified. Their features (for views, user interfaces, types of widgets and events, and for methods, control flow graphs and bytecode) are mapped to a set of v-cores (Section 3.2) and m-cores (Section 3.3) through calculating the geometric centers of the view graphs and control-flow graphs respectively. The app's v-cores are first used to query the database through a binary search. Once a match is found, which happens when there exists another app with a similar AngryBird user interface structure, the repackaged app is compared with the app already on the market at the method level to identify their difference. Such different methods (*diff* for short) are then automatically analyzed to ensure that they are not ads libraries and indeed suspicious, and if so, are reported to the market (Section 3.2). When the search on the v-core database comes back with nothing[2], MassVet continues to look for the AngryBird's m-cores in the method database. If a similar method has been found, our approach tries to confirm that indeed the app including the method is unrelated to the submitted AngryBird and it is not a legitimate code reuse (Section 3.3). In this case, MassVet reports that a suspicious app is found. All these steps are fully automated, without human intervention.

3.2 Fast User-Interface Analysis

As discussed before, the way MassVet vets an app depends on whether it is *related* to any other app already on the market. Such a relation is established in our research through a quick inspection of apps' user interfaces (UI) to identify those with similar view structures. When such apps are not "officially" connected, e.g., produced by the same party, the chance is that they are of the same repackaging origin, and therefore their diffs become interesting for malicious code detection. This interface-based relation identification is an alternative to code-based identification: a malicious repackaged app can be obfuscated and junk code can be easily added to make it look very different from the original version in terms of the similarity between their code (e.g., percentage of similar methods shared between them). On the other hand, a significant change to the user interface needs more effort and most importantly affects user experience, making it more difficult for the adversary to free ride the popularity of the original app. Therefore, most repackaged apps preserve their original UI structures, as found by the prior research [50]. In our research, we further discovered that many repackaged apps incorporate a large amount of new code, even more than that in their original versions, but still keep those apps' UI structures largely intact.

The idea of using view structures to detect repackaged apps has been preliminarily explored in prior research [50], which utilizes subgraph isomorphism algorithms to measure the similarity between two apps. However, the approach is less effective for the apps with relatively simple user-interface structures, and most impor-

[2] The market can also choose to perform both differential and interaction analyses for all new apps (Section 3.3).

tantly, agonizingly slow: it took 11 seconds to compare a pair of apps [50], which would need 165 days to analyze one submission against all 1.3 million apps on the Google Play store.

Following we elaborate our new solution designed for an accurate and high performance app-view analysis.

Feature extraction. An app's user interface consists of a set of views. Each view contains one or more visual widgets such as Button, ListView, TextView, etc. These UI components respond to users' input events (e.g., tapping and swiping) with the operations specified by the app developer. Such responses may cause visible changes to the current view or transitions to other views. This interconnection structure, together with the layouts and functionalities of individual views, was found to be sufficiently unique for characterizing each app [50].

In our research, we model such a UI structure as a *view graph*, which is a directed weighted graph including all views within an app and the navigation relations (that is, the transition from one view to another) among them. On such a graph, each node is a view, with the number of its *active* widgets (those with proper event-response operations) as its *weight*, and the arcs connecting the nodes describe the navigation (triggered by the input events) relations among them. According to the types of the events (e.g., `onClick`, `onFocusChange`, `onTouch`, etc.), edges can be differentiated from each other.

Such a view graph can effectively describe an app with a reasonably complicated UI structure. However, it becomes less effective for the small apps with only a couple of views and a rather straightforward connection structure. To address this issue, we enrich the view graph with additional features, including other UIs and the types of widgets that show up in a view. Specifically, in addition to view, which is displayed through invocation of an Android *Activity*, the UIs such as `AlertDialog` are also treated as nodes for the graph. Custom dialogs can be handled by analyzing class inheritance. Further, each type of widgets is given a unique value, with a sole purpose of differentiating it from other types. In this way, we can calculate a UI node's weight by adding together the values associated with the widgets it carries to make a small view graph more distinctive from others. An example is illustrated in Figure 2.

Note that we avoid using text labels on UI elements or other attributes like size or color. All the features selected here, including UIs, types of widgets and events that cause transitions among UIs, are less manipulable: in the absence of serious effort, any significant change to them (e.g., adding junk widgets, modifying the widget types, altering the transitions among views) will perceivably affect user experience, making it more difficult for the adversary to use them to impersonate popular apps.

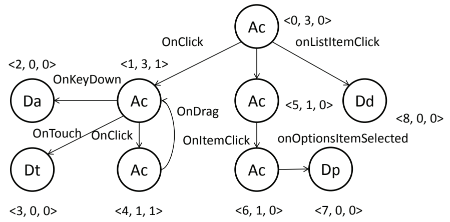

Figure 2: A View-graph example.
Ac: Activity; Da: AlertDialog; Dt: TimePickerDialog
Dp: ProgressDialog; Dd: DatePickerDialog

To construct the view graph for a submitted app, the preprocessing module automatically analyzes its code to recover all UI-related interprocess communication (IPC), the channel through which an Android app invokes user interfaces. Such IPC calls include `startActivity` and `startActivityForResult`. For each call, our approach locates it within a UI and further identifies the UI it triggers. Specifically, the program location of the IPC is examined to determine whether it is inside a UI-related class v. Its parameter is parsed to find out the class it calls (v'). In this case, nodes are created on the view graph for both classes (UIs) and an edge is added to link v to v'. Also, the type of the edge is determined by the event handler at which the IPC is located: for example, when the call is found inside the `onClick` function for a button, we know that this widget is used to cause a view transition. All such widgets are identified from each class for determining the weight of its node.

Design for scale. Once a view graph is recovered from an app, we want to quickly compare it across a market (or markets) to identify those related to the app. This operation needs to be of high-performance, capable of processing over one million apps within seconds. To this end, we applied a recently proposed similarity comparison algorithm, called *Centroids* [7], to the view-graph analysis. Centroid maps the features of a program's control-flow graph (CFG) into a value, which is calculated as the geometric center of the program. This value has a *monotonicity* property: that is, whenever a minor change happens to the CFG, the value changes accordingly at a small scale, reflecting the level of the difference made to the program. This property localizes the global comparison to a small number of "neighbors" to achieve high scalability without losing accuracy. The approach was used for the method comparison in our research (Section 3.3). However, it cannot be directly adopted for analyzing the UI structure, as the view graph is quite different from the CFG. Also, an app's graph is often fragmented due to the unusual ways to trigger some of its modules: e.g., most advertisement views are invoked through callbacks using the APIs of their library; as a result, their graph becomes separated from that of the main program. Here we describe how we address these issues.

Given a set of subgraphs for an app UI, $G_{i=1\cdots n}$, our preprocess module analyzes them one by one to calculate their individual geometric centers, i.e., v-cores. For a subgraph G_i, the first thing that needs to be done is to convert the features of each of its nodes (i.e., view) into a three-dimensional vector $\vec{c} = \{\alpha, \beta, \gamma\}$. Here α is a *sequence number* assigned to each node in G_i, which is done through an ordered deep-first traversal of G_i: starting from its main view, we select nodes to visit in the order of the sizes of their subtrees, and use their individual weights to break a tie; each node traversed in this way gets the number based upon its order of being visited. If two subtrees have the same size, we select the one according to their node types. In this way, we ensure that the assignment of sequence numbers is unique, which only depends on the structure of the directed weighted graph. The second element, β, in the vector is the out degree of the node: that is, the number of UIs the node can lead to. Finally, γ is the number of "transition loops" the current node is involved: i.e., the structure that from the node, there exists a navigation path that by visiting each node on the path only once, the user is able to navigate back to the current view. Figure 2 presents an example that show how such a vector is constructed.

After every node k on G_i has been given a vector $\vec{c}_k$, we can calculate its geometric center, i.e., v-core vc_i, as follows:

$$vc_i = \frac{\sum_{e(p,q) \in G_i} (w_p \vec{c}_p + w_q \vec{c}_q)}{\sum_{e(p,q) \in G_i} (w_p + w_q)}$$

where $e(p,q)$ denotes an edge in G_i from node p to q and w_p is the weight of node p. With the monotonicity of v-cores, we can sort them for a large number of apps to support a binary search. In this way, the subgraph G_i can be quickly compared with millions of graphs to identify similar ones. Specifically, given another graph G_t with a v-core vc_t, we consider that it matches G_i if $|vc_i - vc_t| \leq \tau$, where τ is a threshold. Further, given two apps sharing a subset of their view-graphs $G_{i(l=1\cdots m)}$, we consider that these two apps are similar in their UI structure when the following happens to at least one app: $\sum_l |G_{i(l)}| / \sum_i |G_i| \geq \theta$: that is, most of the app's view structures also appear in the other app (with θ being a threshold). This ensures that even when the adversary adds many new views to an app (e.g., through fake advertisements), the relation between the repackaged app and the original one can still be identified.

In our research, such thresholds were determined from a training process using 50,000 randomly selected apps (Section 3.3). We set different thresholds and measured the corresponding false positive/negative rates. For false positives, we randomly sampled 50 app pairs detected by our approach under each threshold and manually checked their relations. For false negatives, we utilized 100 app pairs known to have repackaging relations as the ground truth to find out the number of pairs our approach identified with different thresholds. The study shows that when $\tau = 0$ and $\theta = 0.8$, we got both a low false positive rate (4%) and a low false negative rate (6%). Among these 50,000 apps, we found that 26,317 app pairs had repackaging relations, involving 3,742 apps in total.

Effectiveness of the view-graph analysis. Compared with existing code-based approaches [7], the view-graph analysis turns out to be more effective at detecting apps of the same repackaging origin. Specifically, we randomly selected 10,000 app pairs (involving 17,964 apps) from those repackaged from the same programs, as discovered from 1.2 million apps we collected (Section 4.1). Many of these repackaging pairs involve the apps whose code significantly differ from each other. Particularly, in 14% of these pairs, *two apps were found to have less than 50% of their individual code in common*. This could be caused by a large library (often malicious) added to an app during repackaging or junk code inserted for the purpose of obfuscation. Since these apps look so different based upon their code, their repackaging relations cannot be easily determined by program analysis. However, they were all caught by our approach, simply because the apps' view-graphs were almost identical.

3.3 DiffCom Analysis at Scale

For an app going through the mass vetting process, the view-graph analysis first determines whether it is related to any app already on the market. If so, these two apps will be further compared to identify their diffs for a malware analysis. Otherwise, the app is checked against the whole market at the method level, in an attempt to find the program component it shares with other apps. The diffs and common component are further inspected to remove common code reuse (libraries, sample code, etc.) and collect evidence for their security risks. This "difference-commonality" analysis is performed by the DiffCom module. We also present the brick and mortar for efficient code-similarity analyzer and discuss the evasion of DiffCom.

The brick and mortar. To vet apps at the market scale, DiffCom needs a highly efficient code-similarity analyzer. In our research, we chose Centroids [7] as this building block. As discussed before, this approach projects the CFG of a program to its geometric center, in a way similar to the view-graph analysis. More specifically, the algorithm takes a basic program block as a node, which includes a sequence of consecutive statements with only a single input and output. The weight of the block is the number of the statements it contains. For each node on the CFG, a sequence number is assigned, together with the counts of the branches it connects and the number of loops it is involved in. These parameters are used to calculate the geometric center of the program.

To prepare for mass vetting, our approach first goes through all the apps on a market and breaks them into methods. After removing common libraries, the preprocessing module analyzes their code, calculates the geometric centers for individual methods (i.e., the m-cores) and then sorts them before storing the results in the database. During the vetting process, if a submitted app is found to share the view graph with another app, their diffs are quickly identified by comparing the m-cores of their individual methods. When the app needs to go through the intersection step, its methods are used for a binary search on the m-core database, which quickly discovers those also included in existing apps. Here we elaborate how these operations are performed. Their overhead is measured in Section 4.2.

Analyzing diffs. Whenever an app is found to relate to another one from their common view graph, we want to inspect the difference part of their code to identify suspicious activities. The rationale is that repackaged apps are the mainstay of Android malware, and the malicious payloads are often injected automatically (using tools like smali/baksmali) without any significant changes to the code of the original app, which can therefore be located by looking at the diffs between the apps of the same repackaging origin. Such diffs are quickly identified by comparing these two apps' m-cores: given two ordered sequences of m-cores L and L', the diff between the apps at the method level is found by merging these two lists according to the orders of their elements and then removing those matching their counterparts on the other list; this can be done within $\min(|L|,|L'|)$ steps.

However, similarity of apps' UIs does not always indicate a repackaging relation between them. The problem happens to the apps produced by the same party, individual developers or an organization. In this case, it is understandable that the same libraries and UIs could be reused among their different products. It is even possible that one app is actually an updated version of the other. Also, among different developers, open UI SDKs such as Appcelerator [3] and templates like Envatomarket [13] are popular, which could cause the view structures of unrelated apps to look similar. Further, even when the apps are indeed repackaged, the difference between them could be just advertisement (ad) libraries instead of malicious payloads. A challenge here is how to identify these situations and avoid bringing in false alarms.

To address these issues, MassVet first cleans up a submitted app's methods, removing ad and other libraries, before vetting the app against the market. Specifically, we maintain a white list of legitimate ad libraries based on [6], which includes popular mobile ad platforms such as MobWin, Admob, etc. To identify less known ones, we analyzed a training set of 50,000 apps randomly sampled from three app markets, with half of them from Google Play. From these apps, our analysis discovered 34,886 methods shared by at least 27,057 apps signed by different parties. For each of these methods, we further scanned its hosting apps using VirusTotal. If none of them were found to be malicious, we placed the method on the white list. In a similar way, popular view graphs among these apps were identified and the libraries associated with these views are white-listed to avoid detecting false repackaging relations during the view-graph analysis. Also, other common libraries such as Admob were also removed during this process, which we elaborate later. Given the significant size of the training set (50,000 randomly selected apps), most if not all legitimate libraries are almost certain to be identified. This is particularly true for those associated with advertising, as they need certain popularity to remain profitable. On the other hand, it is possible that the approach may let some zero-day malware fall through the cracks. In our research, we further randomly selected 50 ad-related methods on the list and searched for them on the Web, and confirmed that all of them were indeed legitimate. With this false-negative risk, still our approach achieved a high detection coverage, higher than any scanner integrated in VirusTotal (Section 4.2).

When it comes to the apps produced by the same party, the code they share is less popular and therefore may not be identified by the approach. The simplest solution here is to look at similar apps' signatures: those signed by the same party are not considered to be suspicious because they do have a good reason to be related. This simple treatment works most of time, since legitimate app vendors typically sign their products using the same certificate. However, there are situations when two legitimate apps are signed by different certificates but actually come from the same source. When this happens, the diffs of the apps will be reported and investigated as suspicious code. To avoid the false alarm, we took a close look at the legitimate diffs, which are characterized by their intensive connections with other part of the app. They are invoked by other methods and in the meantime call the common part of the code between the apps. On the other hand, the malicious payload packaged to a legitimate app tends to stand alone, and can only be triggered from a few (typically just one) program locations and rarely call the components within the original program.

In our research, we leveraged this observation to differentiate suspicious diffs from those likely to be legitimate. For each diff detected, the DiffCom analyzer looks for the calls it makes toward the rest of the program and inspects the `smali` code of the app to identify the references to the methods within the diff. These methods will go through a further analysis only when such interactions are very limited, typically just an inward invocation, without any outbound call. Note that current malware authors do not make their code more connected to the legitimate app they repackage, mainly because more effort is needed to understand the code of the app and carefully construct the attack. A further study is needed to understand the additional cost required to build more sophisticated malware to evade our detection.

For the diff found in this way, DiffCom takes further measures to determine its risk. A simple approach used in our implementation is to check the presence of API calls (either Android framework APIs or those associated with popular libraries) related to the operations considered to be dangerous. Examples include `getSimSerialNumber`, `sendTextMessage` and `getLastKnownLocation`. The findings here indicate that the diff code indeed has the means to cause damage to the mobile user's information assets, though how exactly this can happen is not specified. This is different from existing behavior-based detection [27], which looks for much more specific operation sequences such as "reading from the contact list and then sending it to the Internet". Such a treatment helps suppress false alarms and still preserves the generality of our design, which aims at detecting unknown malicious activities.

Analyzing intersections. When no apparent connection has been found between an app and those already on the market, the vetting process needs to go through an intersection analysis. This also happens when DiffCom is configured to perform the analysis on the app that has not been found to be malicious at the differential step. Identification of common methods a newly submitted app carries is rather straightforward: each method of the app is mapped to its m-core, which is used to search against the m-core database. As discussed before, this can be done through a binary search. Once a match is found, DiffCom further inspects it, removing legitimate connections between the apps, and reports the finding to the market.

Again, the main challenge here is to determine whether two apps are indeed unrelated. A simple signature check removes most of such connections but not all. The "stand-alone" test, which checks whether a set of methods intensively interact with the rest of an app, does not work for the intersection test. The problem here is that the common methods between two repackaged apps may not be the complete picture of a malicious payload, making them different from the diff identified in the differential-analysis step: different malware authors often use some common toolkits in their attack payloads, which show up in the intersection between their apps; these modules still include heavy interactions with other components of the malware that are not found inside the intersection. As a result, this feature, which works well on diffs, cannot help to capture suspicious common code among apps.

An alternative solution here is to look at how the seemingly unrelated apps are actually connected. As discussed before, what causes the problem is the developers or organizations that reuse code internally (e.g., a proprietary SDK) but sign the apps using different certificates. Once such a relation is also identified, we will be more confident about whether two apps sharing code are independent from each other. In this case, the common code becomes suspicious after all public libraries (e.g., those on the list used in the prior research [6]) and code templates have been removed. Here we describe a simple technique for detecting such a hidden relation.

From our training dataset, we found that most code reused legitimately in this situation involves user interfaces: the developers tend to leverage existing view designs to quickly build up new apps. With this practice, even though two apps may not appear similar enough in terms of their complete UI structures (therefore they are considered to be "unrelated" by the view-graph analysis), a close look at the subgraphs of their views may reveal that they actually share a significant portion of their views and even subgraphs. Specifically, from the 50,000 apps in our training set, after removing public libraries, we found 30,286 sharing at least 30% of their views with other apps, 16,500 sharing 50% and 8,683 containing no less than 80% common views. By randomly sampling these apps (10 each time) and analyzing them manually, we confirmed that when the portion goes above 50%, almost all the apps and their counterparts are either from the same developers or organizations, or having the same repackaging origins. Also, once the shared views become 80% or more, almost always the apps are involved in repackaging. Based upon this observation, we run an additional correlation check on a pair of apps with common code: DiffCom compares their individual subgraphs again and if a significant portion (50%) is found to be similar, they are considered related and therefore their intersection will not be reported to the market.

After the correlation check, all the apps going through the intersection analysis are very likely to be unrelated. Therefore, legitimate code shared between them, if any, is almost always public libraries or templates. As described before, we removed such common code through white-listing popular libraries and further complemented the list with those discovered from the training set: methods in at least 2,363 apps were considered legitimate public resources if all these apps were cleared by VirusTotal. Such code was further sampled and manually analyzed in our study to ensure that it indeed did not involve any suspicious activities. With all such libraries removed, the shared code, particularly the method with dangerous APIs (e.g., `getSimSerialNumber`), is reported as possible malicious payload.

Evading MassVet. To evade MassVet, the adversary could try to obfuscate app code, which can be tolerated to some degree by the similarity comparison algorithm we use [7]. For example, common obfuscation techniques, such as variable/method renaming, do not affect centroids. Also the commonality analysis can only be defeated when the adversary is willing to significantly alter the attack payload (e.g., a malicious SDK) each time when he uses it for repackaging. This is not supported by existing automatic tools like ADAM [53] and DroidChameleon [32], which always convert the same code to the same obfuscated form. Further, a deep obfuscation will arouse suspicion when the app is compared with its repackaging origin that has not been obfuscated. The adversary may also attempt to obfuscate the app's view graphs. This, however, is harder than obfuscating code, as key elements in the graph, like event functions `OnClick`, `OnDrag`, etc., are hardcoded within the Android framework and cannot be modified. Also adding junk views can be more difficult than it appears to be: the adversary cannot simply throw in views disconnected from existing sub-graphs, as they will not affect how MassVet determines whether two view-graphs match (Section 3.2); otherwise, he may connect such views to existing sub-graphs (potentially allowing them to be visited from the existing UI), which requires understanding a legitimate app's UI structures to avoid affecting user experience.

We further analyzed the effectiveness of existing obfuscation techniques against our view-graph approach over 100 randomly selected Google-Play apps. Popular obfuscation tools such as DexGuard [37] and ProGuard [38] only work on Java bytecode, not the Dalvik bytecode of these commercial apps. In our research, we utilized ADAM [53] and DroidChameleon [32], which are designed for Dalvik bytecode, and are highly effective according to prior studies [53, 32]. Supposedly they can also work on view-related code within those apps. However after running them on the apps, we found that their v-cores, compared with those before the obfuscation, did not change at all. This demonstrates that such obfuscation is not effective on our view-graph approach.

On the other hand, we acknowledge that a new obfuscation tool could be built to defeat MassVet, particularly its view-graph search and the Com step. The cost for doing this, however, is less clear and needs further effort to understand (Section 5).

3.4 System Building

In our research, we implemented a prototype of MassVet using C and Python, nearly 1.2 million apps collected from 33 markets, including over 400,000 from Google Play (Section 4.1). Before these apps can be used to vet new submissions, they need to be inspected to detect malicious code already there. Analyzing apps of this scale and utilizing them for a real-time vetting require carefully designed techniques and a proper infrastructure support, which we elaborate in this section.

System bootstrapping and malware detection. To bootstrap our system, a market first needs to go through all its existing apps using our techniques in an efficient way. The APKs of these apps are decompiled into `smali` (using the tool baksmali [36][3]) to extract their view graphs and individual methods, which are further converted into v-cores and m-cores respectively. We use NetworkX [29] to handle graphs and find loops. Then these features (i.e., cores) are sorted and indexed before stored into their individual databases. In our implementation, such data are preserved using the Sqlite database system, which is characterized by its small size and efficiency. For all these apps, 1.5 GB was generated for v-cores and 97 GB for m-cores.

The next step is to scan all these 1.2 million apps for malicious content. A straightforward approach is to inspect them one by one through the binary search. This will take tens of millions of steps for comparisons and analysis. Our implementation includes an efficient alternative. Specifically, on the v-core database, our system goes through the whole sequence from one end (the smallest element) to the other end, evaluating the elements along the way to form *equivalent groups*: all those with identical v-cores are assigned to the same group[4].

All the subgraphs within the same group match each other. However, assembling them together to determine the similarity between two apps turns out to be tricky. This is because the UI of each app is typically broken into around 20 subgraphs distributed across the whole ordered v-core sequence. As such, any attempt to make the comparison between two apps requires to go through all equivalent groups. The fastest way to do that is to maintain a table for the number of view subgraphs shared between any two apps. However, this simple approach requires a huge table, half of 1.2 million by 1.2 million in the worst case, which cannot be completely loaded into the memory. In our implementation, a trade-off is made to save space by only inspecting 20,000 apps against the rest 1.2 million each time, which requires going through the equivalent groups for 60 times and uses about 100 GB memory at each round.

The inspection on m-cores is much simpler and does not need to compare one app against all others. This is because all we care about here are just the common methods that already show up within individual equiva-

[3] Very few apps (0.01%) cannot be decompiled in our dataset due to the limitation of the tool.

[4] In our implementation, we set the threshold τ to zero, which can certainly be adjusted to tolerate some minor variations among similar methods.

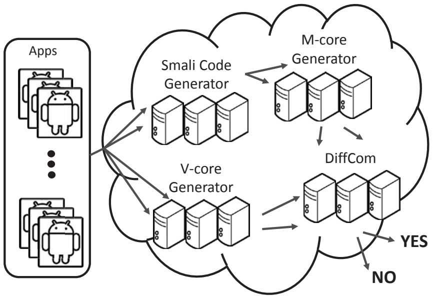

Figure 3: Cloud framework for MassVet.

lent groups. Those methods are then further analyzed to detect suspicious ones.

Cloud support. To support a high-performance vetting of apps, MassVet is designed to work on the cloud, running on top of a stream processing framework (Figure 3). Specifically, our implementation was built on *Storm* [40], an open-source stream-processing engine that also powers leading web services such as WebMD, Alibaba, Yelp, etc. Storm supports a large-scale analysis of a data stream by a set of worker units that connect to each other, forming a topology. In our implementation, the work flow of the whole vetting process is converted into such a topology: a submitted app is first disassembled to extract view graphs and methods, which are checked against the white list to remove legitimate libraries and templates; then, the app's v-cores and m-cores are calculated, and a binary search on the v-core database is performed; depending on the results of the search, the differential analysis is first run, which can be followed by the intersection analysis. Each operation here is delegated to a worker unit on the topology and all the data associated with the app are in a single stream. The Storm engine is designed to support concurrently processing multiple streams, which enables a market to efficiently vet a large number of submissions.

4 Evaluation and Measurement

4.1 Setting the Stage

App collection. We collected 1.2 million apps from 33 Android markets, including over 400,000 from Google Play, 596,437 from 28 app stores in China, 61,866 from European stores and 27,047 from other US stores as elaborated in Table 5 in Appendix. We removed duplicated apps according to their MD5. All the apps we downloaded from Google Play have complete meta data (upload date, size, number of downloads, developer, etc.), while all those from third-party markets do not.

The apps from Google Play were selected from 42 categories, including Entertainment, Tools, Social, Communication, etc. From each category, we first went for its top 500 popular ones (in terms of number of installs) and then randomly picked up 1000 to 30,000 across the whole category. For each third-party market, we just randomly collected a set of apps (Table 5) (190 to 108,736, depending on market sizes). Our collection includes high-profiled apps such as Facebook, Skype, Yelp, Pinterest, WeChat, etc. and those less popular ones. Their sizes range from less than 1 MB to more than 100 MB.

Validation. For the suspicious apps reported by our prototype, we validated them through VirusTotal and manual evaluations. Virustotal is the most powerful public malware detection system, which is a collection of 54 anti-malware products, including the most high-profile commercial scanners. It also provides the scanning service on mobile apps [44]. VirusTotal has two modes, complete scanning (which we call *new scan*) and using cached results (called *cached scan*). The latter is fast, capable of going through 200 apps every minute, but only covers those that have been scanned before. For the programs it has never seen or uploaded only recently, the outcome is just "unknown". The former determines whether an app is malicious by running on it all 54 scanners integrated within VirusTotal. The result is more up-to-date but the operation is much slower, taking 5 minutes for each app.

To validate tens of thousands suspicious cases detected from the 1.2 million apps (Section 4.2), we first performed the cached scan to confirm that most of our findings were indeed malicious. The apps reported to be "unknown" were further randomly sampled for a new scan. For all the apps that VirusTotal did not find malicious, we further picked up a few samples for a manual analysis. Particularly, for all suspicious apps identified by the intersection analysis, we clustered them according to their shared code. Within each cluster, whenever we observed that most members were confirmed malware, we concluded that highly likely the remaining apps there are also suspicious, even if they were not flagged by VirusTotal. The common code of these apps were further inspected for suspicious activities such as information leaks. A similar approach was employed to understand the diff code extracted during the differential analysis. We manually identified the activities performed by the code and labeled it as suspicious when they could lead to damages to the user's information assets.

4.2 Effectiveness and Performance

Malware found and coverage. From our collection, MassVet reported 127,429 suspicious apps (10.93%). 10,202 of them were caught by "Diff" and the rest were discovered by "Com". These suspicious apps are from different markets: 30,552 from Google Play and 96,877 from the third-party markets, as illustrated in Table 5. We first validated these findings by uploading them to VirusTotal for a cached scan (i.e., quickly checking the apps against the checksums cached by VirusTotal),

AV Name	# of Detection	% Percentage
Ours (MassVet)	197	70.11
ESET-NOD32	171	60.85
VIPRE	136	48.40
NANO-Antivirus	120	42.70
AVware	87	30.96
Avira	79	28.11
Fortinet	71	25.27
AntiVir	60	21.35
Ikarus	60	21.35
TrendMicro-HouseCall	59	21.00
F-Prot	47	16.73
Sophos	46	16.37
McAfee	45	16.01

Table 1: The coverages of other leading AV scanners.

which came back with 91,648 confirmed cases (72%), 17,061 presumably false positives (13.38%, that is, the apps whose checksums were in the cache but not found to be malicious when they were scanned) and 13,492 unknown (10.59%, that is, the apps whose checksums were not in VirusTotal's cache). We further randomly selected 2,486 samples from the unknown set and 1,045 from the "false-positive" set, and submitted to VirusTotal again for a new scan (i.e., running all the scanners, with the most up-to-date malware signatures, on the apps). It turned out that 2,340 (94.12%) of unknown cases and 349 (33.40%) of "false positives" are actually malicious apps, according to the new analysis. This gives us a false detection rate (FDR: false positives vs. all detected) of 9.46% and a false positive rate (FPR: false positives vs. all apps analyzed) of 1%, solely based upon VirusTotal's scan results. Note that the Com step found more malware than Diff, as Diff relies on the presence of two apps of same repackaging origins in the dataset, while Com only looks for common attack payloads shared among apps. It turns out that many malicious-apps utilize same malicious SDKs, which make them easier to catch.

We further randomly sampled 40 false positives reported by the new scan for a manual validation and found that 20 of them actually are highly suspicious. Specifically, three of them load and execute suspicious code dynamically; one takes pictures stealthily; one performs sensitive operation to modify the booting sequence of other apps; seven of them get sensitive user information such as SIM card SN number and telephone number/ID; several aggressive adware turn out to add phishing plugins and app installation bars without the user's consent. The presence of these activities makes us believe that very likely they are actually zero-day malware. We have reported all of them to four Antivirus software vendors such as Norton and F-Secure for a further analysis. If all these cases are confirmed, then the FDR of MassVet could further be reduced to 4.73%.

To understand the coverage of our approach, we randomly sampled 2,700 apps from Google Play and scanned them using MassVet and the 54 scanners within VirusTotal. All together, VirusTotal detected 281 apps and among them our approach got 197 apps. The coverage of MassVet, with regard to the collective result of all 54 scanners, is 70.1%, better than what could be achieved by any individual scanner integrated within VirusTotal, including such top-of-the-line antivirus systems as NOD32 (60.8%), Trend (21.0%), Symantec (5.3%) and McAfee (16%). Most importantly, MassVet caught at least 11% malware those scanners missed. The details of the study are presented in Table 1 (top 12).

# Apps	Pre-Processing analysis	v-core database search	differential	m-core database search (Intersection)	sum
10	5.84	0.15	0.33	1.80	8.12
50	5.85	0.15	0.34	1.99	8.33
100	5.85	0.14	0.35	2.23	8.57
200	5.88	0.16	0.35	3.13	9.52
500	5.88	0.16	0.35	3.56	9.95

Table 2: Performance: "Apps" here refers to the number of concurrently submitted apps.

Vetting delay. We measured the performance of our technique, on a server with 260 GB memory, 40 cores at 2.8 GHz and 28 TB hard drives. Running on top of the Storm stream processor, our prototype was tested against 1 to 500 concurrently submitted apps. The average delay we observed is 9 seconds, from the submission of the app to the completion of the whole process on it. This vetting operation was performed against all 1.2 million apps.

Table 2 further shows the breakdown of the vetting time at different vetting stages, including preprocessing (v-core and m-core generation), search across the v-core database, the differential analysis, search over the m-core database and the intersection analysis. Overall, we show that MassVet is indeed capable of scaling to the level of real-world markets to provide a real-time vetting service.

4.3 Measurement and Findings

Over the 127,429 malicious apps detected in our study, we performed a measurement study that brings to light a few interesting observations important for understanding the seriousness of the malware threat to the Android ecosystem, as elaborated below.

Landscape. The malware we found are distributed across the world: over 35,473 from North America, 4,852 from Europe and 87,104 from Asia. In terms of the portion of malicious code within all apps, Chinese app markets take the lead with 12.90%, which is followed by US, with 8.28%. This observation points to a possible lack of regulations and proper security protection in many Chinese markets, compared with those in other countries. Even among the apps downloaded from Google Play, over 7.61% are malicious, which is different from a prior report of only 0.1% malware discovered there [15]. Note that most of the malware here has been confirmed by VirusTotal. This indicates that indeed the portion of the apps with suspicious activities on leading app stores could be higher than previously thought. De-

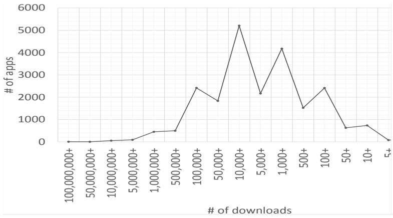

Figure 4: The distribution of downloads for malicious or suspicious apps in Google Play.

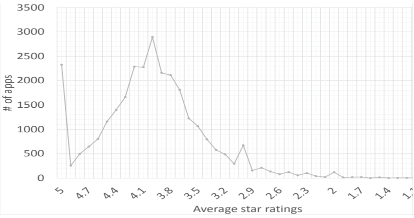

Figure 5: The distribution of rating for malicious or suspicious apps in Google Play.

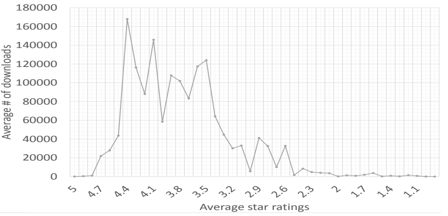

Figure 6: The distribution of average number of downloads for malicious or suspicious apps in Google Play.

tailed numbers of malicious apps are shown in Appendix (Table 5).

We observed that most scanners react slowly to the emergence of new malware. For all 91,648 malicious apps confirmed by VirusTotal, only 4.1% were alarmed by at least 25 out of 54 scanners it hosts. The results are present in Figure 7. This finding also demonstrates the capability of MassVet to capture new malicious content missed by most commercial scanners.

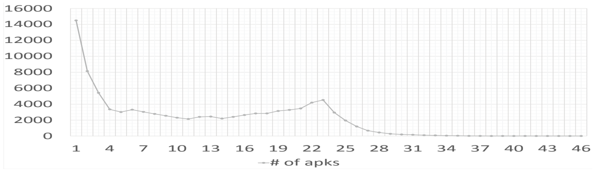

Figure 7: Number of malware detected by VirusTotal.

The impacts of those malicious apps are significant. Over 5,000 such apps have already been installed over 10,000 times each (Figure 4). Also, there are a few extremely popular ones, with the install count reaching 1 million or even more. Also, the Google-Play ratings of the suspicious APKs are high (most of them ranging from 3.6 to 4.6, Figure 5), with each being downloaded for many times (100,000 to 250,000) on average (Figure 6). This suggests that hundreds of millions of mobile devices might have already been infected.

Existing defense and disappeared apps. Apparently, Google Play indeed makes effort to mitigate the malware threat. However, our measurement study also shows the challenge of this mission. As Figure 8 illustrates, most malware we discovered were uploaded in the past 14 months. Also the more recently an app shows up, the more likely it is problematic. This indicates that Google Play continuously inspects the apps it hosts to remove the suspicious ones. For the apps that have already been there for a while, the chance is that they are quite legitimate, with only 4.5% found to be malicious. On the other hand, the newly released apps are much less trustworthy, with 10.69% of them being suspicious. Also, these malicious apps have a pretty long shelf time, as Google needs up to 14 months to remove most of them. Among the malware we discovered, 3 apps uploaded in Dec. 2010 are still there in Google Play.

Interestingly, 40 days after uploading 3,711 apps (those we asked VirusTotal to run *new scan* upon, as mentioned earlier) to VirusTotal, we found that 250 of them disappeared from Google Play. 90 days later, another 129 apps disappeared. Among the 379 disappeared apps, 54 apps (14%) were detected by VirusTotal. Apparently, Google does not run VirusTotal for its vetting but pays close attention to the new malware it finds.

We further identified 2,265 developers of the 3,711 suspicious apps, using the apps' meta data, and monitored all their apps in the follow-up 15 weeks (November 2014 to February 2015). Within this period, we observed that additional 204 apps under these developers disappeared, all of which were detected by MassVet, *due to the suspicious methods they shared with the malware we caught before that period*. The interesting part is that we did not scan these apps within VirusTotal, which indicates that it is likely that Google Play also looked into their malicious components and utilized them to check all other apps under the same developers. However, apparently, Google did not do this across the whole marketplace, because we found that other apps carrying those methods were still there on Google Play. If these apps were missed due to the cost for scanning all the apps on the Play Store, MassVet might actually be useful here: our prototype is able to compare a method across all 1.2 million apps within 0.1 second.

Another interesting finding is that we saw that some of these developers uploaded the same or similar malicious apps again after they were removed. Actually, among the 2,125 reappeared apps, 604 confirmed malware (28.4%) showed up in the Play Store *unchanged*, with the same MD5 and same names. Further, those developers also published 829 apps with the same malicious code (as that of the malware) but under different names. The fact that the apps with known malicious payloads still got slipped in suggests that Google might not pay adequate attention to even known malware.

Repackaging malware and malicious payload. Among the small set of repackaging malware captured by the differential analysis, most are from third-party stores (92.35%). Interestingly, rarely did we observe that malware authors repackaged Google Play apps

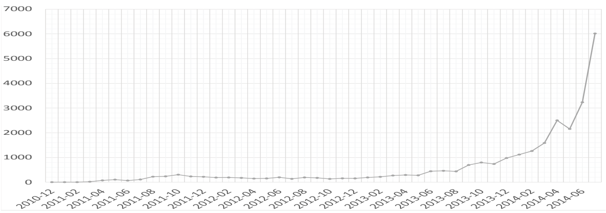

Figure 8: Number of malicious apps overtime.

and distributed them to the third-party stores in China. Instead, malware repackaging appears to be quite localized, mostly between the app stores in the same region or even on the same store. A possible explanation could be the effort that malware authors need to make on the original app so that it works for a new audience, which is certainly higher than simply repackaging the popular one in the local markets.

Figure 9 illustrates the distribution of common code across malware, as discovered from the intersection analysis. A relatively small set of methods have been reused by a large number of malicious apps. The leading one has been utilized by 9,438 Google-Play malware and by 144 suspicious apps in the third-party markets. This method turns out to be part of the library ("com/startapp") extensively used by malware. Over 98% of the apps integrating this library were flagged as malicious by VirusTotal and the rest were also found to be suspicious through our manual validation. This method sends users' fine-grained location information to a suspicious website. Similarly, all other popular methods are apparently also part of malware-building toolkits. Examples include "guohead", "purchasesdk" and "SDKUtils". The malware integrating such libraries are signed by thousands of different parties. An observation is that the use of these malicious SDKs is pretty regional: in Chinese markets, "purchasesdk" is popular, while "startapp" is widely used in the US markets. We also noticed that a number of libraries have been obfuscated. A close look at these attack SDKs shows that they are used for getting sensitive information like phone numbers, downloading files and loading code dynamically.

Signatures and identities. For each confirmed malicious app, we took a look at its "signature", that is, the public key on its X.509 certificate for verifying the integrity of the app. Some signatures have been utilized by more than 1,000 malware each: apparently, some malware authors have produced a large number of malicious apps and successfully disseminated them across different markets (Table 3). Further, when we checked the meta data for the malware discovered on Google Play, we found that a few signatures have been associated with many *identities* (e.g., the `creator` field in the metadata). Particularly, one signature has been linked to 604 identities, which indicates that the adversary might have created many accounts to distribute his app (Table 4).

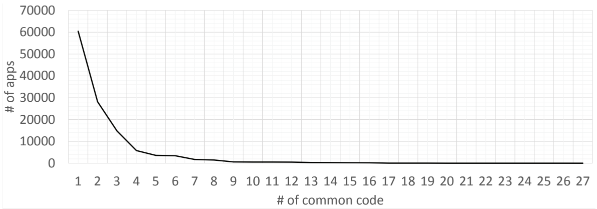

Figure 9: The distribution of common code across malware.

86c2331f1d3bb4af2e88f485ca5a4b3d	469

Table 3: Top 5 signatures used in apps.

Case studies. Among the suspicious apps MassVet reported are a set of APKs not even VirusTotal found to be malicious. We analyzed 40 samples randomly chosen from this set and concluded that 20 of them were indeed problematic through manual analysis, likely to be zero-day malware. We have reported them to 4 malware companies (F-Secure, Norton, Kaspersky, Trend Micro) for further validations. The behaviors of these apps include installing apps without user's consent, collecting user's private data (e.g., take screen shots of other apps) even though such information does not serve apps' stated functionalities, loading and executing native binary for command and control.

These apps use various techniques to evade detection. For example, some hide the suspicious functionality for weeks before starting to run it. "Durak card game" is such an game, which has been downloaded over 5,000,000 times. It was on Google Play before BBC reported it on February 4th 2015 [25]. So far, only two scanners hosted by VirusTotal can detect it. This malware disguises as warning messages when the user unlock her Android smartphone. It waits for several weeks before performing malicious activities. Its advertisements also do not show up until at least one reboot. Although Google removes "Durak card game", other apps with similar functionalities are still on the Play Store now. We also found that some malicious apps conceal their program logic inside native binaries. Some even encrypt the binaries and dynamically decrypt them for execution. Further some utilize Java reflection and other obfuscation techniques to cover their malicious code.

5 Discussion

As discussed before, MassVet aims at repackaging malware, the mainstay of potentially harmful mobile apps: this is because malware authors typically cannot afford to spend a lot of time and money to build a popular app just for spreading malware, only to be forced to do this all over again once it gets caught. Our technique exploits a weakness of their business model, which relies on repackaging popular apps with a similar attack payload to keep the cost for malware distribution low. With the fundamentality of the issue and the effectiveness of the technique on such malware, our current implementation, however, is still limited, particularly when it comes to the defense against evasion.

Specifically, though simply adding the junk views connected to an existing app's view graph can affect user experience and therefore may not work well (Section 3.3), a more effective alternative is to obfuscate the links between views (calls like `StartActivity`). However, this treatment renders an app's UI structure less clear to our analyzer, which is highly suspicious, as the vast majority of apps' view graphs can be directly extracted. What we could do is to perform a dynamic analysis on such an app, using the tools like *Monkey* to explore the connections between different views. Note that the overall performance impact here can still be limited, simply because most apps submitted to an app store are legitimate and their UI structures can be statically determined.

Further, to evade the commonality analysis, the adversary could obfuscate the malicious methods. As discussed earlier (Section 3.3), this attempt itself is nontrivial, as the m-cores of those methods can only be moved significantly away from their original values through substantial changes to their CFGs each time when a legitimate app is repackaged. This can be done by adding a large amount of junk code on the CFGs. Our current implementation does not detect such an attack, since it is still no there in real-world malware code. On the other hand, further studies are certainly needed to better understand and mitigate such a threat.

Critical to the success of our DiffCom analysis is removal of legitimate libraries. As an example, we could utilize a crawler to periodically gather shared libraries and code templates from the web to update our whitelists. Further, a set of high-profile legitimate apps can be analyzed to identify the shared code missed by the crawler. What can also be leveraged here is a few unique resources in the possession of the app market. For example, it knows the account from which the apps are uploaded, even though they are signed by different certificates. It is likely that legitimate organizations are only maintaining one account and even when they do have multiple ones, they will not conceal the relations among them. Using such information, the market can find out whether two apps are actually related to identify the internal libraries they share. In general, given the fact that MassVet uses a large number of existing apps (most of which are legitimate) to vet a small set of submissions, it is at the right position to identify and remove most if not all legitimate shared code.

6 Related Work

Malicious app detection. App vetting largely relies on the techniques for detecting Android malware. Most existing approaches identify malicious apps either based upon how they look like (i.e., content-based signature) [20, 27, 21, 45, 51, 57, 19, 54, 17, 22, 4] or how they act (behavior-based signature) [11, 31, 48, 47, 42, 18, 34]. Those approaches typically rely on heavyweight static or dynamic analysis techniques, and cannot detect the unknown malware whose behavior has not been modeled a priori. MassVet is designed to address these issues by leveraging unique properties of repackaging malware. Most related to our work is PiggyApp [54], which utilizes the features (permissions, APIs, etc.) identified from a major component shared between two apps to find other apps also including this component, then clusters the rest part of these apps' code, called *piggybacked payloads*, and samples from individual clusters to manually determine whether the payloads there are indeed malicious. In contrast, MassVet *automatically* detects malware through inspecting the code diff among apps with a similar UI structure and the common methods shared between those unrelated. When it comes to the scale of our study, ANDRUBIS [26, 46] dynamically examined the operations of over 1 million apps in four years. Different from ANDRUBIS, which is an off-line analyzer for recovering detailed behavior of individual malicious apps, MassVet is meant to be a fast online scanner for identifying malware without knowing its behavior. It went through 1.2 million of apps within a short period of time.

Repackaging and code reuse detection. Related to our work is repackaging and code reuse detection [55, 21, 1, 9, 10, 41, 35, 5]. Most relevant to MassVet is the Centroids similarity comparison [7], which is also proposed for detecting code reuse. Although it is a building block for our technique, the approach itself does *not* detect malicious apps. Significant effort was made in our research to build view-graph and code analysis on top of it to achieve an accurate malware scan. Also, to defeat code obfuscation, a recent proposal leverages the similarity between repackaged apps' UIs to detect their relations [50]. However, it is too slow, requiring 11 seconds to process a pair of apps. In our research, we come up with a more effective UI comparison technique, through mapping the features of view graphs to their geometric centers, as Centroids does. This significantly improves the performance of the UI-based approach, enabling it to help vet a large number of apps in real time.

7 Conclusion

We present MassVet, an innovative malware detection technique that compares a submitted app with all other apps on a market, focusing on its diffs with those having a similar UI structure and intersections with others. Our implementation was used to analyze nearly 1.2 million apps, a scale on par with that of Google Play, and discovered 127,429 malicious apps, with 20 likely to be zero-day. The approach also achieves a higher coverage than leading anti-malware products in the market.

Acknowledgement

We thank our shepherd Adam Doupé and anonymous reviewers for their valuable comments. We also thank Dr. Sencun Zhu and Dr. Fangfang Zhang for sharing their ViewDroid code, which allows us to understand how their system works, and VirusTotal for the help in validating over 100,000 apps discovered in our study. You Shouldn't Collect My Secrets:
Thwarting Sensitive Keystroke Leakage in Mobile IME Apps

Abstract

IME (input method editor) apps are the primary means of interaction on mobile touch screen devices and thus are usually granted with access to a wealth of private user input. In order to understand the (in)security of mobile IME apps, this paper first performs a systematic study and uncovers that many IME apps may (intentionally or unintentionally) leak users' sensitive data to the outside world (mainly due to the incentives of improving the user's experience). To thwart the threat of sensitive information leakage while retaining the benefits of an improved user experience, this paper then proposes I-BOX, an app-transparent oblivious sandbox that minimizes sensitive input leakage by confining untrusted IME apps to predefined security policies. Several key challenges have to be addressed due to the proprietary and closed-source nature of most IME apps and the fact that an IME app can arbitrarily store and transform user input before sending it out. By designing system-level transactional execution, I-BOX works seamlessly and transparently with IME apps. Specifically, I-BOX first checkpoints an IME app's state before the first keystroke of an input, monitors and analyzes the user's input, and rolls back the state to the checkpoint if it detects the potential danger that sensitive input may be leaked. A proof of concept I-BOX prototype has been built for Android and tested with a set of popular IME apps. Experimental results show that I-BOX is able to thwart the leakage of sensitive input for untrusted IME apps, while incurring very small runtime overhead and little impact on user experience.

1 Introduction

The Problem. With large touch screens, modern mobile devices typically feature software keyboards to allow users to enter text input. This is different compared to traditional desktops where we use the hardware keyboards. These soft keyboards are known as Input Method Editor (IME) apps, and they convert users' touch events to text. Since IME apps process almost all of a user's input in mobile devices, it is critical to ensure that they are not keyloggers and they do not leak any sensitive input to the outside world.

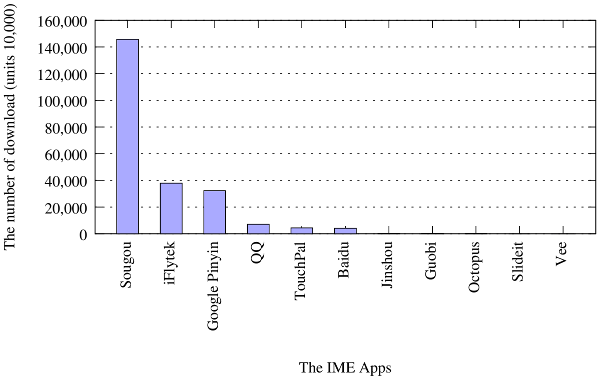

Figure 1: Download statistics of IME apps in our study.

While all mobile devices have a default IME app installed, users often demand third-party IME apps with expanded feature sets in order to gain a better user experience. This is especially common for non-Latin languages. In order to accommodate this need, mobile operating systems such as Android and iOS provide an extensible framework allowing alternate input methods. Due to the ease of making third-party IME apps and high demand for customization, there are currently thousands of IME apps in major App market like Google Play and Apple's App Store. Many of which have gained hundreds of millions downloads, as shown in Fig. 1. For instance, the Sogou IME apps has in total 1.6 billion downloads in Google Play and several third party app vendors such as 360, and Baidu. Meanwhile, a recent survey [13] found that 68.3% of smartphones in China are using third-party IME apps. This survey did not include statistics from Japan or Korea, where such apps are also very popular.

Unfortunately, despite these advantages, using a third-party IME app also brings security and privacy concerns (assume the default IME app does not have these problems). First, IME app developers have incentives to log and collect user input in order to improve the user's experience with their products, and user input is as valuable as email content, from which they can learn user's needs and push customized advertising or other business activities. Although an IME app may state a policy of not collecting certain input from a user, the policies implemented in the app may unintentionally send sensitive input outside the phone. In §2.3 we show that such a threat is real by observing the output of a popular IME app that periodically sends out user input to a remote server. In addition, we collected the network activities of a set of IME apps during a user input study and showed that they also likely send out private data. In light of this information leakage threat, the Japanese government's National Information Security Center has warned its central government ministries, agencies, research institutions and public universities to stop using IME apps offered by the search engine provider Baidu [1].

Even if a user trusts benign IME apps to properly secure private data, there is still a risk from repackaging attacks targeting benign apps. In fact, prior study has shown that around 86% of Android malware samples are repackaged from legitimate apps [49]. It is also surprisingly simple to repackage an IME app with a malicious payload, as we demonstrate in §2. Essentially, a repackaged malicious IME app is essentially a keylogger, which has been one of the most dangerous security threats for years [39]. Also, evidence has shown that IME apps are popular for attackers to inject malicious code [29].

Challenges. While it may seem trivial to detect these repackaged malicious IME apps by comparing a hash of the code with the corresponding vendor in the official market, the widespread existence of third-party markets makes such checks more difficult. It is also easy for attackers to plant repackaged malware into these markets, as is shown by the fact that a considerable amount of repackaged malware has been found in them [48].

Of further concern is the fact that it is very challenging to analyze whether even "benign" IME apps will leak any sensitive data or not. There are several reasons why detecting privacy leaks in IME apps is challenging. First, many commercial IME apps use excessive amounts of native code, which makes it very difficult to understand how they log and process user input. Second, many of the IME apps use unknown, proprietary protocols, which makes it especially hard to analyze how they collect and transform user input. Third, many of them utilize encryption, and their algorithms are also unknown. Therefore, we eventually must treat the IME apps as black boxes for current privacy-preserving techniques on mobile devices, and users must either trust them completely (and risk leaking their private data) or switch to the default IME app (and lose the improved user experience).

At a high level, it would seem that existing techniques such as taint tracking would be viable approaches to precisely tracking and containing sensitive input. For example, TaintDroid [16, 17] and its follow-up work have been shown to very effective to track sensitive input and detect when it is leaked. There will still be the following additional challenges to be overcome. First, current IME apps tend to use excessive native code in their core logic, and TaintDroid currently does not track tainted data in native code. Second, it is a well-known problem that data-flow based tracking for taint-tracking systems to capture control-based propagation. In fact, many of the keystrokes are generated through lookup tables, as reported in Panorama [46]. Third, sensitive information is often composed of a sequence of keystrokes, making it challenging to have a well-defined policy to differentiate between sensitive and non-sensitive keystrokes in TaintDroid. Therefore, we must look for new techniques.

Our approach. In this paper, we present I-BOX, an app-oblivious IME sandbox that prevents IME apps from leaking sensitive user input. In light of the opaque nature of third-party IME apps, the key idea of I-BOX is to make an IME app oblivious to sensitive input by running IME apps transactionally; I-BOX eliminates sensitive data from untrusted IME apps when there is sensitive input during this process. Specifically, I-BOX checkpoints the states of an IME app before an input transaction. It then analyzes the user's input data using a policy engine to detect whether sensitive input is flowing into an IME app. If so, I-BOX rolls back the IME app's states to the saved checkpoint, which essentially makes an IME app oblivious to what a user has entered. Otherwise, I-BOX commits the input transaction by discarding the checkpoint, which enables the IME app to leverage users' input to improve the user experience.

One key challenge faced when building I-BOX is how to make the checkpointing process efficient and consistent, which is unfortunately complicated by Android's design, especially its hybrid execution (of Java and C), multi-threading, and complex IPC mechanism (e.g., Binder). Fortunately, I-BOX addresses this challenge by leveraging the *event-driven* nature of an IME app. More specifically, we present a novel approach by creating the checkpoint at a *quiescent point*, in which its execution states are inactive. Such a design significantly simplifies many issues such as handling residual states in the local stack of native code, the Dalvik VM and IPCs.

We have implemented I-BOX based on Android 4.2.2 running on a Samsung Galaxy Nexus smartphone. Performance evaluations show that I-BOX can checkpoint and restore a set of third-party popular IME apps within a very tiny amount of time, and thus cause little impact on user experience. A security evaluation using a set of popular IME apps shows that I-BOX mitigates the leakage of sensitive input. Case studies using a popular "benign" IME app and a repackaged IME app confirm that I-BOX accurately conforms to the predefined security policies to prevent sending of sensitive input data.

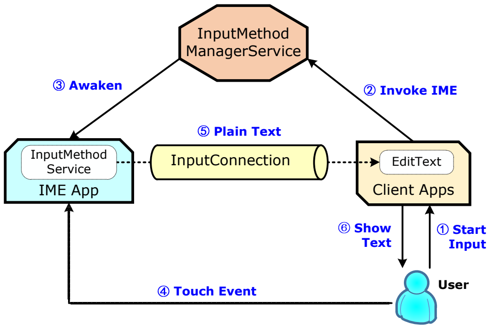

Figure 2: The workflow when using an IME app.

Contributions. In short, we make the following contributions:

- **New Problem**. This is the first attempt to systematically understand the threat caused by the leakage of private sensitive keystrokes in third-party IME apps. Our discovery shows the pervasive presence of such attacks, and the seriousness of the problem.

- **New Technique**. We introduce oblivious sandboxing for IME apps that embraces both security and usability and *quiescent points* based checkpoint/restore that significantly simplifies the design and implementation of I-Box.

- **New System**. We demonstrate a working prototype of the techniques and a set of evaluations confirming the security threat of commercial IME apps and the effectiveness of I-Box.

2 Background and Motivation

In this section, we first describe the necessary background on IME architecture in Android, and then discuss why commercial IME apps have the incentive to collect a user's data, followed by the case studies showing how IME apps can leak users' sensitive data to remote parties.

2.1 Input Method Editor

Though Android provides a default IME app for each language, many end users prefer using third-party IME apps for better user experiences, such as changing the screen layout for faster input, generating personalized phrases to provide intelligently associational input, and providing more accurate translation from keystrokes to the target languages. As a result, mobile operating systems such as Android provide an extensible IME infrastructure to allow third-party vendors to develop their own IME apps.

Figure 2 gives an overview of the involved IME components when entering text in a client app. Specifically, third-party IME apps must conform to the IME framework so that the Android Input Method Management Service (IMMS) can recognize and manage them. For example, every IME app contains a class that extends from `InputMethodService`, which helps Android recognize it as an input service and add it into the system as an IME app. When an end user clicks a textbox to invoke an IME app, Android IMMS will start the default IME activity and build an `InputConnection` between the IME app and the client app that helps the IME app to commit the user input to the client app. In particular, the IME app first gets the touch event containing the position data and translates it to meaningful characters or words based on its keyboard layout and internal logic. Then it sends the keystrokes to the client app through `InputConnection`.

The IME architecture is clean with well-defined classes. This not only significantly saves programmer's effort in developing a new IME app, but also makes it easy for attackers to locate key points of a victim IME app. For instance, our study found that simply hooking the function `BaseInputConnection.commitText` can intercept all the user's input in many IME apps. This can be done by simply searching for the keyword `BaseInputConnection.commitText` in the decompiled code to locate all of its occurrences.

2.2 Why IME Apps Collect Users' Input

Third-party IME apps usually extend the standard IME apps with lots of rich features to provide a better user experience. Such features usually require collecting users' input data to learn users' habits to allow personalizing IME apps. Further, such data may also collectively be used to improve experiences of other users, i.e., pushing phrases learned from a set of users to others. In fact, there are many features that require collecting user input data. The following lists a few of them:

- **Personal dictionary**. Commercial IME apps usually remember the words and phrases from user input to speed up follow-up input (especially for non-Latin languages) by prompting potential results when input is not finished. To achieve this, they need to maintain a personal dictionary for each user to save frequently typed or self-made words.

- **Cloud input**. As users usually have multiple devices and need to synchronize personal dictionary among them, IME apps utilize cloud-based services to store the dictionary and to synchronize the dictionary and personal settings between different devices.

  Meanwhile, some non-Latin languages such as those eastern languages differ from English in that IMEs need to translate users' keystrokes to words in those languages. To accelerate input speed, IMEs may usually need to leverage cloud services to analyze and predict users' intended words based on the current input.

In addition, for some latin-based languages, some IME apps provide a feature that leverages the current input to predict the intended phrases and adjust the layout of the soft keyboard to make the soft key of the next character close to users' current figure. To better predict user intent, some IME apps usually leverage the abundant resources in cloud to analyze and predict user input. Meanwhile, they also collect users' habits to improve the accuracy of prediction.

- **Search mediation**. Some IME apps have a new feature named "search mediation", which intercepts user input and returns some search result back to the user. However, this means that user inputs will be unrestrictedly sent to the search engine.

Note that due to the unstable network connectivity of mobile devices, almost all IME apps can work properly with and without network connections. When network is disconnected, an IME app may store current input (like frequently used phrases) for later use when the network connection is on. Besides, Android's configurable permission model indicates that an IME app usually works normally even without grants of certain permissions.

2.3 Possible Threats Posed by IME Apps

While third-party IME apps do offer useful features and better user experiences, they may unduly collect user data or be repackaged to be malicious. Next, we study the possible threats an IME app could impose.

Privacy leakage in "benign" IME apps. Conventional wisdom is to trust a respected service provider, in the hope that the provider will enforce policies in the cloud to faithfully provide user secrecy [30]. Unfortunately, this exposes users' sensitive keystrokes from two threats. First, a curious or malicious operator may stealthily steal such data [47, 41], which has been evidenced by numerous insider data theft incidents even from reputed companies [40]. Second, even reputed cloud providers provide no guarantee on the security of user data, which is evidenced by their user agreements. Hence, it is reasonable to not trust an IME app to securely protect users' data.

More specifically, a severe threat from "benign" IME apps is that they may have unduly collected user data without users' awareness. Given that we do not have their source code and they often use proprietary protocols with encryption, it thus remains opaque to end users how the IME apps really handle the sensitive input data. At a high level, since they have been collecting user data for better experiences (especially the personal dictionary and cloud input), it is highly likely that much of a user's sensitive input has been leaked to these IME providers.

To confirm our hypothesis, we conducted an experimental study by performing a man-in-the-middle attack on a popular IME app, namely TouchPal Keyboard (in version chubao 5.5.5.67049, cootek). This IME app provides multiple rich functionalities such as cloud input and a personal dictionary and has been installed more than 7.09 million times from a third-party market. By intercepting its network packages using Wireshark[1], we found that its cloud input is implemented using an HTTP POST command which carries several parameters in plain text. Therefore, we are able to see how it works without any protocol reverse engineering and packet decryption. A deep investigation revealed that these parameters include a `userid`, the `keycode` that a user just entered, and *the existing words* of the target input control that user is focusing on. This contradicts its privacy statement of "No collection of personal information that you type" in a prior statement[2], and thus poses a serious threat to user privacy.

We suspect there may be many other commercial IME apps that also leak users' sensitive input. Currently, we only used side-channel analysis [11] to analyze the packet size between the IME apps and their servers. We did notice there are notable differences in the number of packets (as reported in §5.2).

Privacy leakage in malicious IME apps. Even if all third-party IME apps did not leak any user's private data, there are still other attack vectors such as repackaging attacks. In fact, a prior study uncovers that repackaged malware samples account for 86% of all malware [49]. Moreover, there are also trojans that serve as key loggers but masquerade as IME apps [29]. Finally, IME apps may also be vulnerable to component-hijacking attacks. It has been shown that input methods have been a popular means to inject malicious code [29]. While currently we are not aware of any repackaged malicious IME apps in Android, we envision that there will be such malware given the large popularity of the official apps and the easiness of repackaging them as shown below.

To understand the repackaging threat of IME apps, we conducted an attack study by repackaging a popular commercial IME app called Baidu IME, which has been downloaded more than 100 million times in a third-party market. In this study, we repackage the IME app by inserting a malicious payload into the original program. The payload records all user input and sends them to a specific server.

While the core logic of the Baidu IME app is written

[1] http://www.wireshark.org/

[2] We noted that the newer versions of TouchPal changed their privacy statement indicating that they will collect user privacy data.

using C, the other components are written in Java which enables an easy reverse engineering of the bytecode especially with existing tools. Specifically, we used baksmali [2], a popular Dalvik disassembler to reverse `classes.dex` into an intermediate representation in the form of smali files. Then we directly modified smali code to insert our payload, which captures the text committed by the function `BaseInputConnection.commitText` and then sends the data out. A caveat in this study is that we found it would not work if we simply repackaged the app because the IME app has a checksum protection. However, the protection mechanism is rather simple, as it just calls a self-crash function when detecting repackaging. However, the self-crash function is not self-protected and thus we rewrote it to return directly to disable the protection.

We conducted our experiment in a contained environment and did not upload this repackaged IME app to any third-party Android market, but attackers can easily do this, as reported before [49, 48]. We installed this repackaged IME app on our test smartphone and all data we input through it was divulged. Our attack study shows all critical data that a user inputs will be compromised if the IME app is malicious. The popularity of third-party markets aggravates this problem, especially considering that 5% to 13% of apps are repackaged in a number of third-party markets [48].

3 Overview

The goal of I-BOX is to protect users' sensitive input, while still preserving the usability of (curious or malicious) IME apps such that users can still benefit from the rich features. One possible approach might be letting users switch to a trusted IME app when they want to type some sensitive information. While this may work for simple sensitive data like passwords, some users' sensitive input (like addresses and diseases) is scattered in a long conversation. It is cumbersome for users to constantly keep this in mind and do the switch. Another intuitive approach would be to block all network connections during user input, but doing so will negatively affect the user experience. Besides, there are also other channels like third-party content providers and external storages that an IME app may temporally store input data to be leaked later. Therefore, we have to look for new approaches.

Approach overview. As discussed, the key challenges of securely using third-party IME apps are that such apps are usually closed-source and they may do arbitrary processing and transformation of users' input data before sending it out. It is thus hard to model or predict their behavior. Hence, I-BOX instead treats an IME app as a black box and makes it *oblivious* to users' sensitive input data. To achieve this, I-BOX borrows the idea from execution transactions by running an IME app *transactionally*. Consequently, if an IME app touches users' sensitive input data, I-BOX will roll back the IME app's states to make it oblivious to what it has observed so as to address the problem where an IME app stores and transforms users' input data.

I-BOX regards the user input process as a transaction, which begins when a user starts to enter the input and ends when the input session ends. A clean snapshot of an IME app will be saved before an input transaction starts. For normal input transactions without touching sensitive input data, I-BOX will commit the IME app's state such that the IME app can use these data to improve the user experience. To prevent malicious IME apps from sending private data out during the input transaction, the network connection of the IME app will be restricted when the current transaction is marked as sensitive. When an input session ends and thus the client app has received all user input, I-BOX will abort the input transaction from the view of the IME app, by restoring the IME app's state to a most-recent checkpoint. This makes the IME app oblivious to the sensitive data it observed. Hence, even if the IME app locally saves a user's input to be sent later, the input data will be swiped during restoring.

As input data is provided in a streaming fashion by a user, there is no general way to know the input stream in advance. Because the IME app gets the input data prior to I-BOX, it would be too late to stop an IME app's leaking channels like network connection after it gets the whole input since it may have sent it out or store it locally. Hence, it is generally impossible for an approach not leaking any user input before I-BOX can determine if the current input stream is sensitive or not.

As a result, I-BOX chooses to use a combination of context-based and policy-driven approaches based on the state of the IME app, with the goal of striking a balance between user experience and privacy. For specific input such as passwords, which I-BOX can determine through input context, I-BOX can immediately know they are sensitive and thus constrains IME app's behavior (like blocking networking for the app). For general input, I-BOX uses a state-machine based policy engine to predict whether the current input transaction is sensitive. This is done continuously during the input process, where I-BOX uses the current partial input stream to determine if the next string is sensitive or not.

An architectural overview of I-BOX is presented in Figure 3. I-BOX consists of an isolated user-level policy engine that decides whether I-BOX shall commit or roll back the execution of an IME app's state. The sandbox module is implemented as a kernel module, which saves and restores the states of an IME app as needed.

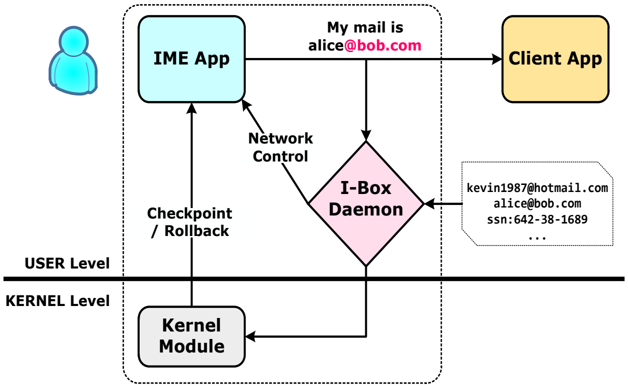

Figure 3: An Architectural Overview of I-BOX

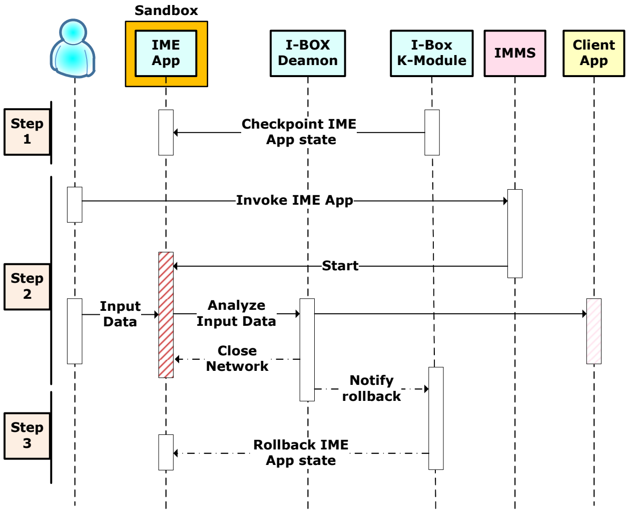

Figure 4: I-BOX work flow.

Challenges. To realize I-BOX, we are facing several challenges. In particular:

- **How to express and enforce security policies?** As users' privacy policies are usually vague, it is critical to efficiently represent users' policies such that there won't be a state explosion problem. This is especially challenging to handle for non-Latin languages as they usually require an additional layer of translation to represent them. Further, once the policies are represented, it should also be relatively easy to check the current input against the policies, which is critical to the latency of the checking.

- **How to efficiently perform the checkpoint and rollback?** As checkpoint and rollback are triggered during input, lengthy checkpoint and rollback may extend the latency of users' input. However, traditional checkpoint and rollback usually require either expensive copying of applications' states, or heavyweight recording of applications' execution. For example, prior checkpointing on server platforms takes around 600ms without copying files [28].

- **How to ensure consistency upon rollback?** By considering the user's input process as a transaction, I-BOX can ignore the implementation details of different IME apps and take them as normal processes from the kernel's viewpoint. However, there also intensive cross-layer and cross-component interactions between an IME app and the rest of the environment, like the Dalvik VM, the application framework and the client app. Further, the IME app is essentially multi-threaded. Hence, consistently checkpointing and rolling back an IME app's states while preserving the states of other components is another key technical challenge for I-BOX.

Threat model and assumptions. As third-party IME apps have the incentive to collect and send out users' data and some IME apps are even malicious (repackaged or even faked), I-BOX considers all third-party IME apps as untrusted. However, I-BOX trusts the underlying smartphone OS, including the OS kernel, system services and any process with root or system privileges. Also, we assume the user's smartphone has not been rooted such that the untrusted IME app cannot break the default security isolation between different apps, especially for system and user-level apps.

I-BOX relies on input contexts and a user's policy to distinguish private data from normal input data. It is possible that I-BOX may leak sensitive user input if the policy is incomplete or inaccurate, or the user's intent has changed after specifying the policy. Further, depending on the state machine, I-BOX may leak a prefix of some sensitive input.

I-BOX also trusts the end user and rely on her as a witness to prevent a malicious IME app from tampering with the user's input during typing. This should be easy as she can tell the difference between what she typed and what she observed from the input screen.

We consider the client app that uses the services from an IME app as trusted. While a rogue or malicious client app may also steal users' sensitive input, a malicious IME app causes more security impact than a malicious client app as it leaks all user input to all client apps (including system apps) in contrast to only input to a specific (third-party) client app. How to protect third-party client apps is out of the scope of this work and many prior efforts have intensively studied solutions to prevent information leakage from apps [24, 51, 34].

4 Design and Implementation

The work flow of how I-Box works is illustrated in Figure 4. Specifically, I-Box intercepts a user's input data by placing hooks into Android Input Method Service (IMS) and detects the sensitive data from the input stream based on the policy engine. I-Box uses both context-based and prefix-matching policies (§4.1) and enforces them using transactional execution (§4.2) to protect sensitive data such as passwords. Before diving into the details how we design and implement I-Box, we first use a running example to illustrate how it really works.

A running example. Assuming a sensitive string "IsUsenixSec2015" is being typed by a user through an IME app, I-Box first makes a checkpoint of the IME app as a clean snapshot before input. If this string is being typed to a password textbox (*context-based policy*), I-Box immediately knows that the string to type is sensitive and will restrict the IME app's behavior (such as stopping network connections). Otherwise, I-Box intercepts the characters and runs the analysis through the policy engine. After getting the characters 'I', 's', 'U', and 's', I-Box predicts that the user may be typing the sensitive string "IsUsenixSec2015" and I-Box restricts the IME app's behavior immediately to prevent it from sending further keystrokes out (*prefix-matching policy*). Afterwards, the IME app continues to accept input from users' typing and I-Box monitors the file operations of the IME app to record the files that may log the input data. After the user finishes typing, I-Box confirms that a sensitive string was typed into the IME app and restores the states of the IME app with the checkpoint to clean the sensitive string out.

4.1 Policy Engine

The policy engine of I-Box separates sensitive input from normal input such that different policies can be applied to different types of data. I-Box uses both context-based and prefix matching strategies to derive policies, with the first strategy having higher priority.

Context-based policy. We first provide an automated approach to deriving which input would be sensitive based on the type of the input and execution context of an app. Specifically, Android uses text fields to help the user type text into client apps. Text fields can have different input types, such as numbers, dates, passwords, or email addresses. In fact, the type information of text fields in the client app has been used to help an IME app to optimize its layout for frequently used characters. I-Box also leverages the type information of the text fields to decide whether the input is sensitive or not, and passwords and email addresses are by default sensitive. In addition, based on the user defined per-client app policy (e.g., an IME app is providing services to a banking application), I-Box will automatically treat all the input consumed by a sensitive app according to context [44] as sensitive.

Prefix-matching policy. For general input streams, I-Box leverages prefix matching to distinguish which input stream is sensitive or not. One challenge for defining policies for I-Box is that IME apps may need to handle multiple languages, including both Latin languages and non-Latin languages. For non-Latin languages, I-Box can only get the text in the target languages after an IME app has translated the keystrokes for the corresponding text. Hence, it is not viable to simply use keystrokes to represent the current input. To address this problem, I-Box instead uses the UTF-8 (8-bit Unicode Transformation Format) of the translated keystrokes to represent current keystrokes as well as those in the policy engine.

As there may eventually be multiple data instances that should be considered as sensitive, I-Box uses a trie-like structure to maintain which data should be considered as sensitive. A trie-like structure is very space-efficient for data with a common prefix and is very efficient for look-up. I-Box maintains a global trie structure to represent the global policy. I-Box may also provide an application-specific trie structure if an end user demands more strict policy. During a query, I-Box queries the global and application-specific trie structures in parallel but prefers application-specific policies over the global one.

While much of the sensitive data like contacts and cookies can be automatically translated to the trie structure as the default policies, I-Box also allows end users to use regular-expressions when they manually specify the policy. For example, user may define "abc*" to indicate any word starting with "abc" as sensitive input. Associated with the regular expression, there is also an *acceptable disclosure rate* (ADR), which defines how many characters can be exposed in an input stream. The larger the ADR, the more information may be leaked but the more chances are allowed for cloud assistance. Using regular expression is easy for experienced users to specify sensitive input, as it does not require them to fully remember all such sensitive data and thus matches users' ambiguous and incomplete memory. This also avoids asking users to input full secrets to I-Box. Alternatively, average users may also specify full secret names (i.e., a special case of regular expression) to I-Box.

I-Box provides a simple script to add such regular-expressions to the trie-like structure and report any conflicts if they occur. For example, for a sensitive string of 15 characters (such as 'IsUsenixSec2015') and an ADR of 0.2, I-Box will restrict an IME app's behavior when the first three characters ('IsU') are typed. I-BOX runs the trie-structure as a state machine to predict the input stream by matching the typed characters with the trie structures. Since any substring in the input data may be sensitive, I-BOX needs to check all of them. To speed up this process, I-BOX searches all possible substrings when a new character is typed. Intermediate states are maintained so that only new characters need to be handled instead of new substrings constructed by the character.

Note that currently I-BOX directly searches over the plain text of the policy file and relies on the Android permission system to protect it for simplicity. This can be further enhanced by encrypting the policy file and using regular expressions to search over the encrypted file, which was shown to have small runtime and space overhead [36].

Prefix-substitution attacks. At first glance, the prefix-matching policy used by I-BOX would appear to be vulnerable to a prefix-substitution attack by a malicious IME App. Specifically, a malicious IME app might first replace the prefix of a typed string with a non-sensitive one so that I-BOX wouldn't recognize this prefix and thus no oblivious sandbox would be applied for this input session. Fortunately, we note that users, the ultimate *witness*, would immediately notice this by observing the difference between what they typed and what was displayed on the screen.

Note that as I-BOX monitors all keystrokes sent from IME apps to user apps, I-BOX will adjust the state machine accordingly for any cursor movement and special characters like deletion. This can detect the case where a malicious IME app stealthily moves the cursor to deceive I-BOX on the input sensitivity.

Overall, I-BOX requires users' awareness of what she types from what she observes to detect malicious behavior from an IME app. If a user does not pay enough attention to the input process, a malicious IME app may still have the chance to fool I-BOX about the sensitivity of the input streams.

4.2 Enabling Transactional Execution

To enable transactional execution of an IME app, I-BOX needs to provide a checkpoint and rollback mechanism. The key challenges here lie in how to provide *low-latency* and ensure *consistency*, which are made especially difficult by Android's unique design. For example, Android uses a Dalvik virtual machine (VM) to run the Java code of the IME app, which interacts intensively with the application framework. Further, the native code of an IME app also interacts with the Dalvik VM through the Java Native Interface (JNI). Finally, Android intensively uses Binder, a complex IPC mechanism for communication among isolated apps. Such hybrid execution and complex communication make it hard to efficiently and consistently checkpoint the states of an IME app.

I-BOX addresses the above challenges by leveraging a set of *quiescent points*. A quiescent point is a point such that all threads of an application have stopped execution and there are no pending states and requests to be processed. Doing checkpointing at quiescent points frees I-BOX from handling a number of subtle states like residual states in stack or other communication peers. Further, it also requires less states to be checkpointed. Finally, when I-BOX rolls back the states of an IME app, the states can be restored consistently without having to deal with some subtle residual states in other apps.

In the following, we describe in greater detail how we choose the quiescent points (§4.2.1), how I-BOX performs the checkpoint and restore of the local states of an IME app (§4.2.2), and how I-BOX handles interactions of an IME app with others through IPCs (§4.2.3).

4.2.1 Quiescent Points

Our key observation is that an IME app is essentially an event-driven app that provides services to the client app. Consequently, it shall be usually in a quiescent point when a user is not typing, as no event will be delivered to the IME app at that time. At this state, the IME app's states are stable and consistent. Thus, I-BOX can be relaxed from handling a lot of complex and subtle local states. To achieve this, I-BOX first checks if an IME app is in a quiescent point by checking the process and thread states (sleeping or not) and the IPC states. The checking result is very likely to be true for most cases. Even if the IME app refuses to cooperate with I-BOX and keeps itself busy, I-BOX can first wait a short time and then enforce a quiescent point by blocking new requests and then forcing the IME app to sleep to do the checkpoint. Here, a non-cooperative IME app could also be a sign of being malicious. However, we never encountered this case as the IME apps we tested always conform to Android IME architecture. Even if so, I-BOX may always roll back the IME app to a clean state checkpointed early.

4.2.2 Checkpointing and Restoring Local States

Since data typed by a user can be stored into any place of the IME app in any form, it requires that all process states restore in order to wipe out any sensitive data. The traditional way of doing checkpoints is copying all related process states into storages, which is very heavyweight and would incur long latency. As the main purpose of I-BOX's checkpoint is to either rollback or discard later, I-BOX chooses a lightweight approach to checkpointing, which creates a shadow process and then tracks all later changes by using copy-on-write (COW) features provided by Linux.

Saving and restoring file states. As typical IME apps usually only modify a small amount of files during one input transaction, I-BOX currently records and copies such files during checkpointing and restores them during rollback for simplicity. Another option is using a COW file system like Btrfs or ext3cow to avoid copying. This requires replacing Android's file system with one with a COW feature, which will be our future work.

Android provides several options to save persistent application data. Based on the position where the data is stored, we can divide these options into two categories: internal and external storage. Every Android app will be assigned with a private directory in the internal storage to store files and data. By default, data saved to the internal storage are private to an app and other apps cannot access them (nor can the user). I-BOX just copies all files in the IME app's private directory and then restores the files modified during the input transaction upon rollback. Since there are usually only a small number of files in the internal storage for an IME app and the modified ones are even less, the time cost is negligible.

For external storage, any Android apps with proper permissions (e.g., `android.permission.WRITE_EXTERNAL_STORAGE`) can access the whole external storage. It would be very lengthy if I-BOX scanned the whole external storage to find the modified files. Hence, I-BOX records all the files modified by the IME app during the input transaction and then restores them as needed. Specifically, once I-BOX detects the IME app tries to write some data into a file, it duplicates the file for subsequent restoring.

Note that as the checkpointed files are created by I-BOX, which runs as a system process, the files are with system privilege and thus cannot be read/written by the IME app itself. This ensures that an IME app cannot first save sensitive key logs into such files and later read them out. Actually, I-BOX also removes the checkpointed files after rolling back an IME app.

Saving and restoring memory states. Memory states include the IME app process's data in memory and process-related metadata maintained by the OS kernel (i.e., Linux). Linux uses a lot of data structures to manage a process and maintain its state, such as `task_struct`, `thread_info` and others. I-BOX relies on a kernel module to save and restore such data structures. Specifically, this module maintains a shadow process in the kernel to store the data of each running IME app. The shadow process duplicates the process states of the original IME app by copying the metadata of the IME app into its own `task_struct` but with some modifications for consistency. For example, it has its own kernel stack and redirects the stack pointer in the `task_struct` to its own one, although the content on the stack is the same as in the original IME app. For independent states like process ID or kernel stack, I-BOX just copies the data into a buffer and writes them back later. As for other states connected with other processes or other events like a pipe or waitqueue, I-BOX needs to record the states and the relationships so that it can recover it correctly later. Besides this, I-BOX also needs to save the process memory. Instead of really copying the memory pages, I-BOX simply creates a shadow page table that shares the memory with the target IME app process and marks the page table of the target process as COW. This omits lots of unnecessary page copying since most pages will not be modified during the input transaction and it just needs to switch the page table root to restore the memory, which is very fast. This helps reduce the stop-time of each IME app process when I-BOX tries to do checkpoint and restore.

Multi-thread rollback. Most Android applications run in the Dalvik virtual machine and have multiple threads for different purposes. Besides the main thread for UI and the core logic of the IME app, there are about another 10 threads for garbage collection, event handling, Binder IPC, and so on. To roll back the process states of an IME app correctly, I-BOX needs to deal with such threads properly. Linux assigns `task_struct` to a thread just like a process to maintain its state and groups all threads belonging to one process together through a list. So I-BOX saves each thread with a separated shadow process and groups these processes together through a list to maintain their parent-child relationships just like the original one. The sharing resources between threads will be duplicated too. For example, I-BOX will save the pipe states between two threads and restore it later.

4.2.3 Handling IPCs

One major challenge I-BOX faces in checkpoint and rollback is how to deal with the IPC states of an IME app process. An IPC involves multiple processes or even multiple machines, but I-BOX can only control one end in the communication. One potential problem is that the other side of an IPC may wait for a reply that will never be sent, since the IME app process has forgotten this request after rollback. Another serious problem is that the client app may communicate with an inactive IPC that has been erased from the IME app process due to rollback.

As a result, I-BOX needs to find proper timing to do checkpoint and rollback such that the consistency of an IPC is not violated. Proper timing requires several conditions. First, there should not be any data in transmission between two processes; otherwise it will lead to a corrupted request with incorrect semantics. Second, there should be no pending IPC requests. This means an IME app shall wait for all replies before doing checkpoint and ensure that no request is pending to the process before rollback. Fortunately, it is not hard for I-BOX to find suitable timing because I-BOX only does checkpoint and rollback when a user does not input. In most cases, the IME app processes should be sleeping at that point. If not, we can safely enforce it without disturbing other client apps since the user is not typing.

Inter-threads IPC. Linux provides a set of IPC mechanisms such as pipe, socket, and shared memory. Android inherits such mechanisms but only uses them as a method for communication between threads within a single process. Hence, I-BOX can control both ends of these inter-threads IPC, which avoids the inconsistency issues due to unilateral actions. For example, the two communicating parties of a pipe in a single process have a pair of pipe `fd`; the OS kernel allocates a buffer for them to pass the message. To restore the pipe correctly, I-BOX just keeps a record of current pipe status and its buffered data, then restores it as needed. There is no restriction on the timing for checkpoint and rollback. Other IPCs within the same process are done similarly to this.

Android Binder. Android heavily uses its own IPC mechanism: *Binder*, which helps the Android permission system to provide access control to Android services and resources. By mapping kernel memory into user space, Binder IPC only requires one data copy for one transmission, i.e., from the sender's user space to the kernel buffer of the Binder driver. Then the receiver can directly read the data from its read-only user space mapping, which is more performance-friendly. There are two issues I-BOX needs to take care for a consistent restore of the Binder. More specifically:

- **Reference counting for Binder proxies**. An Android app uses Binder proxies (e.g., BBinder, BpBinder) as the reference to remote processes instead of simple file descriptors. The Binder driver in the kernel needs to manage the reference counter for such proxies so that it can know whether a binder instance is useless or not. I-BOX needs to track and record modifications to references to Binder proxies so that it can keep the consistency of the reference counters.
- **Conversation between the Binder request and response**. I-BOX also needs to keep the conversation between the Binder transaction request and response. As an Android service provider, an IME app process will accept a Binder transaction request from the client app and it will send back the transaction response after disposing the request. To achieve this, I-BOX tracks the transaction request and response to find a right timing when all requests have been handled. It is not hard to find such a point because usually I-BOX tries to do checkpoint or rollback when IME is idle without new requests.

Content Provider. An IME app may also interact with both third-party and system content providers. For example, our analysis with TouchPal IME app reveals that this app accesses third-party content providers like `content://com.tencent.mm.sdk.plugin.provider/sharedpref` and `content://com.facebook.katana.provider.AttributionIdProvider`; our analysis with Guobi IME app shows that this app accesses `content://com.iflytek.speechcloud.providers.LocalResourceProvider` and `content://com.tencent.mm.sdk.plugin.provider/sharedpref`. TouchPal accesses the system content provider like `content://sms/inbox` and both TouchPal and Guobi access `content://telephony/carriers/preferapn`. In Android, all requests to content providers are issued through the Binder mechanism, we rely on the Binder mechanism to detect a quiescent point. Fortunately, we note that accesses to content providers are request-oriented and thus connection-less. Thus, there is no request on-the-fly and thus I-BOX can checkpoint such states accordingly.

Network. Different from Binder, the network driver does not expose any semantic information to an upper layer's connections. Hence, it seems hard to maintain the consistency of request and response between an IME app process and its cloud-based server. Fortunately, there are two observations that help relax the strict consistency requirement. First, network connections between an IME app and the cloud-based server, like fetching the words by sending the keystrokes, synchronizing the user's library, and downloading news or advertisements, are usually stateless and non-transactional; a redo operation does not cause any consistency issues. Second, network connections during input transactions are mostly short-time synchronized requests that are finished when input is done; hence they will not be affected by rollback.

Lessons Learned. While it is generally hard to checkpoint a complex app like an IME app, the event-driven nature of I-BOX greatly helps simplify the design and implementation of I-BOX. By leveraging a quiescence-point based approach and conduct checkpointing at the time at which an IME app likely to be quiescent (e.g., before an input session start), I-BOX enjoys both less implementation complexity and runtime overhead.

4.3 Restricting IME Apps' Behavior

When I-BOX detects a sensitive input session, it needs to restrict an IME app's behavior such that no sensitive data should be leaked during this process. A malicious IME app may leverage various means to store and transform the data during this process. For example, it may directly send input data to the network, or store the input data to a content provider to be restored and sent out later. To this end, I-BOX needs to restrict an IME app's behavior to stop such channels for a sensitive input stream.

I-BOX constrains an IME app from using network and accesses to content provider and services during a sensitive input session. Specifically, during a sensitive input session, I-BOX only grants an IME app with read accesses (like query) to such content providers and services. This is done by interposing the *binder_transaction* and acts according to the access types from the transaction code (i.e., query, insert, update or delete).

One potential issue would be that the IME app may not function correctly without such accesses. Fortunately, most Android apps (including IME apps) are designed to work gracefully with different permissions, due to the fact that the user may grant different permissions and an IME app may work without network accesses. As a result, it is non-intrusive to dynamically deprive the IME app from certain accesses as evidenced by prior research on dynamic permissions on Android [32]. After a rollback, as all residual states inside an IME app have been cleaned, any pending actions like insertion or deletion will not cleared as if they never happen. Thus, there won't be any confusions to the content provider and services.

5 EVALUATION

We have implemented I-BOX based on Android 4.2.2 and Linux kernel OMAP 3.0.72. It consists of two main parts: i) a user-level modification of the Android application framework to insert the I-BOX policy engine and network control module; ii) a kernel module to handle checkpoints and rollback of IME apps.

Experimental Setup. All of our experiments were performed on a Samsung Galaxy Nexus smartphone with a 1.2 GHz TI OMAP4460 CPU, a 1GB memory and 16GB internal storage. We evaluate I-BOX using 11 popular IME apps to measure the performance overhead of I-BOX. The 11 IME apps (as shown in the first column of Table 1) are ranked among the highest in popularity in a large third-party market[3]. Many of these IME apps have been installed more than millions of times (Figure 1). In our testing, we set the security policies to include all contacts in the phone and all commonly used accounts and passwords. This forms a trie containing around 400 words.

5.1 Performance Evaluation

The time overhead of I-BOX comes from three parts: (1) time to find the quiescent points; (2) time to perform memory checkpoint and rollback, and (3) time to perform file save and restore. To measure the performance overhead, we asked a volunteer with an average typing speed of about 100 characters per minute to enter a 10 word paragraph in an SMS app using the tested IME apps. We did not use an automation tool like an Android Monkey as it cannot handle the complex UI interface of these IME apps.

Latency. As shown in Table 1, the time to find a quiescent point is very small (less than 14ms). This confirms our observation that it is very easy and fast to find or force a quiescent point to do checkpoint and rollback on an IME app. The time of saving and restoring an IME app's memory state is also very small (less than 29ms) since I-BOX does not really copy the whole memory but just mark them as COW. Based on the files touched by the IME app process during the typing, I-BOX needs to restore a few files to prevent the IME app from concealing the secret inside files. Hence, the time for file save and restore is a little bit lengthy (60 ms), which can further be improved by using a copy-on-write file system. In total, the maximum total time to do a checkpoint (including finding a quiescent point) is less than 103ms (14ms + 29ms + 60ms). In contrast, the world record of texting is typing a complicated 25 word message (159 characters) in 25.94 seconds [5], which corresponding to 163 ms/character and 1.0376 second/word. Hence, the time to do checkpointing is very small compared to user typing. As the time to search the trie is negligible, we didn't report it here.

Power. To measure the power overhead incurred by I-BOX, we used the TouchPal IME to input an article and its non-Latin translation to a text-note app called Catch and count its power status. The total input process spans 30 minutes for both unmodified Android and I-BOX-capable Android. We found that in both cases the power dropped from 100% to 99%, whose differences were indistinguishable. This is probably because the IME app is not power-hungry and the additional power consumed by I-BOX was evened by the reduced network transmissions, which is thus hard to be distinguished without a highly accurate power meter. In our future, we plan to further characterize the power consumption using an accurate power meter.

5.2 Security Evaluation

Here, we evaluate whether I-BOX indeed has mitigated the leakage of a user's sensitive keystrokes. We still use the IME apps in our performance testing, along with a

repackaged malicious IME app (described in §2.3), to evaluate its effectiveness. According to the accessibility of these IME apps, we conducted three sets of experiments to determine effectiveness: black-box testing, gray-box testing, and white-box testing.

5.2.1 *Black-box Testing*

Since most of the IME apps use proprietary unknown protocols with unknown encryptions, we cannot directly trace the network packets to confirm our effectiveness. Therefore, we take a black-box approach to approximating our result. That is, instead of inspecting the packet contents, we inspect the packet differences sent by the IME-apps with I-BOX and without I-BOX, within an identical experiment setup and time window.

In particular, we ran all these apps using a two-minute time window, and we typed around 30 non-Latin words with "aa@usenix.org" as the sensitive word and then observed the packet differences using the Wireshark tool. Usually, these IME apps will send some packages out when a user types something that triggers the cloud input function. Interestingly, we found 6 out of the 11 tested apps have a different number of packages, as shown in Table 2. With I-BOX being enabled, there are less packages to be sent out compared to normal ones. This is because I-BOX controls the network of the target IME app when it detects sensitive input data and prevents the target IME app from leaking the data out.

While such side-channel based black-box testing cannot fully confirm that we have prevented all leaks, we believe it is highly likely that I-BOX has stopped them, even for the other 5 apps that we did not observe package differences for. (It is highly likely that these IME apps have buffered the input with the intent to send the data out later. However, our oblivious sandboxing mechanism will clear the buffered sensitive data).

Figure 5: Hexdump of the traced Touchpal package. The leaked SSN is highlighted.

5.2.2 *Gray-box Testing*

Among these 11 IME apps, we are able to observe the packet payload of TouchPal (as in discussed in §2.3) because it uses a plain-text protocol. Therefore, we conducted gray-box testing to confirm I-BOX indeed mitigated the privacy leakage. In this experiment, we open a client "SMS" app to send a short message to one friend with a social security number (SSN), which is private and sensitive by default. The text to send is a mixture of both Latin and non-Latin languages, as well as the number. Cloud input functionality will be triggered in this case.

Interestingly, without I-BOX's protection, we found that Touchpal uploaded not only the keycodes the user typed as arguments of cloud input, but also the text message before the current input cursor that includes the sensitive social security number to the cloud through an HTTP POST method. We intercepted this packet using a man-in-the-middle attack. Part of the packet is displayed in Figure 5. However, with I-BOX's protection, we found that I-BOX successfully detected the critical number and shutdown its network to stop the leakage of data, and we did not observe any network trace.

We also studied the privacy warnings generated by Android on which data an IME may collect. Figure 6 shows that Android generates privacy warnings for two popular IME apps, Sogou and TouchPal, indicating that they may collect users' passwords, credit card number, etc. This further confirms our conclusion that they collect users' privacy data.

Apps	Without I-BOX	With I-BOX
SMS (phone number)	`6204562244`	`62045`
SMS (message)	`Let’s meet tomorrow noon at room 302`	`Let’s meet tomorrow noon at room 302`
Instagram (account)	`thisisfortest@gmail.com`	`thisisf`
Instagram (password)	`fakepassword`	
Facebook (account)	`thisisfortest@gmail.com`	`thisisf`
Facebook (password)	`dontbelieveit`

5.2.3 *White-box Testing*

As discussed in §2.3, we repackaged a very popular Baidu IME app to log all of the user input data and send them out to a malicious server we controlled. Hence, this repackaged IME app is essentially a keylogger. We were able to perform white-box testing by inspecting the packet payloads and confirming them with the source code of our malicious payload. We installed this IME app on our test phone and then used this phone to enter some user-defined private sensitive data with different client apps ranging from SMS, Facebook, and Gmail, etc. Table 3 shows the data we collected at the server side with and without I-BOX’s protection.

From this table we can clearly observe that without I-BOX, the malicious IME app will steal all the data that a user enters. Consequently, all sensitive data has been leaked out; with I-BOX, it automatically blocks the network connection so that the server cannot receive any complete sensitive information. For instance, for passwords, the malicious server cannot receive anything as shown in the Instagram and Facebook case. As I-BOX shuts down the malicious IME app’s network when it finds character sequences that have matched part of the sensitive phrase in our security policy, the server side can only receive the parts of the typed characters. For example, when a user tries to type her Facebook account *thisisfortest@gmail.com*, the server side can only receive a part of it, i.e. *thisisf*[4]. While partial sensitive input is still being leaked, we believe it is still hard for attackers to guess the original message.

5.3 Users Experience

One principal goal of I-BOX is to limit the negative influence on an end user’s experience as little as possible. To evaluate this, we tested latency by determining how an end user would feel when typing characters on devices protected by I-BOX. For this, we invited a dozen students (6 undergraduate and 6 master students) in our Lab to install I-BOX on their phones, and asked them to use our system and provide us with feedback. By default, I-BOX uses the context-based policy and derives all sensitive data from the contacts and cookies. Two of them also tried to input their girl-friend’s names and birth dates into I-BOX.

To our pleasure, none of the users complained of any latency imposed by our system. As shown in Table 4, there is only 0.4 milliseconds (ms) overhead per character imposed by our policy checking. While network shutdown takes about 180 ms, it is not executed per word and is instead triggered only when certain sensitive words are going to be formed. Therefore, the additional overhead added by I-BOX cannot be detected by end users. This is because the typing speed for a normal user is 625ms per character, and the world fast record is 160 ms per character, as shown in Table 4.

One complaint we received so far is that the users now need to manually type their account instead of using the automation features provided by the IME apps. We believe this is worthwhile for better privacy protection. Another complaint is that they need to specify their additional secrets manually; this will motivate us to design better UI interface in our future work.

[4] Note that we regard the sequence after @ as one character because an attacker can guess the rest by the first character most of the time.

Policy Checking	0.4ms/char
Network Shutdown	180ms
Checkpoint/Restore	103ms
Guinness World Records of fastest texter	160ms/char
normal user speed	625ms/char

Table 4: Statistics regarding the usage latency of I-BOX.

6 DISCUSSIONS AND LIMITATIONS

While I-BOX has made a first step to mitigate keystroke leakage against untrusted IME apps, there are still a number of limitations in its design and implementation.

Side-channel attacks It has been viable to use side channels to infer some keystroke information [9, 4]. I-BOX currently cannot prevent such side channel attacks. However, such threats are usually less severe than those of malicious IME apps, which can accurately observe all user input. We leave it as our future work to address issues related to the side-channel leakages.

Colluding malware As I-BOX currently only runs an IME app inside in a sandbox transactionally, it is still possible that an IME app could collude with another malware to leak information (i.e., the colluding attack [8]). For example, an IME app could first save the user input in a local file, and inform a colluding malware to read the file when the transaction has not been rolled back and then divulge the input. This essentially violates the policies of I-BOX. However, it is challenging for sandboxing to reliably prevent this, as studied by TxBox [25].

Security of I-BOX Any new security tools may bring new security implications as they usually touch security-sensitive data and I-BOX is of no exception. As I-BOX can essentially touch all users' sensitive data, it is essentially a key logger as well. Yet, I-BOX is much simpler than close-sourced proprietary IME apps (1,700 LOCs vs. hundreds of thousands LOCs). Regarding whether to trust I-BOX or other IME apps, third-party agents need to only audit the code of I-BOX instead of using gray-box based approaches to auditing the behavior of dozens of third-party IME apps. Meanwhile, I-BOX is completely a local service and will not send any private data out of the phone.

Permission Attacks As I-BOX's security is based on Android permission systems, it cannot defend against attacks against the permissions like component hijacking attacks and confused deputy attacks [23]. We consider this out of the scope of this paper; actually there have been a number of prior systems that statically and dynamically detect and prevent such attacks (e.g., [12, 43]). Actually, Android has significantly improved its permission systems since version 4.2 [3].

Voice input Currently we limit input data protection to handwriting input and keystroke input and do not consider voice input as it does not have keystrokes. Yet, users usually use dedicated system services like Apple Siri, Google Now and Microsoft voice recognition. How to handle voice input and preserve its privacy is very challenging and will be our future work.

Beyond Mobile IME Apps Note that the approach of I-BOX does not necessarily only apply to mobile platforms; Similar techniques can also be applied to desktops, which suffer from a similar dilemma between privacy and usability. We may provide a similar oblivious sandbox for each IME app, which should be straightforward as Android actually runs atop Linux. We leave this as our future work. Besides, other applications that requires a tradeoff between privacy and usability may use execution transaction like I-BOX.

7 RELATED WORK

Privacy leakage detection in mobile devices. Recently, there have been significant efforts on the detection of privacy leakage in mobile devices. Early attempts include TaintDroid [16, 17] and PiOS [15], and recent efforts include such as Woodpecker [22], AndroidLeaks [20], ContentScope [50], and Appprofiler [35]. In particular, TaintDroid [16] uses dynamic taint analysis to track whether sensitive information (e.g., address book) can be leaked through the network. PiOS [15] uses static analysis and focuses on the privacy leakage in iOS apps. Woodpecker [22] leverages an inter-procedural data-flow analysis to inspect whether an untrusted app can obtain unauthorized access to sensitive data. ContentScope [50] detects passive content leak vulnerabilities, by which in-app sensitive data can be leaked.

AndroidLeaks [20] instead uses static analysis to detect data leakage in Android apps. Chan et al. [10] further leverages mobile forensics to correlate user actions with privacy leakages. Appprofiler [35] creates a mapping between high-level API calls and low-level privacy-related behavior, which is then used to provide a high-level profile of App's privacy behavior. Besides, there have also been interests in detecting privacy leakage due to mobile ads [38]. In contrast, I-BOX focuses on preventing leakage of sensitive keystrokes.

Privacy leakage prevention in mobile devices. Other than detecting privacy leakage, there are also a number of systems that prevent private data from being leaked. By extending TaintDroid [16], AppFence [24] prevents applications from accessing sensitive information using data shadowing, and it also blocks outgoing communications tainted by sensitive data. While I-BOX and AppFence both block network communications when sensitive data is to be leaked, there are substantial differences: AppFence uses shadowing to provide an illusion to the app such that it can continue performing its taint tracking, whereas I-BOX does not use any illusion nor any instruction-level taint tracking, due to the pervasive existence of native code. Meanwhile, AppFence does not encounter the challenges we faced such as consistent rollback, and it only simply blocks the network communication, whereas I-BOX still has to keep the connection and allow other data to be transferred.

TISSA [51] tames information stealing apps to stop possible privacy leakage. SpanDex [14] further uses symbolic execution to quantify and limit the implicit flows through a sandbox, to prevent an untrusted application from leaking passwords. Through automatic repackaging of Android apps, Aurasium [43] attaches sandboxing and policy enforcement atop existing apps, to stop malicious behaviors such as attempts to retrieve users' sensitive information. Unlike Aurasium that adds a sandbox to an app, πBox [30] shifts the sandboxing protection of private data from the app level to the system level, and offers a platform for privacy-preserving apps. However πBox trusts a few app vendors to protect users' privacy data, while I-BOX treats the vendor of IME apps as untrusted, due to their incentives to collect users' input. TinMan [42] instead completely offload passwords-like secret to a remote cloud, but only handles a class of special secrets that are not necessary to be displayed in mobile devices. ScreenPass [31] leverages a trusted software keyboard to input and tag passwords and uses taint tracking to ensure that a password is only used within a specific domain. In contrast, while I-BOX also uses a trusted software keyboard for password input, it focuses more on preventing a malicious IME from leaking sensitive data (not only passwords).

Checkpoint and restore. I-BOX employs a checkpoint and restore mechanism to prevent privacy leakage. Such a mechanism has been built for transactional memory [6], execution transactions [37], as well as whole-system transactions [33]. Retro [26] leverages selective re-execution for intrusion recovery. Storage Capsules [7] also use checkpoint and restore to wipe off residual data after an application has viewed data in a desktop. I-BOX is an instance of a system transaction but designed specially for untrusted IME apps.

Sandboxing. There have been a large number of efforts in building sandboxes to execute untrusted programs, web applications, and native code. These tools were built using a variety of approaches such as kernel-based systems [19], user-level approaches [27], system call interpositions [21], or binary code translation [18], and recompilation [45].

A sandbox that also contains transactions is the TxBox [25], a tool built atop TxOS [33] for speculative execution and automatic recovery. While I-BOX and TxBox share the similarity of using transactions to build a sandbox, there are still significant differences: the goal of TxBox is to confine the execution of native x86 programs atop Linux kernel, whereas I-BOX is to confine the IME apps atop Android OS. Consequently, I-BOX faces additional challenges including resolving IPC bindings. Further, using quiescent points in I-BOX significantly simplifies the design and implementation.

8 CONCLUSION

This paper made a first systematic study on the (in)security of third-party (trusted or untrusted) IME apps, and revealed that these apps tend to leak users' sensitive input (due to their incentives of improving user's experience). To enjoy the rich-experiences offered by such apps while mitigating information leakages, this paper described I-BOX as a first step towards this direction. In light of the opaque nature of an IME app, I-BOX leverages the idea of transactions to run an IME app to make it oblivious to users' sensitive input. Experiments showed that I-BOX is efficient, incurs little impact on users' experiences and successfully thwarted the leakage of sensitive user input.

Abstract

We present the first concept for full-fledged app sandboxing on stock Android. Our approach is based on application virtualization and process-based privilege separation to securely encapsulate untrusted apps in an isolated environment. In contrast to all related work on stock Android, we eliminate the necessity to modify the code of monitored apps, and thereby overcome existing legal concerns and deployment problems that rewriting-based approaches have been facing. We realize our concept as a regular Android app called Boxify that can be deployed without firmware modifications or root privileges. A systematic evaluation of Boxify demonstrates its capability to enforce established security policies without incurring a significant runtime performance overhead.

1 Introduction

Security research of the past five years has shown that the privacy of smartphone users—and in particular of Android OS users, due to Android's popularity and open-source mindset—is jeopardized by a number of different threats. Those include increasingly sophisticated malware and spyware [63, 39, 62], overly curious libraries [25, 32], but also developer negligence and absence of fail-safe defaults in the Android SDK [33, 29]. To remedy this situation, the development of new ways to protect the end-users' privacy has been an active topic of Android security research during the last years.

Status quo of deploying Android security extensions. From a deployment perspective, the proposed solutions followed two major directions: The majority of the solutions [26, 44, 45, 16, 21, 64, 52, 56] extended the UID-centered security architecture of Android. In contrast, a number of solutions [38, 59, 23, 49, 22, 15] promote inlined reference monitoring (IRM) [28] as an alternative approach that integrates security policy enforcement directly into Android's application layer, i.e., the apps' code.

However, this dichotomy is unsatisfactory for end-users: While OS security extensions provide stronger security guarantees and are preferable in the long run, they require extensive modifications to the operating system and Android application framework. Since the proposed solutions are rarely adopted [54, 53] by Google or the device vendors, users have to resort to customized aftermarket firmware [4, 6] if they wish to deploy new security extensions on their devices. However, installing a firmware forms a technological barrier for most users. In addition, fragmentation of the Android ecosystem [46] and vendor customizations impede the provisioning of custom-built ROMs for all possible device configurations in the wild.

In contrast, solutions that rely on inlined reference monitoring avoid this deployment problem by moving the reference monitor to the application layer and allowing users to install security extensions in the form of apps. However, the currently available solutions provide only insufficient app sandboxing functionality [36] as the reference monitor and the untrusted application share the same process space. Hence, they lack the strong isolation that would ensure tamper-protection and non-bypassability of the reference monitor. Moreover, inlining reference monitors requires modification and hence re-signing of applications, which violates Android's signature-based same-origin model and puts these solutions into a legal gray area.

The sweet spot. The envisioned app sandboxing solution provides immediate strong privacy protection against rogue applications. It would combine the security guarantees of OS security extensions with the deployability of IRM solutions, while simultaneously avoiding their respective drawbacks. Effectively, such a solution would provide an OS-isolated reference monitor that can be deployed entirely as an app on stock Android without modifications to the firmware or code of the monitored applications.

Our contributions. In this paper we present a novel concept for Android app sandboxing based on *app virtualization*, which provides tamper-protected reference monitoring without firmware alterations, root privileges or modifications of apps. The key idea of our approach is to encapsulate untrusted apps in a restricted execution environment within the context of another, trusted sandbox application. To establish a restricted execution environment, we leverage Android's *"isolated process"* feature, which allows apps to totally de-privilege selected components—a feature that has so far received little attention beyond the web browser. By loading untrusted apps into a de-privileged, isolated process, we shift the problem of sandboxing the untrusted apps from *revoking* their privileges to *granting* their I/O operations whenever the policy explicitly allows them. The I/O operations in question are syscalls (to access the file system, network sockets, bluetooth, and other low-level resources) and the Binder IPC kernel module (to access the application framework). We introduce a novel app virtualization environment that proxies all syscall and Binder channels of isolated apps. By intercepting any interaction between the app and the system (i.e., kernel and app framework), our solution is able to enforce established and new privacy-protecting policies. Additionally, it is carefully crafted to be transparent to the encapsulated app in order to keep the app agnostic about the sandbox and retain compatibility to the regular Android execution environment. By executing the untrusted code as a de-privileged process with a UID that differs from the sandbox app's UID, the kernel securely and automatically isolates at process-level the reference monitor implemented by the sandbox app from the untrusted processes. Technically, we build on techniques that were found successful in related work (e.g., libc hooking [59]) while introducing new techniques such as Binder IPC redirection through ServiceManager hooking. We realize our concept as a regular app called Boxify that can be deployed on stock Android. To the best of our knowledge, Boxify is the first solution to introduce *application virtualization* to stock Android.
In summary, we make the following contributions:

1. We present a novel concept for application virtualization on Android that leverages the security provided by *isolated processes* to securely encapsulate untrusted apps in a completely de-privileged execution environment within the context of a regular Android app. To retain compatibility of isolated apps with the standard Android app runtime, we solved the key technical challenge of designing and implementing an efficient app virtualization layer.

2. We realize our concept as an app called Boxify, which is the first solution that ports app virtualization to the Android OS. Boxify is deployable as a regular app on stock Android (no firmware modification and no root privileges required) and avoids the need to modify sandboxed apps.

3. We systematically evaluate the efficacy and efficiency of Boxify from different angles including its security guarantees, different use-cases, performance penalty, and Android API version dependence across multiple Android OS versions.

The remainder of this paper is structured as follows. In §2, we provide necessary technical background information on Android. We define our objectives and discuss related work in §3. In §4, we present our Boxify design and implementation, which we evaluate in §5. We conclude the paper in §6.

2 Background on Android OS

Android OS is an open-source software stack (see Figure 1) for mobile devices consisting of a Linux kernel, the Android application framework, and system apps. The application framework together with the pre-installed system apps implement the Android application API. The software stack can be extended with third-party apps, e.g., from Google Play.

Android Security Model. On Android, each application runs in a separate, simple sandboxed environment that isolates data and code execution from other apps. In contrast to traditional desktop operating systems where applications run with the privileges of the invoking user, Android assigns a unique Linux user ID (UID) to every application at installation time. Based on this UID, the components of the Android software stack enforce access control rules that govern the app sandboxing. To understand the placement of the enforcement points, one has to consider how an app can interact with other apps (and processes) in the system:

Like any other Linux process, an app process uses syscalls to the Linux kernel to access low-level resources, such as files. The kernel enforces discretionary access control (DAC) on such syscalls based on the UID of the application process. For instance, each application has a private directory that is not accessible by other applications and DAC ensures

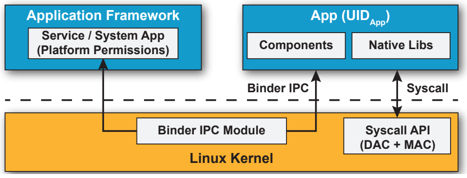

Figure 1: High-level view of interaction between apps, application framework, and Linux kernel on Android.

that applications cannot access other apps' private directories. Since Android version 4.3 this discretionary access control is complemented with SELinux mandatory access control (MAC) to harden the system against low-level privilege escalation attacks and to reinforce this UID-based compartmentalization.

The primary channel for inter-application communication is Binder *Inter-Process Communication* (IPC). It is the fundamental building block for a number of more abstract inter-app communication protocols, most importantly *Inter-Component Communication* (ICC) [27] among apps and the application framework. For sandboxing applications at the ICC level, each application UID is associated with a set of platform permissions, which are checked at runtime by reference monitors in the system services and system apps that constitute the app framework (e.g. `LocationService`). These reference monitors rely on the Binder kernel module to provide the UID of IPC senders to the IPC receivers.

In general, both enforcement points are implemented *callee-sided* in the framework and kernel, and hence agnostic to the exact call-site within the app process. This means that enforcement applies equally to all code executing in a process under the app's UID, i.e., to both Java and native code.

Additionally, Android verifies the integrity of application packages during installation based on their developer signature. The corresponding developer certificate is afterwards used to enforce a same-origin policy for application updates, i.e., newer app versions must be signed with the same signing key as the already installed application.

Isolated Process. The *Isolated Process*, introduced in Android version 4.1, is a security feature that has received little attention so far. It allows an app developer to request that certain service components within her app should run in a special process that is isolated from the rest of the system and has no permissions of its own [2]. The isolated process mechanism follows the concept of *privilege separation* [48], which allows parts of an application to run at different levels of privilege. It is intended to provide an additional layer of protection around code that processes content from untrusted sources and is likely to have security holes. Currently, this feature is primarily geared towards web browsers [35] and is most prominently used in the Chrome browser to contain the impact of bugs in the complex rendering code.

An isolated process has far fewer privileges than a regular app process. An isolated process runs under a separate Linux user ID that is randomly assigned on process startup and differs from any existing UID. Consequently, the isolated process has no access to the private app directory of the application. More precisely, the process' filesystem interaction is limited to reading/writing world readable/writable files. Moreover, the isolated process' access to the Android middleware is severely restricted. The isolated process runs with no permissions, regardless of the permissions declared in the manifest of the application. More importantly, the isolated process is forbidden to perform any of the core Android IPC functions: Sending Intents, starting Activities, binding to Services or accessing Content Providers. Only the core middleware services that are essential to running the service component are accessible to the isolated process. This effectively bars the process from any communication with other apps. The only way to interact with the isolated process from other application components is through the Service API (binding and starting). Further, the transient UID of an isolated process does not belong to any privileged system groups and the kernel prevents the process from using low-level device features such as network communication, bluetooth or external storage. As of Android v4.3, SELinux reinforces this isolation through a dedicated process type. With all these restrictions in place, code running in an isolated process has only minimal access to the system, making it the most restrictive runtime environment Android has to offer.

3 Requirements Analysis and Existing Solutions

We first briefly formulate our objectives (see §3.1) and afterwards discuss corresponding related work (see §3.2 and Table 1).

3.1 Objectives and Threat Model

In this paper, we aim to combine the security benefits of OS extensions with the deployability benefits of application layer solutions. We identify the following objectives:

- **O1 No firmware modification:** The solution does not rely on or require customized Android firmware, such as extensions to Android's middleware, kernel or the default configuration files (e.g., policy files), and is able to run on stock Android versions. This also excludes availability of root privileges, since root can only be acquired through a firmware modification on newer Android versions due to increasingly stringent SELinux policies.

- **O2 No app modification:** The solution does not rely on or require any modifications of monitored apps' code, such as rewriting existing code.

- **O3 Robust reference monitor:** The solution provides a robust reference monitor. This encompasses: 1) the presence of a strong security boundary, such as a process boundary, between the reference monitor and untrusted code; and 2) the monitor cannot be bypassed, e.g., using a code representation that is not monitored, such as native code.

- **O4 Secure isolation of untrusted code:** This objective encompasses fail-safe defaults and complete mediation by the reference monitors. The solution provides a reference monitor that mediates all interaction between the untrusted code and the Android system, or, in case no complete mediation can be established, enforces fail-safe defaults that isolate the app on non-mediated channels in order to prevent untrusted code from escalating its privileges.

Threat model. We assume that the Android OS is trusted, including the Linux kernel and the Android application framework. This includes the assumption that an application cannot compromise the integrity of the kernel or application framework at runtime. If the kernel or application framework were compromised, no security guarantees could be upheld. Protecting the kernel and framework integrity is an orthogonal research direction for which different approaches already exist, such as trusted computing, code hardening, or control flow integrity.

Furthermore, we assume that untrusted third-party applications have full control over their process and the associated memory address space. Hence the attacker can modify its app's code at runtime, e.g., using native code or Java's reflection interface.

3.2 Existing Solutions

We systematically analyze prior solutions on app sandboxing.

O3: Robust reference monitor	✔	✘	✔	✔
O4: Secure isolation of untrusted code	✔	✘	✘	✔

✔= applies; ✘= does not apply.

Table 1: Comparison of deployment options for Android security extensions based on desired objectives.

3.2.1 Android Security Extensions

Many improvements to Android's security model have been proposed in the literature, addressing a variety of shortcomings in protecting the end-user's privacy. In terms of deployment options, we can distinguish between solutions that extend the Android OS and solutions that operate at the application layer only.

Operating system extensions. The vast majority of proposals from the literature (e.g. [26, 44, 45, 16, 21, 58]) statically enhance Android's application framework and Linux kernel with additional reference monitors and policy decision points (see Figure 2). The proposed security models include, for instance, context-aware policies [21], app developer policies [45], or Chinese wall policies [16]. More recent approaches [52, 43, 56] avoid static changes to the OS by dynamically instrumenting core system services (like Binder and Zygote) or the Android bootup scripts in order to interpose [47] untrusted apps' syscalls and IPC. Since in all approaches the reference monitors are part of the application framework and kernel, there inherently exists a strong security boundary between the reference monitor and untrusted code (O3: ✔). Moreover, this entails that these reference monitors are by design part of the callee-side of all interaction of the untrusted app's process with the system and cannot be by-

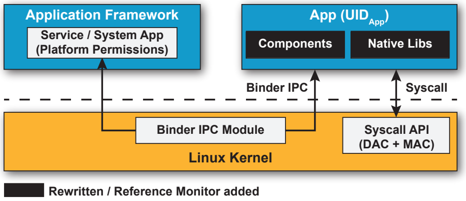

Figure 3: Instrumentation points for application code rewriting and inlining reference monitors.

passed (O4: ✔). On the downside, these solutions require modification of the Android OS (image) or root privileges to be deployed (O1: ✘; O2: ✔).

Additionally, a number of solutions exist that particularly target higher-security deployments [17, 51, 40, 13], such as government and enterprise. Commercial products exist that implement these solutions in the form of tailored mobile platforms (e.g., Blackphone[1], GreenHills[2], or Cryptophone[3]). These products target specialized user groups with high security requirements—not the average consumer—and are thus deployed on a rather small scale.

Application layer solutions. At the application layer, the situation for third-party security extensions is bleak. Android's UID-based sandboxing mechanism strictly isolates different apps installed on the same device. Android applications run with normal user privileges and cannot elevate to root in order to observe the behavior of other apps, e.g., like classical trace or anti-virus programs on desktop operating systems [31]. Also, Android does not offer any APIs that would allow one app to monitor or restrict the actions of another app at runtime. Only static information about other apps on the device is available via the Android API, i.e., application metadata, such as the package name or signing certificate, and the compiled application code and resources.Consequently, most commercially available security solutions are limited to *detecting* potentially malicious apps, e.g. by comparing metadata with predefined blacklists or by checking the application code for known malware signatures, but they lack the ability to observe or influence the runtime behavior of other applications. As a result, their effectiveness is, at best, debatable [50, 62].

Few proposals in the academic literature [38, 59, 23, 49, 15] focus on application layer only solutions (see Figure 3). Existing systems mostly focus on access control by interposing security-sensitive APIs to redirect the control flow to an additionally inlined reference monitor within the app (e.g., Aurasium [59], I-ARM-Droid [23], RetroSkeleton [22], AppGuard [15]). DroidForce [49] additionally preprocesses target apps with static data flow analysis to identify strategic policy enforcement points and to redirect policy decision making to a separate app.

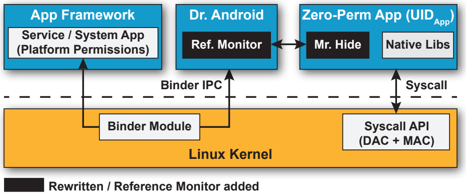

Figure 4: *Dr. Android and Mr. Hide* approach [38].

All these systems are based on rewriting the application code to inline reference monitors or redirect control flows, which works without modifications to the firmware and is thus suitable for large-scale deployment (O1: ✔; O2: ✘). However, app rewriting causes security problems and also a couple of practical deployment problems. First, inlining the reference monitor within the process of the untrusted app itself might be suitable for "benign-but-buggy" apps; however, apps that actively try to circumvent the monitor will succeed as there exists no strong security boundary between the app and the monitor. In essence, this boils down to an arms race between hooking security critical functions and finding new ways to compromise or bypass the monitor [36], where currently native code gives the attacker the advantage (O3: ✘; O4: ✘). Moreover, re-writing application code requires re-signing of the app, which breaks Android's signature-based same origin policy and additionally raises legal concerns about illicit tampering with foreign code. Lastly, re-written apps have to be reinstalled. This is not technically possible for pre-installed system apps; other apps have to be uninstalled in order to install a fresh, rewritten version, thereby incurring data loss.

Separate app. Dr. Android and Mr. Hide [38] (see Figure 4) is a variant of inlined reference monitoring (O1: ✔; O2: ✘) that improves upon the security of the reference monitor by moving it out of the untrusted app and into a separate app. This establishes a strong security boundary between the untrusted app and the reference monitor as they run in separate processes with different UIDs (O3: ✔). Additionally, it revokes all Android platform permissions from the untrusted app and applies code rewriting techniques to replace well-known security-sensitive Android API calls in the monitored app with calls to the separate

[1] https://blackphone.ch
[2] http://www.ghs.com/mobile/
[3] http://esdcryptophone.com

reference monitor app that acts as a proxy to the application framework. The benefit of this design is that in contrast to inlined monitoring, the untrusted, zero-permission app cannot gain additional permissions by tampering with the inlined/rewritten code. However, this enforcement only addresses the platform permissions. The untrusted app process still has a number of Linux privileges (such as access to the Binder interface or file system), and it has been shown that even a zero-permission app is still capable of escalating its privileges and violate the user's privacy [30, 33, 19, 18, 60, 42, 11, 12] (O4: ✗).

3.2.2 Sandboxing on traditional OSes

Restricting the access rights of untrusted applications has a longstanding tradition in desktop and server operating systems. Few solutions set up user-mode only sandboxes without relying on operating system functionality by making strong assumptions about the interface between the target code and the system (e.g., absence of programming language facilities to make syscalls or direct memory manipulation). Among the most notable user-space solutions are *native client* [61] to sandbox native code within browser extensions and the *Java virtual machine* [5] to sandbox untrusted Java applications.

Other solutions, which loosen the assumptions about the target interface to the system rely on operating system security features to establish process sandboxes. For instance, *Janus* [31], one of the earlier approaches, introduced an OS-supported sandbox for untrusted applications on Solaris 2.4, which was based on syscall monitoring and interception to restrict the untrusted process' access to the underlying operating system. The monitor was implemented as a separate process with necessary privileges to monitor and restrict other processes via the `/proc` kernel interface. Modern browsers like *Chromium* [9, 3, 8] employ different sandboxing OS facilities (e.g, seccomp mode) to mitigate the threat of web-based attacks against clients by restricting the access of untrusted code.

App virtualization. Sandboxing also plays a role in more recent *application virtualization* solutions [34, 10, 20, 41], where applications are transparently encapsulated into execution environments that replace (parts of) the environment with emulation layers that abstract the underlying OS and interpose all interaction between the app and the OS. App virtualization is currently primarily used to enable self-contained, OS-agnostic software, but also provides security benefits by restricting the interface and view the encapsulated app has of the system.

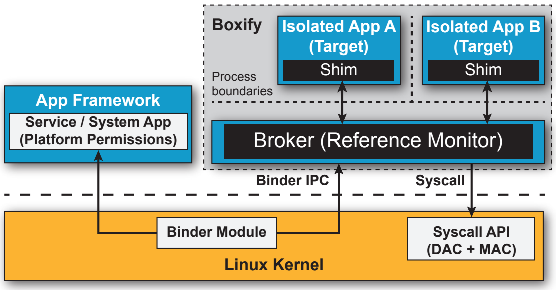

Figure 5: Architecture overview of Boxify.

Similarly to these traditional sandboxes and in particular to app virtualization, Boxify forms a user-mode sandbox that builds on top of existing operating system facilities of Android. Thereby, it establishes app sandboxes that encapsulate Android apps without the need to modify the OS and without the need to make any assumptions about the apps' code.

4 Boxify Architecture

We present the Boxify design and implementation.

4.1 Design Overview

The key idea of Boxify is to securely sandbox Android apps, while avoiding any modification of the OS and untrusted apps. Boxify accomplishes this by dynamically loading and executing the untrusted app in one of its own processes. The untrusted application is not executed by the Android system itself, but runs completely encapsulated within the runtime environment that Boxify provides and that can be installed as a regular app on stock Android (see Figure 5). This approach eliminates the need to modify the code of the untrusted application and works without altering the underlying OS (O1: ✔; O2: ✔). It thus constitutes the first solution that ports the concept of app virtualization to the stock Android OS.

The primary challenge for traditional application sandboxing solutions is to completely mediate and monitor all I/O between the sandboxed app and the system in order to restrict the untrusted code's privileges. The key insight for our Boxify approach is to leverage the security provided by *isolated processes* in order to isolate the untrusted code running within the context of Boxify by executing it in a completely de-privileged process that has no platform permissions, no access to the Android middleware, nor the ability to make persistent changes to the file system.

However, Android apps are tightly integrated within the application framework, e.g., for lifecycle management and inter-component communication. With the restrictions of an isolated process in place, encapsulated apps are rendered dysfunctional. Thus, the key challenge for Boxify essentially shifts from constraining the capabilities of the untrusted app to now gradually permitting I/O operations in a controlled manner in order to securely re-integrate the isolated app into the software stack. To this end, Boxify creates two primary entities that run at different levels of privilege: A privileged controller process known as the Broker and one or more isolated processes called the Target (see Figure 5).

The Broker is the main Boxify application process and acts as a mandatory proxy for all I/O operations of the Target that require privileges beyond the ones of the isolated process. Thus, if the encapsulated app bypasses the Broker, it is limited to the extremely confined privilege set of its isolated process environment (*fail-safe defaults*; O4: ✔). As a consequence, the Broker is an ideal control-flow location in our Boxify design to implement a reference monitor for any privileged interaction between a Target and the system. Any syscalls and Android API calls from the Target that are forwarded to the Broker are evaluated against a security policy. Only policy-enabled calls are then executed by the Broker and their results returned to the Target process. To protect the Broker (and hence reference monitor) from malicious app code, it runs in a separate process under a different UID than the isolated processes. This establishes a strong security boundary between the reference monitor and the untrusted code (O3: ✔). To transparently forward the syscalls and Android API calls from the Target across the process boundary to the Broker, Boxify uses Android's Binder IPC mechanism. Finally, the Broker's responsibilities also include managing the application lifecycle of the Target and relaying ICC between a Target and other (Target) components.

The Target hosts all untrusted code that will run inside the sandbox. It consists of a shim that is able to dynamically load other Android applications and execute them. For the encapsulated app to interact with the system, it sets up interceptors that interpose system and middlware API calls. The interceptors do *not* form a security boundary but establish a compatibility layer when the code inside the sandbox needs to perform otherwise restricted I/O by forwarding the calls to the Broker. All resources that the Target process uses have to be acquired by the Broker and their handles duplicated into the Target process.

By encapsulating untrusted apps and interposing all their (privileged) I/O operations, Boxify is able to effectively enforce security- and privacy-protecting policies. Based on syscall interposition, Boxify has fine-grained control over network and filesystem operations. Intercepting Binder IPC enables the enforcement of security policies that were so far only achievable for OS extensions, but at application layer only.

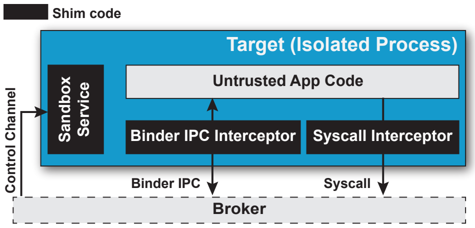

Figure 6: Components of a Target process.

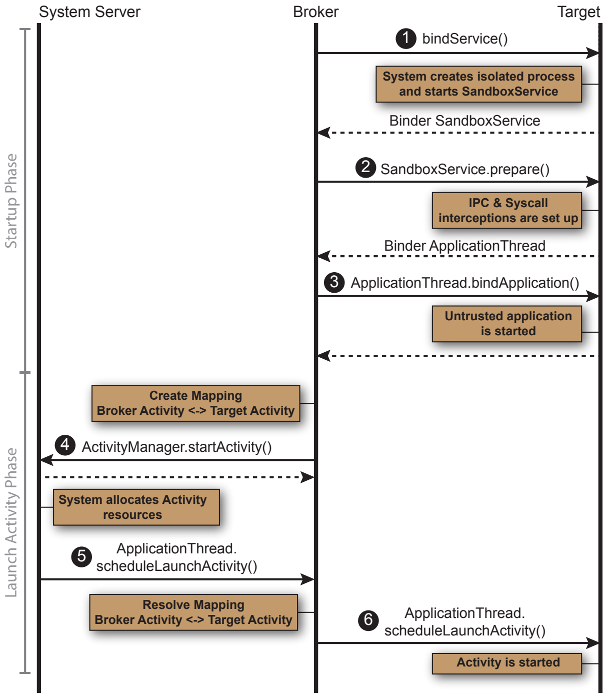
Moreover, with this architecture, Boxify can provide a number of interesting novel features. Boxify is capable of monitoring multiple (untrusted) apps at the same time. By creating a number of Target processes, multiple apps can run in parallel yet securely isolated in a single instance of Boxify. Since the Broker fully controls all inter-component communication between the sandboxed apps, it is able to not only separate different apps from one another but also to allow controlled collaboration between them. Further, Boxify has the ability to execute apps that are not regularly installed on the phone: Since Boxify executes other apps by dynamically loading their code into one of its own processes and handles all the interaction between the sandboxed application and the OS, there is no need to register the untrusted app with the Android system. Hence, applications can be installed into, updated, or removed from Boxify without involving the `PackageInstaller` or having system privileges. A potential application of these features are application containers (e.g., enterprise app domain, see §5.4).

4.2 Target

The Target process contains four main entities (see Figure 6): The SandboxService (1) provides the Broker with a basic interface for starting and terminating apps in the sandbox. It is also responsible for setting up the interceptors for Binder IPC (2) and syscalls (3), which transparently forward calls issued by the untrusted application to the Broker.

1) SandboxService. Isolated processes on Android are realized as specifically tagged Service components (see §2). In Boxify each Target is implemented as such a tagged SandboxService component of the Boxify app. When a new Target should be spawned, a new, dedicated SandboxService is spawned. The SandboxService provides an IPC interface that enables the Broker to communicate with the isolated process and to call two basic lifecycle operations for the Target: `prepare` and `terminate`. The Broker invokes the `prepare` function to initialize the sandbox environment for the execution of a hosted app. As part of this preparation, the Broker and Target exchange important configuration information for correct operation of the Target, such as app meta-information and Binder IPC handles that allow bi-directional IPC between Broker and Target. The `terminate` function shuts down the application running in the sandbox and terminates the Target process.

The biggest technical challenge at this point was *"How to execute another third-party application within the running isolated service process?"* Naïvely, one could consider, for instance, a warm-restart of the app process with the new application code using the `exec` syscall. However, we discovered that the most elegant and reliable solution is to have the Broker initially imitate the `ActivityManager` by instructing the Target process to load (i.e., *bind*) another application to its process and afterwards to relay any lifecycle events between the actual application framework and the newly loaded application in the Target process. The *bind* operation is supported by the standard Android application framework and used during normal app startup. The exact procedure is illustrated in Figure 7. The Broker first creates a new SandboxService process (❶), which executes with the privileges of an isolated process. This step actually involves multiple messages between the Broker process, the Target process and the system server, which we omitted here for the sake of readability. As a result, the Broker process receives a Binder handle to communicate with the newly spawned SandboxService. Next, the Broker uses this handle to instruct the SandboxService to prepare the loading of a sandboxed app (❷) by setting up the Binder IPC interceptor and syscall interceptor (using the meta-information given as parameters of the `prepare` call). The SandboxService returns the Binder handle to its `ApplicationThread` to the Broker. The application thread is the main thread of a process containing an Android runtime and is used by the `ActivityManager` to issue commands to Android application processes. At this point, the Broker emulates the behavior of the `ActivityManager` (❸) by instructing the `ApplicationThread` of the Target with the `bindApplication` call to load the target app into its Android runtime and start its execution. By default, it would be the `ActivityManagerService` as part of the application framework that uses this call to instruct newly forked and specialized Zygote processes to load and execute an application that should be started. After this step, the sandboxed app is executing.



System Server
Broker
Target
Startup Phase
Launch Activity Phase
1 bindService()
System creates isolated process and starts SandboxService
Binder SandboxService
2 SandboxService.prepare()
IPC & Syscall interceptions are set up
Binder ApplicationThread
3 ApplicationThread.bindApplication()
Untrusted application is started
Create Mapping Broker Activity <-> Target Activity
4 ActivityManager.startActivity()
System allocates Activity resources
5 ApplicationThread. scheduleLaunchActivity()
Resolve Mapping Broker Activity <-> Target Activity
6 ApplicationThread. scheduleLaunchActivity()
Activity is started

Figure 7: Process to load an app into a Target process and to launch one its Activities.

As an example how a sandboxed app can be used, we briefly explain how an Activity component of the sandboxed app can be launched, e.g., as result of clicking its entry in a launcher. As explained in §4.3, the Virtualization Layer creates a mapping from generic Boxify components to Target components. In this case, it maps the Activity component of Target to an Activity component of Boxify. The Broker requests the Activity launch from the `ActivityManager` in the `SystemServer` (❹), which allocates the required resources. After allocation, it schedules the launch of the Activity component by signaling the `ApplicationThread` of the targeted app (❺), which in this case is the Boxify app. Thus, the Virtualization Layer resolves the targeted Activity component and relays the signal to the corresponding Target process (❻).

2) Binder IPC Interceptor. Android applications use the Binder IPC mechanism to communicate with the (remote) components of other applications, including the application framework services and apps. In order to interact via Binder IPC with a remote component, apps must first acquire a Binder handle that connects them to the desired component.

To retrieve a Binder handle, applications query the ServiceManager, a central service registry, that allows clients to lookup system services by their common names. The ServiceManager is the core mechanism to bootstrap the communication of an application with the Android application framework. Binder handles to non-system services, such as services provided by other apps, can be acquired from the core framework services, most prominently the ActivityManager.

Boxify leverages this choke point in the Binder IPC interaction to efficiently intercept calls to the framework in order to redirect them to the Broker. To this end, Boxify replaces references to the ServiceManager handle in the memory of the Target process with references to the Binder handle of the Broker (as provided in the prepare function). These references are constrained to a few places and can be reliably modified using the Java Reflection API and native code. Consequently, all calls directed to the ServiceManager are redirected to the Broker process instead, which can then manipulate the returned Binder objects in such a way that any subsequent interactions with requested services are also redirected to the Broker. Furthermore, references to a few core system services, such as the ActivityManager and PackageManager, that are passed by default to new Android app runtimes, need to be replaced as well. By modifying only a small number of Binder handles, Boxify intercepts all Binder IPC communication. The technique is completely agnostic of the concrete interface of the redirected service and can be universally applied to all Binder interactions.

3) Syscall Interceptor. For system call interception, we rely on a technique called libc hooking (used, for instance, also in [59]). Applications use Android's implementation of the Standard C library *Bionic libc* to initiate system calls. With libc hooking, we efficently intercept calls to libc functions and redirect these calls to a service client running in the Target process. This client forwards the function calls via IPC to a custom service component running in the Broker. Due to space constraints, we refer to [7] for a detailed technical explanation of libc hooking.

In contrast to the IPC interception, which redirects all IPC communication to the Broker, the syscall interception is much more selective about which calls are forwarded: We do not redirect syscalls that would be anyway granted to an isolated process, because there is no security benefit from hooking these functions: a malicious app could simply remove the hook and would still succeed with the call. This exception applies to calls to read world-readable files and to most system calls that operate purely on file descriptors (e.g. read, write). Naturally, by omitting the indirection via our Broker, these exempted calls perform with native performance. However, Boxify still hooks calls that are security-critical and that are not permitted for isolated processes, such as system calls to perform file system operations (e.g. open, mkdir, unlink) and network I/O (socket, getaddrinfo). For a few calls, such as file operations, whose success depends on the given parameter, the syscall interception is parameter-sensitive in its decision whether or not to forward this operation to the Broker.

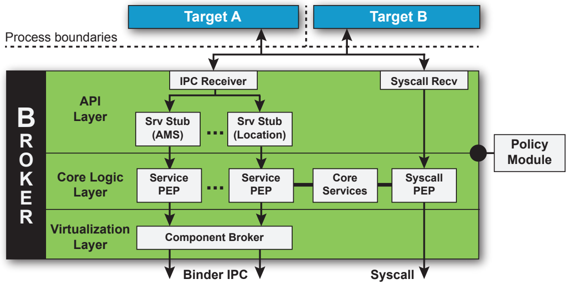


Figure 8: Architecture of the Broker.

4.3 Broker

The Broker is the main application process of Boxify and is thus not subject to the restrictions imposed by the isolated process. It holds all platform permissions assigned to the Boxify app and can normally interact with the Android middleware. The Broker acts as a mandatory proxy for all interactions between the Target processes and the Android system and thus embodies the reference monitor of Boxify. These interactions are bi-directional: On the one hand, the untrusted app running in the Target process issues IPC and syscalls to the system; on the other hand, the Android middleware initiates IPC calls to Target (e.g., basic lifecycle operations) and the Broker has to dispatch these events to the correct Target.

The Broker is organized into three main layers (see Figure 8): The API Layer (4) abstracts from the concrete characteristics of the Android-internal IPC interfaces to provide compatibility across different Android versions. It bridges the semantic gap between the raw IPC transactions forwarded by the Target and the application framework semantics of the Core Logic Layer (5), which implements the fundamental mechanics of the virtual runtime environment that Boxify provides. All interaction with the system happens through the Virtualization Layer (6), which translates between the virtual environment inside of

Boxify and the Android system on the outside. In the following, we will look at every layer in more detail.

4) API Layer. The API Layer is responsible for receiving and unwrapping the redirected syscall parameters from the Syscall Interceptor in the Target and relaying them to the Core Logic Layer for monitoring and execution. More importantly, it transforms the raw Binder IPC parcels received from the IPC Interceptor into a representation agnostic of the Android version.

In order to (efficiently) sandbox applications at the Binder IPC boundary, Boxify must semantically interpret the intercepted Binder parcels. However, intercepted parcels are in a raw representation that consists only of native types that the kernel module supports and the sender marshalled all higher-level objects (e.g., Java classes) to this representation. This impedes an efficient sandboxing. To solve this problem, Boxify leverages the default Android toolchain for implementing Binder-based RPC protocols: To ensure that sender and receiver can actually communicate with each other, the receiver must know how to unmarshal the raw parcel data (exactly like Boxify). Android supports the developers in this process through the *Android Interface Definition Language* (AIDL), which allows definitions of Binder interfaces very similar to Java interfaces, including the names and signatures of remotely callable functions. The Android SDK toolchain generates the required boilerplate marshalling code from AIDL definitions both for the receiver (*Stub*) and the sender (*Proxy*). For system services, these Stubs are automatically generated during system build and Boxify uses the generated Stubs (which ship with Android OS and are conveniently accessible to third-party application) to unmarshal the raw Binder IPC parcel back to their application framework semantic (i.e., Java objects, etc). In essence, this allows us to generate the API layer of the Broker in an almost fully-automatic way for each Android version on which Boxify is deployed. Since Boxify is in full control of the Binder handles of the encapsulated app (i.e., calls to the `ServiceManager`, `ActivityManager`, etc.), it can efficiently determine which Binder handle of the app addresses which system service and hence which Stub must be used to correctly unmarshal the raw Binder parcel intercepted from each handle.

However, the exact structure of the unmarshalled data and the functions (name and signature) depend entirely on the AIDL file. Since the system service interfaces describe the internal Android API, these interfaces change frequently between Android versions. Hence Boxify would have to implement each possible version of a Stub for every available Android version. Since this Stub implementation, in contrast to the marshalling logic, can not be automated, this complicates efficient sandboxing of apps across multiple Android versions. Consequently, it is desirable to transform the unmarshalled IPC data into a version-agnostic representation and then implement each Stub once and for all for this version. To accomplish this in Boxify, we borrow ideas from Google's proprietary *SafeParcel* class: In contrast to the regular Binder parcel, the SafeParcel carries structural information about the data stored in it, which allows the receiver of an IPC request to selectively read parts of the payload without knowing its exact structure. We achieve the same result by transforming the version-dependent parcel into a version-agnostic key-value store (where keys are the parameter names of methods declared in the interface definitions) and adapting the Core Logic Layer and Stub implementations to work with these version-agnostic data stores. Thus, while the API layer is version-dependent and automatically generated for each Android version, the remaining layers of Broker are version-agnostic and implemented only once.

5) Core Logic Layer. The Core Logic Layer provides essential functionality required to run apps on Android by replicating a small subset of the functionality that Android's core system services provide. Most prominently, this layer provides a minimal implementation of the `PackageManager`, which manages the packages installed into the Boxify environment. Every call to a system service that is not emulated by the Core Logic Layer is passed on to the Virtualization Layer and thus to the underlying Android system. Other system services, such as the `LocationManager`, which are not necessarily required, can be instantiated at this layer as well, in case encapsulated apps are supposed to use the local, Boxify service implementation instead of the pristine Android service (e.g., servicing sandboxed apps with fake location data [64]). Hence, this layer decides whether an Android API call is emulated using a replicated service or forwarded to the system (through the Virtualization Layer). This layer is therefore responsible for managing the IPC communication between different sandboxed apps (abstractly like an *"ICC switch"*).

Furthermore, the Core Logic Layer implements the policy enforcement points (PEP) for Binder IPC services and syscalls. Because the API Layer already bridges the semantic gap between kernel-level IPC and Android application framework semantics, this removes the burden for dealing with low-level semantics in the IPC PEPs. We emulate the integration of enforcement points into pristine Android services by integrating these points into our mandatory service proxies. This allows us to instantiate security models from the area of OS security extensions (see §3.2), but at the application layer. One default security model that Boxify provides is the permission enforcement and same origin model of Android. For instance, the replicated `ActivityManager` will enforce permissions on calls between components of two sandboxed apps. We present further security models from related work on OS security extensions that we integrated at this layer in §5.4 and for future work we consider a programmable interface for extending Core Logic Layer security in the spirit of ASM [37] and ASF [14]. For calls that are not protected by a permission, the Broker can also choose to enable direct communication between the target app and the requested Android system service. This can improve performance for non-critical services such as the `SurfaceFlinger` (for GUI updates) at the cost of losing the ability to mediate calls to these services.

The syscall PEP enforces system call policies in the spirit of [47] with respect to network and filesystem operations. Its responsibilities are twofold: First, it functions as a transparent compatibility layer by emulating the file-system structure of the Android data partition (e.g., `chroot` of sandboxed apps by emulating a home directory for each sandboxed app[4] within the home directory of the Boxify app). Second, it emulates the access control of the Linux kernel, i.e., compartmentalization of sandboxed apps by ensuring that they cannot access private files of other apps as well as enforcing permissions (e.g., preventing a sandboxed app without Internet permission from creating a network socket).

6) Virtualization Layer. The sandbox environment must support communication between sandboxed apps and the Android application framework, because certain system resources cannot be efficiently emulated (e.g., `SurfaceFlinger` for GUI) or not emulated at all (e.g., hardware resources like the camera). However, the sandbox must be transparent to the Target and all interaction with the application framework must appear as in a regular app. At the same time, the sandbox must be completely opaque to the application framework and sandboxed apps must be hidden from the framework; otherwise, this leads to inconsistencies that the framework considers as runtime (security) exceptions.

In Boxify, the Virtualization Layer is responsible for translating the bi-directional communication between the Android application framework and the Target. It achieves the required semi-transparent communication with a technique that can be abstractly described as *"ICC Network Address Translator"*: On outgoing calls from Target to framework, it ensures that all ICC appears as coming from the Boxify app instead of the sandboxed app. As described earlier, all Binder handles of a Target are substituted with handles of the Broker, which relays the calls to the system. During relay of calls, the Virtualization Layer manipulates the call arguments to hide components of sandboxed apps by substituting the component identifiers with identifiers of components of the Boxify app. On incoming calls from the framework, the Virtualization Layer substitutes the addressed Boxify component with the actually addressed component of the sandboxed app and dispatches the call. In order to correctly substitute addressed components, the Virtualization Layer maintains a mapping between Target and Boxify component names, or in case the Target component is not addressed by a name but a Binder handle that was given prior to the framework, the mapping is between the released Binder handle and its owning Target component.

A concrete example where this technique is applied is requesting the launch of a Target Activity component from the application framework (see Figure 7). The Virtualization Layer substitutes the Activity component with a generic Activity component of Boxify if a call to the `ActivityManager` occurs. When the service calls back for scheduling the Activity launch, the Virtualization Layer dispatches the scheduling call to the corresponding Target Activity component.

Lastly, we hook the application runtime of Boxify's Broker process (using a technique similar to [55]) in order to gain control over the processing of incoming Binder parcels. This enables the Broker to distinguish between parcels addressed to Boxify itself and those that need to be forwarded to the Target processes.

4.4 System Integration

Lastly, we discuss some aspects of integrating sandboxed apps into the default application framework.

Launcher. Since sandboxed apps have to be started through Boxify (and are not regularly installed on the system), they cannot be directly launched from the default launcher. A straightforward solution is to provide a custom launcher with Boxify in form of a dedicated Activity. Alternatively, Boxify could register as a launcher app and then run the default launcher (or any launcher app of the user's choice) in the sandbox, presenting the union of the regularly installed apps and apps installed in the sandbox environment; or Boxify launcher widgets could be placed

[4] Recall that sandboxed apps are not installed in the system but only in the Boxify environment, and hence do not have a native home directory.

Table 2: Microbenchmarks Middleware (200 runs)

API Call	Native	on Boxify	Overhead
Open Camera	103.24 ms	104.48 ms	1.24ms (1.2%)
Query Contacts	7.63 ms	8.55 ms	0.92 ms (12.0%)
Insert Contacts	66.49 ms	67.51 ms	1.02 ms (1.5%)
Delete Contacts	75.86 ms	76.81 ms	0.95 ms (0.9%)
Create Socket	120.83 ms	121.58 ms	0.75 ms (0.6%)

on the regular home screen to launch sandboxed apps from there.

App stores. Particularly smooth is the integration of Boxify with app store applications, such as the Google Play Store. Since no special permissions are required to install apps into the sandbox, we can simply run the store apps provided by Google, vendors, and third-parties in Boxify to install new apps there. For example, clicking install in the sandboxed Play Store App will directly install the new app into Boxify. Furthermore, Play Store (and vendor stores) even take care of automatically updating all apps installed in Boxify, a feature that IRM systems have to manually re-implement.

Statically registered resources. Some resources of apps are statically registered in the system during app installation. Since sandboxed apps are not regularly installed, the system is unaware of their resources. This concerns in particular Activity components that can receive Intents for, e.g., content sharing, or package resources like icons. However, some resources like Broadcast Receiver components can be dynamically registered at runtime and Boxify uses this as a workaround to dynamically register the Receivers declared statically in the Manifests of sandboxed apps.

5 Evaluation

We discuss the prototypical implementation of Boxify in terms of performance impact, security guarantees, and app robustness, and present concrete use-cases of Boxify. Our prototype comprises 11,901 lines of Java code, of which 4,242 LoC are automatically generated (API Layer), and 3,550 lines of additional C/C++ code. All tests described in the following were performed on an LG Nexus 5 running Android 4.4.4, which is currently the most widely used version in the Android ecosystem.

5.1 Performance Impact

To evaluate the performance impact of Boxify on monitored apps, we compare the results of common benchmark apps and of custom micro-benchmarks for encapsulated and native execution of apps.

Table 3: Microbenchmarks Syscalls (15k runs)

Libc Func.	Native	on Boxify	Overhead
`create`	47.2 μs	162.4 μs	115.2 μs
`open`	9.5 μs	122.7 μs	113.2 μs
`remove`	49.5 μs	159.6 μs	110.1 μs
`mkdir`	88.4 μs	199.4 μs	111.0 μs
`rmdir`	71.2 μs	180.7 μs	109.5 μs

Table 4: Benchmark Tools (10 runs)

Tool	Native	on Boxify	Loss
CF Bench v1.3	16082 Pts	15376 Pts	4.3%
Geekbench v3.3.1	1649 Pts	1621 Pts	1.6%
PassMark v1.0.4	3674 Pts	3497 Pts	4.8%
Quadrant v2.1.1	7820 Pts	7532 Pts	3.6%

Table 2 and Table 3 present the results of our microbenchmarks for common Android API calls and for syscall performance. Intercepting calls to the application framework imposes an overhead around 1%, with the exception of the very fast `Query Contacts` (12%). For syscalls, we measured the performance of calls that request file descriptors for file I/O in private app directories (or external storage) and that are proxied by the Broker. We observe a constant performance overhead of $\approx 100\mu s$, which corresponds to the required time of the additional IPC round trip for the communication with the Broker on our test platform. However, the syscall benchmarks depict a worst-case estimation: The overall performance impact on apps is much lower, since high-frequent follow up operations on acquired file descriptors (e.g., `read`/`write`) need not to be intercepted and therefore run with native speed. We measured the overall performance penalty by excecuting several benchmarking apps on top of Boxify, which show an acceptable performance degradation of 1.6%–4.8% (see Table 4).

5.2 Runtime Robustness

To assess the robustness of encapsulated apps, we executed 1079 of the most popular, free apps from Google Play (retrieved in August 2014) on top of Boxify. For each sandboxed app we used the *monkeyrunner* tool[5] to exercise the app's functionality by injecting 500 random UI events. From the 1079 apps, 93 (8.6%) experienced a crash during testing. Manual investigation of the dysfunctional apps revealed

[5] `http://developer.android.com/tools/help/monkeyrunner_concepts.html`

Table 5: Android versions supported by Boxify.

Version	< 4.1	4.1	4.2	4.3	4.4	5.0	5.1
Supported	✗[†]	✓	✓	✓	✓	✓	✓

✓: supported; ✗: not supported

[†]: no *isolated proccess*

that most errors were caused by apps executing exotic syscalls or rarely used Android APIs which are not covered by Boxify yet and thus fail due to the lack of privileges of the Target process (fail-safe defaults). This leads to a slightly lower robustness than reported for related work (e.g., [59, 15]) where bypassed hooks do not cause the untrusted app to crash but instead silently circumvent the reference monitor. The remaining issues were due to unusual application logic that relies on certain OS features (e.g., the process information pseudo-filesystem `proc`), which the current prototype of Boxify does not yet support. However, all of these are technical and not conceptual shortcomings of the current implementation of Boxify.

5.3 Portability

Table 5 summarizes the Android versions currently supported by our prototypical Boxify implementation. Our prototype supports all Android versions 4.1 through 5.1 and can be deployed on nine out of ten devices in the Android ecosystem [1]. Android versions prior to 4.1 are not supported due to the lack of the *isolated process* feature.

5.4 Use-cases

Boxify allows the instantiation of different security models from the literature on Android security extensions. In the following, we present two selected use-cases on fine-grained permission control and domain isolation that have received attention before in the security community.

Fine-Grained Permission Control. The TISSA [64] OS extension empowers users to flexibly control in a fine-grained manner which personal information will be accessible to applications. We reimplemented the TISSA functionality as an extension to the Core Logic Layer of the Boxify Broker. To this end, we instrumented the mandatory proxies for core system services (e.g. `LocationManager`, `TelephonyService`) so that they can return a filtered or mock data set based on the user's privacy settings. Users can dynamically adjust their privacy preferences through a management Activity added to Boxify. In total, the TISSA functionality required additional 351 lines of Java code to Core Logic Layer.

Domain Isolation. Particularly for enterprise deployments, container solutions have been brought forward to separate business apps from other (untrusted) apps [56, 17, 53].

We implemented a domain isolation solution based on Boxify by installing business apps into the sandbox environment. The Broker provides its own version of the `PackageManager` to directly deliver inter-component communication to sandboxed applications without involving the regular `PackageManager`, enabling controlled collaboration between enterprise apps while at the same time isolating and hiding them from non-enterprise apps and the OS.

To separate the enterprise data from the user's private data, we exploit that the Broker is able to run separate instances of system services (e.g., Contacts, Calendar) within the sandbox. Our custom `ActivityManager` proxy now selectively and transparently redirects `ContentProvider` accesses by enterprise apps to the sandboxed counterparts of those providers.

Alternatively, the above described domain isolation concept was used to implement a privacy mode for end users, where untrusted apps are installed into a Boxify environment with empty (or faked) system ContentProviders. Thus, users can test untrusted apps in a safe environment without risking harm to their mobile device or private data. The domain isolation extension required 986 additional lines of code in the Core Logic Layer of Boxify.

5.5 Security Discussion

Our solution builds on *isolated processes* as fundamental security primitive. An isolated process is the most restrictive execution environment that stock Android currently has to offer, and it provides Boxify with better security guarantees than closest related work [38]. In what follows, we identify different security shortcomings and discuss potential future security primitives of stock Android that would benefit Boxify and defensively programmed apps in general.

Privilege escalation. A malicious app could bypass the syscall and IPC interceptors, for instance, by statically linking `libc`. For IPC, this does not lead to a privilege escalation, since the application framework apps and services will refuse to cooperate with an isolated process. However, the kernel is unaware of the concept of an "isolated process" and will enforce access control on syscalls according to the process' UID. Although the transient UIDs of isolated processes are very restricted in their filesystem access (i.e., only world readable/writable files), a malicious process has the entire kernel API as an attack vector and might escalate its privileges through a root or kernel exploit. In this sense, Boxify is not more secure than existing approaches that rely on the assumption that the stock Android kernel is hardened against root and kernel exploits.

To remedy this situation, additional layers of security could be provided by the underlying kernel to further restrict untrusted processes. This is common practice on other operating systems, e.g., on modern Linux distributions, where Chromium—the primary user of isolated process on Android—uses the *seccomp-bpf* facility to selectively disable syscalls of renderer processes and we expect this facility to become available on future Android versions with newer kernels. Similarly, common program tracing facilities could be made available in order to interpose syscalls more securely and efficiently [31, 47, 52].

Violating Least-Privilege Principle. The Broker must hold the union set of all permissions required by the apps hosted by Boxify in order to successfully proxy calls to the Android API. Since it is hard to predict a reasonable set of permissions beforehand, this means that the Broker usually holds all available permissions. This contradicts the principle of least privilege and makes the Broker an attractive target for the encapsulated app to increase its permission set. A very elegant solution to this problem would be a Broker that drops all unnecessary permissions. This resembles the privilege separation pattern [48, 57] of established Linux services like ssh, which drop privileges of sub-processes based on setting their UIDs, capabilities, or transitioning them to seccomp mode. Unfortunately, Android does not (yet) provide a way to *selectively* drop permissions *at runtime*.

Red Pill. Even though Boxify is designed to be invisible to the sandboxed app, it cannot exclude that the untrusted app gathers information about its execution environment that allow the app to deduce that it is sandboxed (e.g., checking its runtime UID or permissions). A malicious app can use this knowledge to change its runtime behavior when being sandboxed and thus hide its true intentions or refuse to run in a sandboxed environment. Prevention of this information leak is an arms race that a resolute attacker will typically win. However, while this might lead to refused functionality, it cannot be used to escalate the app's privileges.

6 Conclusion

We presented the first application virtualization solution for the stock Android OS. By building on isolated processes to restrict privileges of untrusted apps and introducing a novel app virtualization environment, we combine the strong security guarantees of OS security extensions with the deployability of application layer solutions. We implemented our solution as a regular Android app called Boxify and demonstrated its capability to enforce established security policies without incurring significant runtime performance overhead.

Availability and Future Work. We will make the Boxify source code freely available. Beyond the immediate privacy benefits for the end-user presented in this paper (see §5.4), Boxify offers all the security advantages of traditional sandboxing techniques and is thus of independent interest for future Android security research. As future work, we are currently investigating different application domains of Boxify, such as application-layer only taint-tracking for sandboxed apps [24], programmable security APIs in the spirit of ASM [37]/ASF [14] to facilitate the extensibility of Boxify, as well as Boxify-based malware analysis tools.

Abstract

A cookie can contain a "secure" flag, indicating that it should be only sent over an HTTPS connection. Yet there is no corresponding flag to indicate how a cookie was set: attackers who act as a man-in-the-midddle even temporarily on an HTTP session can inject cookies which will be attached to subsequent HTTPS connections. Similar attacks can also be launched by a web attacker from a related domain. Although an acknowledged threat, it has not yet been studied thoroughly. This paper aims to fill this gap with an in-depth empirical assessment of cookie injection attacks. We find that cookie-related vulnerabilities are present in important sites (such as Google and Bank of America), and can be made worse by the implementation weaknesses we discovered in major web browsers (such as Chrome, Firefox, and Safari). Our successful attacks have included privacy violation, online victimization, and even financial loss and account hijacking. We also discuss mitigation strategies such as HSTS, possible browser changes, and present a proof-of-concept browser extension to provide better cookie isolation between HTTP and HTTPS, and between related domains.

1 Introduction

The same-origin policy (SOP) is a corner stone of web security, guarding the web content of one domain from the access from another domain. The most standard definition of "origin" is a 3-tuple, consisting of the scheme, the domain and the port number. However, the notion of "origin" regarding cookies is fairly unusual – cookies are not separated between different schemes like HTTP and HTTPS, as well as port. The domain isolation of cookie is also weak: different but related domains can have a shared cookie scope. A cookie may have a "secure" flag, indicating that it should only be presented over HTTPS, ensuring confidentiality of its value against a network man-in-the-middle (MITM). However, there is no similar measure to protect its integrity from the same adversary: an HTTP response is allowed to set a secure cookie for its domain. An adversary controlling a related domain is also capable to disrupt a cookie's integrity by making use of the shared cookie scope. Even worse, there is an asymmetry between cookie's read and write operations involving pathing, enabling more subtle form of cookie integrity violation.

The lack of cookie integrity is a known problem, noted in the current specification [2]. However, the real-world implications are under-appreciated. Although the problem has been discussed by several previous researchers [4, 5, 30, 32, 24, 23], none provided in-depth and real-world empirical assessment. Attacks enabled by merely injecting malicious cookies could be elusive, and the consequence could be serious. For example, a cautious user might only visit news websites at open wireless networks like those at Starbucks. She might not know that this is sufficient for a temporary MITM attacker to inject malicious cookies to poison her browser, and compromise her bank account when she later logs on to her bank site at home.

We aim to understand how could attackers launch cookie inject attacks, and what are the damaging consequences to real-world websites. Our study shows that most websites are potentially susceptible to cookie injection attacks by network attackers. For example, only one site in the Alexa top 100 websites has fully deployed HTTP Strict Transport Security (HSTS) on its top-level domain, a sufficient server-side protection to counter cookie injection attacks by network attackers (Section 3). We also found a number of browser vulnerabilities and implementation quirks that can be exploited by cookie injection attacks (Section 4). Notably, all major browsers, except Internet Explorer (IE), respect the "Set-Cookie" header in a 407-response (i.e., an Authentication Required Response) when configured to use a proxy. Because of this vulnerability, even websites adopting sufficient HSTS are subject to cookie injection attacks by a malicious proxy.

Our study also shows that current cookie practices have widespread problems when facing cookie injection attacks (Section 5). We demonstrate multiple exploitations against large websites. For example, we show that an attacker can put his Gmail chat gadget on a victim's screen without affecting the victim's use of Gmail and other Google services. We also demonstrate that an attacker can hijack a victim's online deposit to his account, or even deliver the victim's online purchase to his address. Other exploitations include user tracking, cross-site scripting (XSS) attacks against large financial sites embedded in injected cookies, *etc.*.

We have developed a mitigation strategy (Section 6). By modifying how browsers treat secure cookies, it is possible to largely mitigate cookie injection attacks by network attackers. We have also considered possible browser enhancements to mitigate cookie injection from web attackers. We implement our proposals as a proof-of-concept browser extension. A preliminary evaluation does not encounter compatibility issues.

In summary, this work makes the following main contributions:

- We provided an evaluation of potential susceptible websites to cookie injection attacks, including a detailed measurement of full HSTS adoption and an assessment of shared domains used by Content Delivery Networks (CDNs).

- We examined both browser-side and server-side cookie implementation, in which we found several browser vulnerabilities and a number of non-conforming and/or inconsistent implementations that could be exploited in cookie injection attacks.

- We demonstrated the severity and prevalence of cookie injection attacks in the real world. In particular, our exploitations against a variety of large websites show that cookie injection enables complicated interactions among implements, applications, and various known attacks.

- We developed and implemented browser-side enhancements to provide better cookie isolation. Our evaluation showed promising results in compatibility.

Together, this work provides a close-up picture of the cookie integrity problem and the threats of cookie inject attacks. We intend to provide a context for motivating further discussion in research community and industry.

2 Background

2.1 Cookies

Cookies are a browser-side assisted state management mechanism that are pervasively used by web applications [2]. Cookies can be set by either HTTP servers using "`Set-Cookie:`" header or client side JavaScript with a write to "`document.cookie`". A cookie can have five optional attributes: `domain` and `path` specifying the cookie's scope; `expires` stating when it should be discarded; `secure` specifying that it should only be sent over HTTPS connections, and `HTTPOnly` preventing browser-side scripts from reading the cookie. When sending a request to a server, a web browser includes all unexpired cookies whose domains and paths match the requested URL, excluding those marked as `secure` from the inclusion in an HTTP request.

Cookies have two fairly unusual behaviors. First, there is a critical disconnection between cookie storage and reading. Cookies are set and stored as a name/domain/path to value attributes mapping, but only name-value pairs are presented to both JavaScript and web servers. This asymmetry allows cookies with the same name but different domain and/or path scopes to be written into browser; a subsequent reader can read out all same name cookies together, yet cannot distinguish them because the other attributes such as path are not presented in the reading process. Another complication occurs when writing a cookie, the writer can specify arbitrary value for the `path` attribute, not limited by the URL of the writer's context.

Moreover, the security policy for cookies is not as stringent as the classic SOP. In web security, the SOP is the most important access control mechanism to segregate static contents and active scripts from different origins [3]. An origin for a given URL is defined by a 3-tuple: scheme (or protocol), *e.g.* HTTP or HTTPS, domain (or host), and port (not supported by IE (Internet Explorer)). However, the security policy guarding cookies does not provide separation based on either scheme or port but only on domain [2]. In addition, a website can set cookies with flexible domain scopes: 1) not shared (*i.e.*, host-only), 2) shared with its subdomains, or 3) shared with its sibling domains (i.e., using its parent domain as the scope). For the third case, a restriction is enforced by browser to ensure that a cookie domain scope is not "too wide". For example, `www.example.com` can set a cookie with the scope of `.example.com`, but it cannot set a cookie with `.com` as the scope because `.com` is a public top level domain (TLD). Unfortunately, there is no clear definition of whether a domain scope is "too wide" (See Section 3.2).

The combination of the read/write asymmetry and the lack of domain or scheme segregation implies that a domain cannot protect the integrity of its cookie from an active MITM or a malicious/compromised *related domain* that shares some cookie domain scope with it. There are two forms of cookie integrity violations:

- **Cookie Overwriting.** If a cookie shares the domain scope with a related domain, it can be directly overwritten by that domain using another cookie with the exactly same name/domain/path. Of particular note, although a `secure` cookie can only be read by an HTTPS process, it can be written or overwritten by an HTTP request.
- **Cookie Shadowing.** Alternatively, an attacker with the control of a related domain can intentionally *shadow* a cookie by injecting another one that has the same name, but different domain/path scope. For example, to shadow a cookie with "value=good; domain=www.example.com; path=/; secure", a related domain `evil.example.com` can write a cookie with "value=bad; domain=.example.com; path=/home". Later, when browser issues a request to `https://www.example.com/home`, both cookies match the URL and are included. For most browsers, the cookie header will be "Cookie: value=bad; value=good;". The "good" cookie could be shadowed by the "bad" one if a website happens to prefer the value of "bad" over "good".

  Note while the "good" cookie has a `secure` flag and is sent over HTTPS, it can still be shadowed with a cookie set from an HTTP connection.

2.2 HSTS

HSTS (HTTP Strict Transport Security) allows a server to inform a client to only initiate communications over HTTPS. It was originally proposed by Jackson and Barth to address a number of MITM threats such as cookie sniffing and SSL stripping [18], and is now standardized in RFC6797 as a HTTP response header `Strict-Transport-Security` [15].

The HSTS header requires a `max-age` attribute indicating how long a browser should keep the HSTS policy for that domain. An optional attribute `includeSubDomains` tells a browser to apply the HSTS policy to its all subdomains. After receiving an HSTS header, a conforming browser ensures that all subsequent connections to that domain always take place over HTTPS until the policy expires. Chrome and Firefox also support a preloaded list that contains self-declared websites supporting HSTS. For more information on HSTS, please see [22].

HSTS coverage can often be incomplete. For example, if `example.com` does not specify `includeSubDomains` in its HSTS header, a browser will allow HTTP connection to `foo.example.com`. Worse, even if the HSTS policy of `example.com` specifies `includeSubDomains`, this will not be checked by a browser if a user only visits `bar.example.com` unless the page includes a reference to `example.com`.

2.3 Cookie Injection Attacks

It is a known vulnerability that cookies can be injected by HTTP response into subsequent HTTPS request, and from one domain to another related domain. Johnston and Moore reported such problem in 2004 [19]. Their report already pinpointed the root cause: the loosely defined SOP for cookies. Unfortunately browsers vendors did not fix the problem probably because they were concerned of potential incompatibility issues. In 2008, Evans described an attack called *cookie forcing* that exploits cookie integrity deficiency to overwrite cookies in HTTPS sessions [7]. In 2013, GitHub migrated their domain for hosting users' homepages from `github.com` to `github.io` after they recognized the threat of cookie injection from/to a *shared domain* whose subdomains belong to mutually untrusted users; they described detailed steps of several possible cookie injection exploits and referred to them as *cookie tossing* [11].

The problem was also noted in several more formal publications. Barth *et al.* discussed security implications of cookie overwriting on session initiation [4]. They also proposed a new header `Cookie-Integrity` to provide additional information so that web server can distinguish between cookies set from HTTP and those set from HTTPS. Bortz *et al.* also reviewed the problem and proposed a new header `Origin-Cookie` that guarantees integrity by enforcing a complete 3-tuple SOP [5]. Singh *et al.* referred the difference between the classic SOP and the cookie SOP as inconsistent principal labeling [30]. Both Zalewski's book [32] and the current cookie specification by Barth [2] explained the cookie integrity deficiencies in great detail. We also learned of two technical reports, one from Black Hat EU by Lundeen [23] and the other from Black Hat AD by Lundeen *et al.* [24], that illustrated several subtle attacks initiated by cookie injection.

Although a known threat, previous research fall short of in-depth empirical assessment of its real-world security implications. This work aims to fill this gap. We provide a detailed comparison in Section 7.

3 Threat Analysis

We first present the threat model for cookie injection attacks. For each type of attacker, we analyze its real-world threat. Table 1 gives an overview.

Attacker		Root Cause	Attack Surface	Mitigation
Network Attacker	Active MITM	SOP without protocol & complete domain isolation.	Websites and browsers that allow attackers to reply an unencrypted request to a related domain with forged response.	Full HSTS
	Malicious Proxy			
Web Attacker	Full control of related domain	SOP without complete domain isolation.	Websites using shared domains.	Public suffix list
	XSS on related domain		Websites with compromised related domains.	Out of scope

Table 1: Overview of the threats of cookie injection attacks

3.1 Threat Model

Two classes of attackers can manipulate a target site's cookies: an active network adversary or a remote adversary able to host or inject content on a related domain.

The active MITM attacker (including the classic MITM fully controlling the network and the Man-on-the-Side (*i.e.*, wiretapping and packet-injecting)) can load arbitrary cookies through HTTP into the target's cookie store. The attacker modifies an unrelated HTTP request to create a hidden iframe in a web page. The attacker's iframe then creates a series of HTTP fetches to the target domains, which the attacker responds to with `Set-Cookie` headers to poison the victim's cookie store.

A malicious proxy is at least as powerful as an active MITM in terms of manipulating network traffic. Moreover, because the browser has extra protocol interactions with the proxy, potential logic flaws or implementation bugs might give the malicious proxy additional chances to break in. Chen *et al.* highlighted this threat with a number of logic flaws [6]. Our study also targets this type of issues related to unexpected capabilities for a malicious proxy to inject cookies.

Finally, if an attacker controls a related domain directly, he may launch cookie injection remotely. The attacker does not need full control of the related server, just the ability to host JavaScript. This attacker cannot target arbitrary domains, but can target any other domain under the same "top level" domain.

One key property of all these adversaries is its ability to change state. For example, a victim might only visit her bank from known-good networks, but an attacker can poison the victim's browser when the victim is on an open wireless network. Only later, when the victim has now returned to the "safe" network and visits her bank, does the attack actually affect the victim.

3.2 Attack Surface

Network Attack Surface: The only current protection against an active network attacker requires that the victim's browser *never* issues an unencrypted HTTP connection to a target site or any related domain. This condition holds if 1) the target domain enables HSTS on its *base domain* [1] (*i.e.* the first upper-level domain that is considered "non-public") with the `includeSubDomains` option, which we refer to as *full HSTS*; 2) the browser supports HSTS; and 3) the browser has received the full HSTS policy from the base domain of the target domain.

	Domain Ranking					
	<10	10-10^2	10^2-10^3	10^3-10^4	10^4-10^5	$> 10^5$
Valid HTTPS	7	52	353	2,914	20,548	128,805
Full HSTS	0	1	7	35	212	997

Table 2: Ranking distribution of domains with valid HTTPS and full HSTS.

Unfortunately, the support and adoption of HSTS in the real world is unsatisfactory. First, all current versions of IE, a major browser with considerable marketshare, do not support HSTS (Microsoft announced that its new browser will support HSTS [16]). Second, there is limited adoption of full HSTS among sites. We scanned 961,857 base domains from the Alexa top one million websites and also examined if these domains present in the Chrome's preloaded HSTS list [28]. While we observed 152,679 (15.87%) domains have deployed HTTPS with valid certificates, we only found 1,252 (0.13%) domains have enabled full HSTS. Moreover, most of the full HSTS domains are low ranked domains (see Table 2). A recent study by Kranch and Bonneau also presented a similar total number of full HSTS domains among the Alexa top one million websites [22].

Because of the prevalence of unsafe networks like open wireless networks and the very limited deployment/availability of full HSTS protection, we consider cookie injection by active network attackers a pervasive and severe threat, especially for websites who have deployed HTTPS to prevent active network attackers from launching other possible attacks such as eavesdropping or active script injection, yet have not enabled full HSTS.

Web Attack Surface: Generally, a web attacker might be able to control a related domain in two ways. First, for large websites that all subdomains are used internally, an attacker can fully control one subdomain by compromising its DNS resolution or its hosting server. The attacker can also exploit a XSS vulnerability on a subdomain of a large website. A cookie injection attack can then be launched to target other subdomains.

A greater concern is when a website either hosts user content or shares a domain scope with other possibly untrustworthy sites. This problem is inherent from the

[1] We learned this term from Kranch and Bonneau's recent HSTS study [22].

weaker cookie SOP. As we previously discussed in Section 2.1, a domain is allowed to set cookies with wider domain scope as long as the scope is not considered public. Hence, a clear boundary between "public" and "non-public" domain scope is needed to prevent cookie injection from undesired shared cookie domain. However, this is not easy to define and implement clearly. First, many top-level domains (a.k.a., TLDs), especially country code top-level domains (a.k.a., ccTLDs) have their own reserved suffixes such as `.com.cn`, `.co.uk`, which are mostly TLD-specific. Second, many websites use *shared domains* to assign subdomains to their mutually untrusted clients. Such shared domain providers include cloud hosting providers, web hosting providers, blog providers, CDN providers etc. These shared domains should also be considered as non-public in terms of cookie domain scope.

The problem of cookie domain scope boundary is partially remedied by a community effort initiated by Mozilla called "public suffix list", which maintains an exceptional list containing TLDs, TLD-reserved suffixes, and self-declared shared domains [25]. Public information suggests that the list is enforced by major browser vendors including IE, Chrome, Firefox, and Opera, while our own tests confirm that Safari implements this list.

Our study of the public suffix list shows that the public shared domains list still exposes an attack surface for cookie injection. First, we empirically identified 45 shared domains from the Alexa top one million websites, among which only 10 Google domains and 3 non-Google domains are included in the public suffix list. Among the remaining domains, we found at least 4 domains (`sinaapp.com`, `weebly.com`, `myshopify.com`, and `forumotion.com`) allow customized server-side code or browser-side scripts. Websites hosting on these domains are vulnerable to cookie injection attacks.

Another easy-to-miss corner case is shared domains used by CDNs. CDNs commonly assign subdomains or sub-directories of shared domains to their customers. If a website directly uses a shared domain assigned by its CDN provider, and the CDN provider does not handle the shared domain carefully, then the website is subject to cookie injection attacks from malicious customers of the same CDN provider. While websites rarely use shared domains as their main domains, a common practice is to refer static resources (*e.g.*, JavaScript files, images) using shared domain URLs. Although cookies under these resource URLs are usually not processed by server-side code or browser-side scripts, cookie injection attacks could still cause serious consequences. For example, suppose both websites A and B host their static resource files under one shared domain from the same CDN. Website A can inject garbage cookies from the requests to his resource files with specific paths so that the injected cookies will be sent with the requests of resource files to website B. This type of cookie injection attack could cause performance downgrade, bandwidth consumption, and even denial-of-service (DoS) if the amount of injected cookies exceeds the server's header size limitation[2]. In worst case, DoS of a critical resource file like a JavaScript library could break the whole website.

Vendor	Domain	Publis Suffix List?	Vulnerable?
Akamai	akamai.net	No	n/a [1]
	akamaiedge.net	No	n/a
	akamaihd.net	No	n/a
	edgesuite.net	No	n/a

MaxCDN	netdna-cdn.com	No	Yes
Squixa	squixa.net	No	n/a

1: "n/a" refers to the case that we were not able to test.
2: CDNs attempting to defend cookie related attacks on shared domains by filtering the `Set-Cookie` header.
3: CDNs allowing shared cookie scopes in customer-specific prefixes of shared domains.

Table 3: Assessment of cookie injection attacks on shared domains used by CDNs.

We empirically collected 28 shared domains used by 23 CDNs [3], in which only 2 domains are registered in the public suffix list, as presented in Table 3. We were also able to sign up and test 13 shared domains from 12 CDNs. While we confirmed that `cloudfront.net` is immune because of its presence in the public suffix list, for each of the other 12 domains, we successfully launched DoS attack on one test URL by injecting 72KB cookies from another test URL. Our experiments also found two problematic behaviors. First, CacheFly and KeyCDN attempt to defend cookie related attacks by filtering the `Set-Cookie` header in response instead of utilizing the public suf-

[2] Although the current HTTP specification does not define any limitation on the size of request header [9], most of web server implementations do so by default. For example, nginx by default limits a single HTTP header not to exceed 8KB [26].

[3] We collected most of the CDNs from `http://www.cdnplanet.com/cdns/`.

fix list, which fails to prevent JavaScript from injecting cookies. Second, although Fastly has declared several subdomains of `fastly.net` as public suffix, its naming mechanism enables shared scopes in customer-specific prefixes, making its customers still vulnerable to cookie injection attacks. For example, for a customer `foo.com`, Fastly assigns a customer subdomain `foo.com.global.prod.fastly.net`. Although the suffix `global.prod.fastly.net` is present in the public suffix list, the prefix causes a cookie scope `com.global.prod.fastly.net` shared with other customer subdomains such as `bar.com.global.prod.fastly.net`. CloudFlare also has the same problem. We have reported this problem to all vulnerable vendors. CloudFlare and CDN77 have acknowledged our reports. The response from CloudFlare said that they are considering to disable direct access of all `cloudflare.net` URLs to defend against this problem.

4 Pitfalls in Cookie Implementations

Based on the threat model and the understanding of potential attack surfaces, we then turn to understand how cookie related mechanisms are implemented in browsers and web applications. Our study pinpointed a number of inconsistent and/or non-conforming behaviors in major browsers and web frameworks, as summarized in Table 4. We also identified several vulnerabilities in major browsers allowing an active network attacker to inject cookies even when the full HSTS is deployed. We have reported these vulnerabilities to browser vendors.

4.1 Uncovered Implementation Quirks

Browser-side Cookie Ordering. The current cookie specification [2] suggests that browsers should rank cookies first by path specificity and then by the creation time in ascending order. We found all major browsers follow this suggestion except Safari, which ranks cookies first by the specificity of the domain attribute then by the path specificity.

Server/script-side Cookie Preference. The cookie header is semantically a list. For the same name cookies in the list, the specification states that the server should not rely upon cookie's ordering presented by the browser. We examined popular web programming languages, web frameworks, and third-party libraries including PHP, Python, Java, Go, ASP, ASP.NET, JavaScript, Node.js, JQuery, JSF, SpringMVC. At the language level, only Java, JavaScript and Go provide built-in or standard library interfaces to read cookies as a list. Other languages, and all web frameworks and third-party libraries treat the cookie list as a name-value map that only returns one value for each cookie name in the list. For cookies with the same name, while the name-value map interface in Python standard library prefers the last-ordered cookie, all others prefers the first-ordered one. This explains why cookie shadowing is possible and the example given in Section 2.1 works in many cases.

Cookie Storage Limitation. The specification has several vague suggestions for browsers to limit the number and size of stored cookies. We found all major browsers set the maximum size of a single cookie to 4 KB. Chrome, Firefox, and Opera implements a cookie jar for every base domain, with the total numbers of cookies limited to 180, 150, and 180, respectively. IE's cookie jar implementation is per cookie domain scope, with the total number of cookies limited to 50. We did not reach Safari's cookie storage limit after writing and reading 1,000 cookies.

Cookie Header Size Limit. While Safari does not seem to have a limit for the number of cookies, it truncates the matching cookie list if the length of the cookie header exceeds 8 KB. We did not observe similar behaviors in other browsers.

Cookie Name. The cookie name can contain all US-ASCII values except control characters and separator characters (see definition in [2] and [8]). We found that Safari mistakenly stores cookie name in case-insensitive manner. Some programming languages also implement cookie names incorrectly. Previously Lundeen *et al.* reported that ASP.NET implements cookie names case-insensitively [24]. We found that ASP makes same mistake. In addition, PHP performs percent-decoding on cookie names. For these languages, different cookie names sent by browser are possibly recognized as same name cookies, which embraces another vector for cookie shadowing. For example, PHP interprets a cookie header "%76alue=bad; value=good;" as "value=bad; value=good;", causing the "good" cookie to be shadowed by the "bad" one.

Cookie Path. According to the specification, a cookie matches a URL only when the path scope of the cookie is a sub-directory of (or identical to) the URL path. When a cookie does not specify the `path` scope, the browser is required to set its default path as the directory-portion of the URL path without any trailing slash. We found 4 violations to the standard: 1) Safari[4] implements a substring other than sub-directory matching rule; 2) Firefox and IE match cookie path with not only the URL path, but also the URL query and the URL fragment portion match; 3) Firefox matches a cookie path with a URL path when the former has one more slash than the later; 4) Chrome, Safari, and Opera (Linux and iOS versions) include the trailing slash in default cookie path.

[4] Also Chrome on iOS, but as iOS browsers need to use Apple's rendering engine rather than their own, this is probably due to Apple's decision, not Google's

Cookie Property	Specification	Non-conforming/inconsistent behaviors
Browser-side priority	Cookies SHOULD be ranked by specificity of path then by creation time in ascending order.	1. Safari ranks cookies by specificity of domain then by specificity of path.
Server/script-side preference	Server SHOULD NOT rely on cookie's ordering presented by browsers.	1. Most standard libs and frameworks only provide name-value map interfaces; 2. For each name in the cookie list, Python prefers the last-ordered cookie, others prefer the first-ordered one.
Cookie storage limitation	Several vague suggestions	1. Safari seemingly does not have limitation on the number of stored cookies; 2. Chrome and Firefox limit the size of the cookie store per base domain, IE does so per specific domain scope.
Cookie header size limitation	Not specified	1. Safari truncates the cookie header not to exceed 8,192 bytes.
Cookie name	US-ASCII values except control characters and separator characters (see definition in [2] and [8])	1. Safari is case-insensitive with cookie name; 2. ASP and ASP.NET are case-insensitive; 3. PHP performs percent-decoding on cookie name.
Cookie path	1. Cookie path and URL path MUST be identical or sub-directory matching; 2. Trailing slash MUST NOT be included in default cookie path.	1. Firefox and IE matches cookie path not only with URL path, but also with URL query and URL fragments; 2. Safari implements sub-string matching other than sub-directory matching; 3. Firefox allows cookie path has one more slash than the URL path; 4. Chrome, Safari, and Opera under some platforms include trailing slash in the default cookie path.

Table 4: Summaries of non-conforming and inconsistent behaviors found in browser and web server cookie implementations.

4.2 Uncovered Vulnerabilities

Vulnerabilities in Handing Proxy Response. In [6], Chen *et al.* found a number of flaws in major browsers. The root problem resided in the handling of HTTPS responses. Essentially, all browsers at that time could not differentiate an HTTPS response from a proxy and an HTTPS response from the intended server. The flaws were patched after disclosure. However, we found the patches are incomplete: if a proxy replies to a HTTPS `CONNECT` request with an unencrypted 407 (proxy authentication required) response, all major browsers except IE accept the cookies set in 407 response. While some vulnerable browsers display a pop-up window, some accept cookies silently (Table 5).

	Windows	Mac OS	Linux	Android	iOS
IE	–	N/A	N/A	N/A	N/A
Chrome	①	①	①	①	①
Firefox	②	②	②	②	N/A
Safari	②	③	N/A	N/A	②
Opera	①	①	N/A	①	N/A

①: cookie injection with pop-up window.
②: cookie injection without pop-up window.
③: cookie injection and script injeciton.

Table 5: Browser vulnerabilities in handling 407 response by a malicious proxy.

These vulnerabilities allow a malicious proxy to launch cookie injection attacks against a full HSTS site. Users who use proxies or have them set automatically, these vulnerabilities can also be exploited by an active MITM between the victim and the proxy, even if a victim user does not intentionally use the attacker as the proxy.

Vulnerability in Handing Public Suffixes in Safari. As described in Section 3.2, the public suffix list enforces the boundary between public and non-public cookie domain scopes. However we found the implementation of Safari is vulnerable under certain conditions. When Safari issues a request `http://tld/`, it accepts cookies in the response with domain scope as `.tld`, which are shared by all `subdomains.tld`. Because HSTS is not enabled on an entire TLD (in general, there is no A record indicating a server at the TLDs), this vulnerability is exploitable by active network attackers who can forge a DNS response as well as an HTTP response.

Vulnerability in Safari's HSTS Implementation. We also found a vulnerability in Safari's HSTS implementation. When receiving a URL, Safari does percent-decoding and upper-to-lower case conversion on its domain name before issuing a request. However, the HSTS check is performed before the conversion process completes, enabling an attacker to bypass Safari's HSTS check if both capital and percent-encoding are used in the domain name.

5 Real-World Exploitations

Our study aims at understanding the prevalence and severity of potential exploitation by cookie injection in real-world websites. In particular, we are curious about how web developers use cookies, whether they are aware of this problem explicitly and have developed best practices accordingly. With these questions in mind, we conducted black box penetration tests on a number of popular websites with our test accounts. We also reviewed several well-known open source web applications. For penetration tests, we first used browser extensions like EditThisCookie [1] to test manually. For possible exploitations, we then implemented with Bro [27] (for packet sniffing and injection with the `rst` tool) in an open wireless network setting.

We found cookie injection attacks are possible with very large websites and popular open source applications including Google, Amazon, eBay, Apple, Bank of America, BitBucket, China Construction Bank, China UnionPay, JD.com, phpMyAdmin, and MediaWiki, among others. The consequences of attacks include, but are not limited to, XSS, privacy leakage, bypassing of cross-site request forgery (CSRF) defenses, financial loss, and account hijacking. The varieties of vulnerable web applications and exploitations suggest cookie injection is a serious threat in the real world, and deserves a greater attention from the web security community.

The exploitations we found indicate three common cookie usages: 1) using cookies as authentication tokens; 2) associating important and session independent states with cookies; 3) reflecting cookies into HTML. These cookie usages often lead to cookie injection attacks if specific defensive measures are not in place.

We present our exploitations based on these categories, along with the necessary background and additional observations. Please refer Section 4 and Table 4 for the details of different cookie implementations involved in some cases. We extensively make use of cookie shadowing. For these cases, unless otherwise specified, we assume that the web server has the common behavior of preferring the first-ordered cookie for each name in the cookie list.

5.1 Cookies as Authentication Tokens

A common practice in web development is to use a cookie to identify a user session. Many websites further set long expiration durations on session cookies to avoid having users sign in every time. This practice itself is somewhat questionable, because session cookies are sent along with HTTP requests automatically, which facilitate CSRF attacks. Nevertheless, Barth *et al.* showed that CSRF attacks can be defeated with specific defensive principles and techniques in web applications [4].

Also in [4], Barth *et al.* noted a special form of CSRF which they called *login CSRF*. In this attack, an attacker signs in with his own account on the victim's browser. If not noticed, the victim might visit targeted web site on behalf of the attacker's account, resulting in security and privacy consequences such as search history leakage, credit card stealing, and XSS. The authors also pointed out that login CSRF is a special form of a threat they called *Authenticated-as-Attacker*, which can also be carried out by injecting malicious session cookies to overwrite original ones.

In fact, the consequences of cookie injection on session cookies can go beyond those described in [4]. We found that, by using cookie shadowing, similar attacks could be carried out without noticeable evidences by the victim. We call our attacks *sub-session hijacking attacks*.

5.1.1 Exploiting Google Chat and Search

We first present two exploits targeting Google, which lead our observation of the sub-session hijacking attack. Google's base domain `google.com` is not protected with full HSTS, so in most cases it is subject to cookie injection by an active network attacker.

Case-1: Gmail chat gadget hijacking. The web interface of Gmail at `https://mail.google.com/` shows a chat gadget at the bottom left corner. If an attacker hijacks the gadget without affecting Gmail and other Google services, he can fake the victim's friend list and chat with the victim to initiate advanced phishing, intercept communication, or perform other disruptive activity. This could be particularly deceptive in a targeted attack scenario.

We have confirmed this attack. Although the browser displays everything as one page, the chat gadget and Gmail content are actually loaded with different URLs then composed together. Both the chat gadget and Gmail use cookies for authentication. If an attacker injects his Google session cookies in a way that the injected cookies shadow the original ones only at the chat gadget related URLs, then the attacker can put his chat gadget on the victim's screen, without disturbing the victim's use of Gmail and other Google services.

We demonstrated this attack by injecting a total of 25 cookies: five session cookies "SID/SSID/HSID/APISID/SAPISID", each with five specific paths. Meanwhile most Google services are not affected because the specific paths of the injected cookies do not match with their URL paths. This is sufficient to cause the chat window to load with the attacker's cookies, while all other components are loaded as the victim.

Case-2: "Invisible" Google search history stealing. Another attack is to use cookie shadowing to steal Google search history (which is automatically logged and retrievable with the login cookie) without being noticed. We assume that a user has visited `https://www.google.com/`, which shows the search box and her profile name and icon. When she types in the search box, browser-side script issues AJAX requests to `https://www.google.com/search` to get search results.

Our original goal was to only shadow the session cookies of the AJAX request, so that we could steal search history without affecting the web interface loaded by `https://www.google.com/`. But it turned out we could not achieve this. We first injected three relevant session cookies "SID/SSID/HSID" with path "/search". However, this attempt failed because we found the server unusually preferred the last-ordered cookie, and the injected cookies were ranked before the legitimate ones because of the specific path. We then found out a way to only shadow the session cookies of the AJAX request on Safari by exploiting its cookie header limitation (see Case-5 in Section 5.1.5 for the details). However, the server seemed to check whether session cookies under `https://www.google.com/search` are consistent with those under `https://www.google.com/`. Once receiving inconsistent session cookies from the AJAX request, it navigated the web interface to `https://www.google.com/search`, which still showed the attacker's profile name and icon.

Our final attack was to inject session cookies with domain scope "`www.google.com`" and path "/", so that for non-Safari browsers, the attacker could steal the victim's search history. Although this attack affects the web interface, causing to show the attacker's profile name and icon, it does not affect most other Google services. We also verified an invisible attack by spoofing the victim's profile name and icon.

5.1.2 Sub-session Hijacking Attacks

The two cases above show a common pattern: the attacker intends to limit the effective scope of injected session cookies as small as possible to reduce the visibility of his attack.

Essentially, web applications require one or more request-reply pairs with different URLs, which we view as different *sub-sessions*. In a normal case, when a user views a web page or performs a certain action through a series of pages, the corresponding sub-sessions carrying the same user authentication tokens are attributed to the user's account. However, when using cookies as authentication tokens, the cookie-URL matching rules and implementations often allow the attacker to selectively associate one or more sub-sessions to the attacker's account by cookie shadowing. That is why we call this type of attack sub-session hijacking attacks.

The impact of such attacks varies by the applications. In general, the attacker's strategy is to select a minimum set of sub-sessions that achieve his attack goals meanwhile keep the visibility of the attack as small as possible. However such attack could be made difficult by some implementation choices.

First, in general, a victim could notice a sub-session hijacking attack if she views abnormal changes of some visual elements on her screen. Typically such elements include username, email, a profile icon *etc.*, which we refer to as *ID-indicators*. If a website uses less URLs in one page or one certain functionality, and makes the important URLs related with the ID-indicators, the attacker is less likely to perform sub-session hijacking without being noticed. For example, in Case-2, the attacker has to hijack both of the URL that shows the search interface, and the AJAX request that performs the search. This limitation causes the expose of his profile name and icon, which may be noticed by the victim. However, if the attacker can only hijack an AJAX request which is not related to the interface, especially ID-indicators, the attack could be launched invisibly.

Second, explicit and session dependent verifiers could bind separate URLs together, so that the attacker needs to hijack more URLs. One example is using a session dependent nonce to counter CSRF attacks. Suppose the attacker wants to steal some sensitive information submitted by a form which is fetched from URL `GetForm` then submitted through URL `SubmitForm`. If the CSRF protection of the form is session dependent, *e.g.* a nonce associated with user session embedded in the form and verified when submitting, the attacker must hijack both `GetForm` and `SubmitForm` so that the CSRF verification does not fail. Otherwise he only needs to hijack `SubmitForm`.

It turns out that sub-session hijacking can be a powerful attack against today's websites. Because many web applications do not adopt mechanisms to bind sub-sessions together, and, for many operations, hijacking one sub-session is sufficient to cause serious consequences. Below we describe three common functionalities that are often vulnerable to sub-session hijacking, demonstrated with real-world cases.

5.1.3 Payment Account Stealing

Many websites require users to associate one or more payment accounts to pay their bills or online purchases. If the attacker hijacks the payment account submission form, he could get sensitive information, or even spend money using the victim's payment account.

Case-3: Credit card stealing on China UnionPay. China UnionPay, a government-owned financial corporation in China, has an online third-party payment service in which users can add their credit/debit cards. Although the process of adding a card involves four URLs as well as authentication via text message, all the URLs merely use one session cookie "uc_s_key" for authentication and the actual data submission is performed at one URL that is not related to any ID-indicator. We have verified that by shadowing the session cookie at the submission URL, the attacker can hijack China UnionPay's credit card association invisibly to obtain the victim's (obfuscated) credit card number and its spending history when the victim uses this interface in the future.

5.1.4 Online Deposit Hijacking

A common feature in many Chinese websites is the ability to deposit money from an online bank (or a third-party payment service like Alipay) into a website for future spending. We found this feature is particularly vulnerable to sub-session hijacking.

The process of online deposit usually includes six steps: 1) the user enters deposit amount; 2) the website generates an ID as a unique identifier of this transaction; 3) the website redirects the user to the selected online bank with the transaction ID; 4) the user authenticates and confirms to withdraw money from the online bank; 5) the online bank notifies the website with the transaction ID and redirects the user back to the website; 6) the website receives the notification from the online bank, and adds the corresponding amount on the user's account according to the transaction ID. The bank site only shows the transaction ID on its interface which is usually an unmeaningful string. If the attacker can hijack the step 2 to associate the transaction ID with his account without being noticed, the victim user is likely to finish all steps on the online bank because there is no abnormal visual indication. Once the victim does so, the money is deposited to the attacker's account.

Case-4: Deposit hijacking on JD.com. `JD.com` is a popular E-commerce website in China. In its implementation of the online deposit feature, the second step uses an AJAX request that is not related to any ID-indicator. We have verified that by shadowing `JD.com`'s session cookie "ceshi3.com" at the `AJAX` request, the attacker can hijack the online deposit invisibly, redirecting funds from the victim into the attacker's `jd.com` account.

5.1.5 Account Hijacking in SSO Association

Single Sign On (SSO) is a technique where an Identity Provider (IdP) provides authentication assertions for a logged-in user to relying parties (RP) for them to authenticate the user. SSO usually enables automatic login on the relying party, providing a better user experience and in some cases better security. This is a popular technique deployed by a number of large websites such as Google and Facebook as IdPs, and many other web sites as relying parties. Popular web protocols used for SSO implementation include OpenID [10] and OAuth [14].

Under certain conditions, SSO systems face a threat called *association violation* [31], in which a victim account on an RP is associated with an attacker's account on an IdP, so that the attacker gains control of the victim's account on the RP. This is likely to happen when 1) the victim is logged-in in the IdP as the attacker, 2) the RP has a feature for its users to associate with their accounts on the IdP, 3) the feature is implemented through redirections without further confirmation. The first condition can be mounted by cookie injection, and the websites satisfying the latter two conditions are not hard to find.

Case-5: Account hijacking against Google OAuth and BitBucket. BitBucket, a popular code hosting service, provides account association with Google by OAuth. If a user is already logged in with Google and has authorized BitBucket to access her Google profile through OAuth, the association is accomplished with two forth-and-back redirections with `https://accounts.google.com/o/oauth2/auth` without confirmation except a final message saying *"You've successfully connected your Google account"*.

Our goal is to hijack the Google OAuth URL to invisibly cause an association violation. There are 5 relevant session cookies: "SID/SSID/HSID" with domain scope ".google.com" and path "/", and "LSID/LSOSID" with domain scope ".accounts.google.com" and path "/". This is challenging because the server seemingly has deployed specific defense to counter cookie injection. First, `accounts.google.com` has enabled HSTS with `includeSubDomains`. Second, if we inject cookies with the same names, the server redirects us to a "CookieMismatch" warning page.

We successfully launch the attack on Safari by taking advantage of Safari's quirks. First, we exploit the HSTS implementation bug (Section 4.2) to inject the attacker's five session cookies with domain scope ".accounts.google.com" and path "/o/oauth2/". Recall that Safari ranks cookies by domain specificness then by path specificness, therefore the injected cookies shadows the legitimate ones. Then, we make use of Safari's 8 KB limitation on the cookie header (see Section 4.1) to get around the same name cookie detection. To achieve this, we inject a number of cookies with specific names and domain/path scopes, so that they are ranked between the injected session cookies and the legitimated session cookies. We control the length of these cookies to "overflow" the cookie list so that Safari truncates the legitimated session cookies when issuing requests to the OAuth URL. This allows us to bypassed all restrictions.

5.2 Cookies as References to Session Independent States

Session fixation is a well-known attack in which an attacker holds a session ID, then persuades a victim to authenticate with that ID so that he gains control of the victim's account [21]. Cookie injection can be used to exploit vulnerable websites that use cookies to store session IDs. Standard defenses, *e.g.* regenerating session ID after login, have been widely adopted.

However, we found that, although some websites have implemented defenses for typical session fixation attacks, they still have similar vulnerabilities for cookie injection. The root cause is that they associate important server-side states with long-term cookies. Moreover, they do not bind these states with user sessions.

The attacker can fixate such cookies by cookie injection (*e.g.*, through cookie overwriting) in order to access and manipulate the associated states. Interestingly, most of the vulnerable websites we found vulnerable are E-commerce websites.

Case-6: Shopping cart tracking/manipulation on popular E-commerce websites. We demonstrate this type of issues on 3 popular E-commerce websites: Apple, eBay, and JD.com. These websites allow unregistered visitors to add items in shopping carts. For better user experience, they never expire the shopping carts on the server side, and use long-term cookies on the browser side as references. We have verified that if the attacker fixates the corresponding cookies using cookie injection, he can track or manipulate shopping carts of the unregistered visitors.

We also found similar problems on Amazon, which are much more serious in terms of the real-world consequences, because they compromise security for registered users.[5]

Case-7: Browsing history and purchase tracking/hijacking on Amazon. Amazon's E-commerce websites use two long-term cookies "session-id" and "ubid-main" to associate with a user's browsing history and the ongoing purchase. Surprisingly, these important states are not associated with the user session (Not as its name suggests, "session-id" is not used for user authentication). Once the attacker fixates the two cookies, he can launch various attacks remotely.

The first exploitation is to track and manipulate the user's browsing history. Amazon keeps all previous viewed items in a user's browsing history. Upon fixating the two referencing cookies, the attacker can track what the victim have viewed on Amazon in real-time. He can also inject unwanted items into the browsing history, which affects the recommendation system.

Moreover, from what we observed, we infer that Amazon keeps a session independent data structure for an on-going purchase, which stores the user, the purchased items, the total amount, the delivery address, and other payment information. The structure is likely created by clicking the "proceed to checkout" button, and released after clicking of the "place your order" button. This structure is associated with the same two cookies referencing the browsing history. By fixating the two cookies and consequently gaining access of the data structure, the attacker has various ways to manipulate the victim's purchase remotely. Below we describe two exploitations:

- **Tracking of all purchases.** First, the attacker can track all purchases of the victim. To do so, he first creates an on-going purchase, of which the internal data structure is also shared with the victim. Later, when the victim makes a purchase, the information is updated to the shared data structure, consequently retrieved by the attacker. On Amazon China, the attacker can see all information of the victim's purchase including items, amount, the victim's name, delivery address, and cellphone number. On Amazon U.S., the delivery address and cellphone number are not visible by the attacker.

- **Potential hijacking of purchases.** When detecting an ongoing purchase by the victim, the attacker can change the delivery address so that the purchase is paid by the victim but sent to the attacker. If the victim confirms the hijacked purchase, she cannot even see where the purchase is hijacked to in her order history, because Amazon only shows "Gifting address". The attacker can even manipulate the purchase in such a way that it is paid by the victim, delivered to the attacker, and only recorded in the attacker's order history. The only limitation of the attack is that if the delivery address is new to the payment option, Amazon requires the victim to confirm the card number, however the interface is arguably not alarming. On Amazon China, this limitation does not apply if the victim chooses to pay with a third-party service like Alipay.

5.3 Cookies reflected into HTML

Another common practice is to store auxiliary variables like preferred language or username as cookies, and reflect these cookies into HTML or script snippets. If not implemented carefully, this practice could make websites vulnerable to various attacks in face of cookie injection.

5.3.1 XSS via Cookie Injection

A direct threat is XSS: if reflected cookies are not sanitized sufficiently, the attacker can embed malicious scripts in reflected cookies to launch XSS attacks through cookie injection.

Case-8: XSS via cookie injection on China Construction Bank, Amazon Cloud Drive, eBay and others. We found a number of websites do not validate reflected cookies sufficiently. Using cookie injection, we successfully mounted XSS against China Construction Bank, Amazon Cloud Drive, eBay and several other websites.

Case-9: Insufficient cookie validation on Bank of America. Among the XSS vulnerabilities we found, the one on the Bank of America website is fairly unique. We

[5] However, we note that many E-commerce sites, including Amazon, use mixed content, and thus are also vulnerable to attackers injecting scripts into the insecure domain that remain in the browser cache.

found that one cookie with path "/" on Bank of America's website could be exploited to inject XSS. At first, our naïve exploitation by overwriting the cookie with a XSS payload failed. The limitation was that the website performed a strict validation on the cookie at the login URL. Only if the cookie was absent would the website set a clean value on the cookie from the response of the login URL, then used it in subsequent requests without validation. Our naïve exploitation was prevented by the strict validation at the login URL.

We found a technique to bypass the limitation, so that the XSS payload can be buried into the victim's browser and triggered when next time the victim logs in by injecting multiple cookies. We injected two cookies. The first one had the same 3-tuple identifier as the legitimate one, but with an expired time to ensure the legitimate cookie was discarded and absent at the login URL. The second injected cookie contained the XSS payload and had a different cookie path "/myaccount" that matched with the first URL after login. Although the server set a clean cookie in the response of the login URL, the specific path of the second injected cookie not only avoid being overwritten by the clean cookie, but also shadowed the clean cookie in subsequent requests, triggering a successful XSS attack.

This case implies a possible misconception that performing a complete cookie validation on one "entry point" is sufficient. In fact, because of the asymmetry between cookie read and write operations, every different URL might bring different and unexpected cookie values no matter how server set cookies in previous responses. Developers must treat every request as a new entry point and carefully validate all associated cookies.

5.3.2 BREACH Attacks through Cookie Injection

In 2002, Kelsey observed that when combining encryption with some compression algorithms, the size of compressed data can be used as a side channel, potentially causing plaintext leakage under certain conditions [20]. Rizzo and Duong found a real-world case in 2012, named as CRIME attack, in which an active network attacker initiates encrypted HTTP requests from a victim browser with different URLs as partially-chosen plaintexts, then infer embedded secrets like session cookies by observing the sizes of the compressed and encrypted requests [29]. Rizzo and Duong also mentioned that a similar attack could also be mounted to infer secrets in encrypted HTTP responses. This was explored and demonstrated by Gluck *et al.*, named as the BREACH attack [12].

BREACH requires the attacker to be able to 1) inject a partially-chosen plaintext into the HTTP response of one webpage, and 2) measure the size of the compressed then encrypted response. An active network attacker satisfies the second condition. If a webpage contains a reflected cookie, the attacker can abuse it with cookie injection as the first vector to launch the BREACH attack to infer secrets in this webpage.

Case-10: BREACH attacks on phpMyAdmin and MediaWiki. We found phpMyAdmin, a popular open source web application for remote database management, reflects a cookie for language preference after sanitization in error page if its value is invalid. The BREACH attack using this cookie can reliably infer the CSRF token in the error page, enabling further CSRF attacks. Similarly, MediaWiki reflects a cookie into its login form, also allowing the BREACH attack to infer the CSRF token in the login page.

5.4 Summary

These exploitations show that cookie injection enables undesired and complicated interactions among cookie implementations, web applications, and various known threats. It is clear that our empirical assessment only touches a part of the whole problem space. Nevertheless, we believe these cases demonstrate that the security implications of cookie's lack of integrity are not well and widely understood by the community, and current cookie practices have widespread problems when cookie injection is taken into consideration.

Report and Response. We have reported all vulnerabilities to the affected websites. Some have acknowledged (*e.g.*, Amazon), and some (*e.g.*, Bank of America) have fixed the issues.

6 Possible Defenses

Some existing techniques can help mitigate this threat, including full HSTS, public suffix list, defensive cookie practices, and anomaly detection.

Full HSTS and Public Suffix List. We strongly recommend that websites deploy full HSTS to prevent cookie injection from active network attackers, as this provides complete protection once a site is pinned by a user visit. The community should also make the effort to raise the awareness of cookie injection attacks, and clarify the different levels of security provided by HTTPS, HSTS, and full HSTS. For websites that host shared domains, the best practice is to use separate domains and register them on the public suffix list. Efforts also should be made to increase the awareness of cookie injection from shared domains and the public suffix list.

Defensive Cookie Practices. For websites that cannot enable full HSTS, and have concerns about cookie injection from related domains, defensive cookie practices may mitigate certain cookie injection threats. For example, frequently invalidating session cookies could reduce the risk of sub-session hijacking. Instead of using cookies, Websites can also use new features in HTML5 like `localStorage` and `sessionStorage` to facilitate browser-side state management, which does not have cookie's integrity deficiencies, although these mechanisms are less convenient for cross-protocol and cross-domain state sharing.

Anomaly Detection. Websites should consider detecting same name cookies in the cookie header, as we discussed in the `accounts.google.com` case. This is reasonable because same name cookies should not be considered a legitimate use according to both the specification and the inconsistent implementations. This detection would protect non-Safari users from attacks using cookie shadowing.

6.1 Proposed Browser Enhancements

We propose several browser-side enhancements to mitigate cookie injection attacks. Our proposals do not require any server-side change, so they would benefit many legacy websites.

6.1.1 Mitigating Active Network Attackers

Currently, Chrome, Firefox and Safari, but not Internet Explorer, have deployed the HSTS support. We believe that if all major browsers could deploy it, websites with full HSTS would be capable of defending against active network attackers in most cases. However, deploying full HSTS needs all subdomains to support HTTPS with valid certificates. There are a number of practical hurdles for websites to satisfy such a strict requirement. For example, Google cannot enable full HSTS, because it is required to support non-HTTPS access for mandatory adult-content filtering at school and some other locations [13]. Kranch and Bonneau also reported the current incapability of Facebook and Twitter to deploy full HSTS [22]. Hence, we believe full HSTS is not likely to be adopted widely in the near future.

To protect a site which cannot deploy full HSTS, a browser must not allow an HTTP connection to replace or shadow secure cookies, effectively adding an HSTS-like pin for any secure cookie. We propose to modify the semantics of the existing cookie store by adding a "do not send" flag and changing the cookie store behavior with the following semantics. We believe these semantic change should provide protections while minimizing the disruption to existing sites:

1. A browser MUST NOT accept a cookie presented in an HTTP response with the `secure` flag set, nor overwrite an unexpired `secure` cookie, except the case in 5.
2. Cookies with the `secure` flag MUST be given higher priority over non-secure cookies.
3. A browser MUST only send the highest priority cookie for any cookie name.
4. In removing cookies due to a too-full cookie store, the browser MUST NOT remove a `secure` cookie when there are non-secure cookies that can be removed.
5. The browser MUST allow an HTTP connection to clear a `secure` cookie by setting an already-expired expiration date, but the browser MUST NOT remove the cookie from the store. Instead, the browser MUST set the "do not send" flag and maintain the original expiration date.
6. The browser MUST NOT send a cookie with the "do not send" flag, nor send any non-secure cookie with the same name.

The first rule prevents an active network attacker from injecting or replacing `secure` cookies. The second and third rules combined prevent an active network attacker from shadowing a secure cookie. The fourth rule prevents an attacker from flooding the cookie store to evict secure cookies. The fifth and sixth rules are subtle but necessary: mixed-content sites might have a "logout" button in HTTP which clears `secure` session cookies. We wish to enable this functionality without allowing attackers to remove and replace a `secure` cookie.

Taken together, our proposals should add HSTS-like pinning to secure cookies within the existing cookie store. If a cookie was set with `secure` flag, an active network attacker can only delete it, which largely mitigates cookie injection attacks [6].

Compatibility. We implemented the first three rules as a Chrome extension[7], and used the extension to manually examined the Alexa top 40 websites. We found one broken case: the signing out operation on `http://www.bing.com/` results in a request-reply with `http://login.live.com/logout.srf` which expires several `secure` session cookies under its SSO IdP domain `live.com`. Allowing HTTP to clear secure cookies should improve compatibility with such signing-out practice.

We also crawled the Alexa top 100,000 domains with both HTTP and HTTPS. In total, 48,039 domains responded with cookies. 152 (0.32%) domains returned `secure` cookies over HTTP; 570 (1.19%) domains responded with cookies that have same name yet different

[6] The non-conforming cookie name behaviors of PHP, ASP, and ASP.NET described in Section 4.1 still expose some possibilities for cookie shadowing. We suggest vendors to fix these incorrect implementations.

[7] `https://github.com/seccookie/ExtSecureCookie`

domains and/or paths. These numbers suggest `secure` cookies over HTTP (incompatible with the first rule) and same name cookies (related to the second and third rules) are rare in real-world websites. We manually examined 10 domains in each case with our extension and did not observe evidence of broken behaviors.

While the results from our compatibility testing are promising, we acknowledge they are preliminary. First, we may have missed subtle incompatibility issues in our manual testing. Second, some incompatibility behaviors may only occur with logged-in sessions and/or specific paths, which our testing may have failed to uncover. We hope our limited experiments will motivate browser vendors to conduct large-scale in-depth compatibility evaluation.

6.1.2 Mitigating Web attackers

A domain can set cookies with a more specific domain scope (*e.g.* host-only) to prevent cookie stealing by XSS from sibling domains. But this currently has no effect on cookie injection since injected cookies with shared domain scopes yet longer paths are effective for cookie shadowing, and longer paths are available in most cases if an adversary is in control of a related domain. Combining the second rule of the above proposals, we suggest:

7. When issuing a request, the browser MUST rank the cookie list by a) presence of the `secure` flag, and b) specificity of the domain scope.

Together with the third rule presented above, this should enable developers to prevent cookies from being overwritten or shadowed by using specific domain scope (together with the `secure` flag when using HTTPS). We have also implemented this policy in the same Chrome extension mentioned above.

7 Related Work

Comparison to Previous Work. We are aware of several research papers that are directly related to cookie's weak SOP and integrity problem [4, 30, 24, 23, 5, 2, 32], and some other papers that are comparable to our work [17, 22]. Among the directly related research, Barth's [2] and Zalewski's work [32] focused on explaining the cause of the cookie integrity problem. Most previous research only briefly touched cookie integrity as a relevant subproblem rather than main topic [4, 30, 24, 23]. Bortz *et al.* 's research is close to ours. Especially, they introduced the notion of a related domain attacker which we use throughout this paper. However, their work is limited to high-level discussion [5]. In summary, previous research has discussed the problem of cookie's lack of integrity, its root cause, and its security implications. However, prior understanding of the subtlety, prevalence, and severity of this problem in the real world is limited. We take a much closer look at the problem space, provide a number of new empirical assessments which we believe will help the community understand the problem more deeply and know the status quo better. Specifically, we conduct a detailed measurement of full HSTS adoption and reveal the threat to CDN customers. Prior to our work, Kranch and Bonneau recently studied full HSTS deployment practice but within a different context [22]. The cookie related problems revealed in our assessment of browser and server libraries are largely unknown, except a few fragmented knowledge from Lundeen's [23] and Lundeen *et al.* 's work [24]. The attack cases we present also supplement previous discussion on potential exploitations in both breadth and depth. Our close-up study also leads us to find promising cookie isolation enhancements that only require browser-side adoption. In contrast, the previous proposed defenses need both browser- and server-side changes [4, 5].

Broadly, our work can be viewed as an in-depth case study of inconsistent access control policies in web. Jackson and Barth's [17] and Singh *et al.* 's work [30] explored this general problem, and each provided various instances. One example illustrated by Jackson and Barth is the ability of JavaScript to read all cookies with matching domain scopes regardless of their paths [17]. This behavior has now been noted explicitly in the current specification [2].

Security Related Cookie Measurement. Zhou and Evans studied the rare deployment of the `HTTPOnly` cookies at the time [33]. They believed that the requirement of both client and server changes played an important hurdle in its adoption. Kranch and Bonneau found many websites deploy HSTS yet do not marked their cookies with the `secure` flag, which are vulnerable to cookie theft in certain conditions [22]. These two measurements were concerned with cookie's confidentiality, while our work looks at the other property, *i.e.* cookie's integrity. Singh *et al.* measured the real-world usages of `secure` cookies (0.07%, 62 out of 89,222 sites) over HTTP and same name cookies (they called duplicate cookies) (5.48%, 4,893 out of 89,222 sites) [30]. Our assessment obtains similar results.

8 Conclusions

Cookies lack integrity. Although long known in community lore, the community has under-appreciated the implications. We have attempted to systematically evaluate the implications of cookie integrity, including evaluating weaknesses and evaluation artifacts in both browser and server libraries, building real-world attacks against major sites including Google and Bank of America, including subtle account-hijack attacks and XSS attacks buried in injected cookies, and developing an alternate browser cookie policy that mitigates the threat from network-level attackers. We expect our work to raise the awareness of the problem, and to provide a context for further discussion among researchers, developers and vendors.

Abstract

Modern Web sites frequently generate JavaScript on-the-fly via server-side scripting, incorporating personalized user data in the process. In general, cross-domain access to such sensitive resources is prevented by the Same-Origin Policy. The inclusion of remote scripts via the HTML script tag, however, is exempt from this policy. This exemption allows an adversary to import and execute dynamically generated scripts while a user visits an attacker-controlled Web site. By observing the execution behavior and the side effects the inclusion of the dynamic script causes, the attacker is able to leak private user data leading to severe consequences ranging from privacy violations up to full compromise of user accounts.

Although this issues has been known for several years under the term Cross-Site Script Inclusion, it has not been analyzed in-depth on the Web. Therefore, to systematically investigate the issue, we conduct a study on its prevalence in a set of 150 top-ranked domains. We observe that a third of the surveyed sites utilize dynamic JavaScript. After evaluating the effectiveness of the deployed countermeasures, we show that more than 80% of the sites are susceptible to attacks via remote script inclusion. Given the results of our study, we provide a secure and functionally equivalent alternative to the use of dynamic scripts.

1 Introduction

Since its beginning in the early nineties, the Web evolved from a mechanism to publish and link static documents into a sophisticated platform for distributed Web applications. This rapid transformation was driven by two technical cornerstones:

1. Server-side generation of code: For one, on the server side, static HTML content was quickly replaced by scripting to dynamically compose the Web server's HTTP responses and the contained HTML/JavaScript on the fly. In turn, this enabled the transformation of the Web's initial document-centric nature into the versatile platform that we know today.

2. Browser-driven Web front-ends: Furthermore, the Web browser has proven to be a highly capable container for server-provided user interfaces and application logic. Thanks to the flexible nature of the underlying HTML model and the power of client-side scripting via JavaScript, the server can push arbitrary user interfaces to the browser that rival their counterparts of desktop application. In addition, and unlike monolithic desktop applications, however, browser-based UIs enable easy incorporation of content from multiple parties using HTML's inherent hypertext capabilities.

Based on this foundation, the recent years have shown an ongoing shift from Web applications that host the majority of their application logic on the server side towards rich client-side applications, which use JavaScript to realize a significant portion of their functionality within the user's browser.

With the increase of the functionality implemented on the client side, the necessity for the JavaScript code to gain access to additional user data rises natrually. In this paper, we explore a specific technique that is frequently used to pull such data from the server to the client-side: Dynamic JavaScript generation.

Similar to HTML, which is often generated dynamically, JavaScript may also be composed on the fly through server-side code. In this composition process, user-specific data is often included in the resulting script code, e.g., within the value of a variable. After delivering the script to the browser, this data is immediately available to the client-side logic for further processing and presentation. This practice is potentially dangerous as the inclusion of script files is exempt from the Same-Origin Policy [23]. Therefore, an attacker-controlled Web page is able to import such a dynamically generated script and observe the side effects of the execution, since all included scripts share the global object of the embedding web document. Thus, if the script contains user-specific data, this data might be accessible to other attacker-controlled JavaScript. Although this attack, dubbed *Cross-Site Script Inclusion* (XSSI), has been mentioned within the literature [31], the prevalence of flaws which allow for this attack vector has not been studied on real-world Web sites.

In this paper we therefore present the first, systematic analysis of this vulnerability class and provide empirical evidence on its severeness. First, we outline the general attack patterns and vectors that can be used to conduct such an attack. Furthermore, we present the results of an empirical study on several high-profile domains, showing how these domains incorporate dynamic scripts into their applications. Thereby, we find evidence that many of these scripts are not or only inadequately protected against XSSI attacks. We demonstrate the sever consequences of these data leaks by reporting on real-world exploitation scenarios ranging from de-anonymization, to targeted phishing attacks up to complete compromise of a victim's account.

To summarize, we make the following contributions:

- We elaborate on different ways an attacker is capable of leaking sensitive data via dynamically generated scripts, enabled by the object scoping and dynamic nature of JavaScript.

- We report on the results of an empirical study on several high-ranked domains to investigate the prevalence of dynamic scripts.

- Using the data collected during our empirical study, we show that many dynamic scripts are not properly protected against XSSI attacks. To demonstrate the severity of the outlined vulnerabilities, we present different exploitation scenarios ranging from de-anonymization to complete hijacking of a victim's account.

- Based on the observed purposes of the dynamic scripts encountered in our study, we discuss secure ways of utilizing such data without the use of dynamically generated scripts.

The remainder of the paper is structured as follows: In Section 2, we explain the technical foundations needed for rest of the paper. Section 3 then covers the general attack patterns and techniques to exploit cross-domain data leakage vulnerabilities. In Section 4, we report on the results of our empirical study and analyze the underlying purposes of dynamic scripts. Furthermore, in Section 5, we provide a scheme that is functionally equivalent, but is not prone to the attacks described in this paper. Section 6 covers related work, Section 7 gives an outlook and Section 8 concludes the paper.

2 Technical Background

In this section, we cover the technical background relevant for this work.

2.1 The Same-Origin Policy

The *Same-Origin Policy* (SOP) is the principal security policy in Web browsers. The SOP strongly separates mutually distrusting Web content within the Web browser through origin-based compartmentalization [23]. More precisely, the SOP allows a given JavaScript access only to resources that have the same *origin*. The origin is defined as the triple consisting of scheme, host, and port of the involved resources. Thus, for instance, a script executed under the origin of `attacker.org` is not able to access a user's personal information rendered under `webmail.com`.

While JavaScript execution is subject to the SOP, the same does not hold true for cross-domain inclusion of Web content using HTML tags. Following the initial hypertext vision of the WWW HTML-tags, such as `image`, may reference resources from foreign origins and include them into the current Web document.

Using this mechanism, the HTML `script` tag can point to external script resources, using the tag's `src` attribute. When the browser encounters such a tag, it issues a request to the foreign domain to retrieve the referenced script. Important to note in this instance is the fact that the request also carries authentication credentials in the form of cookies which the browser might have stored for the remote host. When the response arrives, the script code inherits the origin of the *including* document and is executed in the context of the hosting page. This mechanism is used widely in the Web, for instance to consume third party JavaScript services, such as traffic analysis or advertisement reselling [24].

2.2 JavaScript Language Features

In the following, we cover the most important JavaScript concepts necessary for the rest of the paper.

Scoping In JavaScript, a scope is "a lexical environment in which a function object is executed" [6]. From a developer's point of view, a scope is the region in which an identifier is defined. While C++ or Java make use of block scoping, JavaScript utilizes so-called function scoping. This means that the JavaScript engine creates a new scope for each new function it encounters. As a consequence, an identifier that is locally defined in such a function is associated with the corresponding scope. Only code that is defined within the same function is thus able to access such a variable residing in the *local scope*, whereas global variables are associated with the *global scope*.

Listing 1 shows an example for local and global variables. A local variable in JavaScript can be created by utilizing the var keyword. All variables defined outside of a function are associated with the global scope, whereas code within a function can define variables in the global scope by either omitting the var keyword or explicitly assigning to window.varname.

Listing 1 Example for global and local variables

```
// A global variable
var globalVariable1 = 5;

function globalFunction(){
  // A local variable
  var localVariable = 2;

  // Another global variable
  globalVariable2 = 3;

  // Yet another global variable
  window.globalVariable3 = 4;
}
```

The Prototype Chain As opposed to classical programming languages such as C++ or Java, JavaScript is a prototype-based language. This means that JavaScript's inheritance is not based on classes but directly on other objects, whereas "each object has a link to another object called its prototype" [21]. On creation of an object, it either automatically inherits from Object.prototype or if a prototype object is explicitly provided, the prototype property will point to this object. On access to an object's property, the JavaScript runtime checks whether the current object contains a so-called *own property* with the corresponding name.

If no such property exists, the object's prototype is queried for the same property and if lookup fails again, the process is recursively repeated for the object's prototypes. Hence, objects in JavaScript form a so-called *prototype chain*. Listing 2 gives a commented example for this behavior.

Listing 2 The prototype chain

```
var object1 = {a: 1};
// object1 ---> Object.prototype ---> null

var object2 = Object.create(object1);
// object2 ---> object1
//         ---> Object.prototype ---> null
console.log(object2.a); // 1 (inherited)
```

3 Cross-Domain Data Leakages

In this section, we show how an adversary can utilize an external JavaScript file, which is dynamically generated at runtime, to leak security sensitive data. After first covering the different types of these dynamic scripts, we elaborate on the attacker model and then demonstrate different attack vectors that can be leveraged to leak sensitive data from such a script.

3.1 Dynamic Scripts

As discussed in Section 2.1, Web pages can utilize script-tags to import further JavaScript resources. For the remainder of this paper, we define the term *dynamic script* to describe such a JavaScript resource in case it is generated by the Web server on the fly via server-side code.

As opposed to static scripts, the contents of dynamic scripts may vary depending on factors such as input parameters or session state. In the context of this paper, the latter type is of special interest: If a dynamic JavaScript is generated within a user's authenticated Web session, the contents of this script may contain privacy or security sensitive data that is bound to the user's session data. Thus, an execution of the script can potentially lead to side effects which leak information about this data.

3.2 Attack Method

HTML script tags are not subject to the Same-Origin Policy (see Section 2.1). Hence, script resources can be embedded into cross-domain Web pages. Although such cross-domain Web pages cannot access the source code of the script directly, this inclusion process causes the browser to load and execute the script code in the context of the cross-domain Web page, allowing the importing page to observe the script's behavior. If a dynamic script exposes side effects dependent on sensitive data in the script code, the execution of such a script may leak the secret data.

Figure 1 depicts an example attack. A user is authenticated to his mail provider at webmail.com, thus his browser automatically attaches the corresponding session cookies to all requests targeting webmail.com, which utilizes session-state dependent dynamic scripts. Thus, whenever a user is logged in, the script at webmail.com/script.js creates a global variable containing the current user's email address. In the same browser, the user now navigates to an attacker-controlled Web site at attacker.org. The attacker includes the dynamic script in his own Web page and subsequently, the browser requests the script with attached authentication cookies. Although the script originates

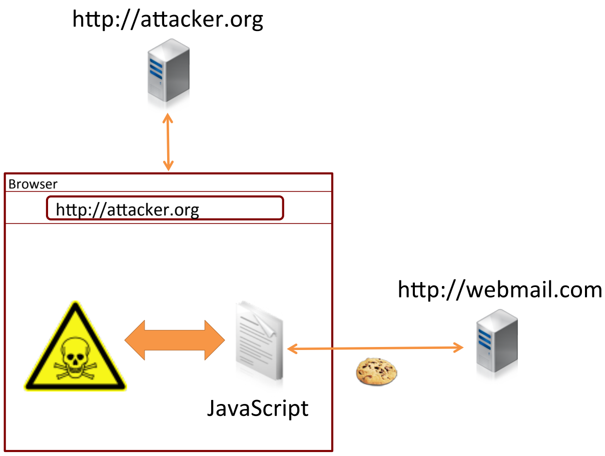

Figure 1: Attacker Model

from `webmail.com`, it is now executed in the context of `attacker.org`, creating the global variable with the user's email in the corresponding context. The global variable is now accessible to any other script executed by `attacker.org`. Hence, the attacker can simply access the value of this global variable, effectively leaking the user's email address.

3.3 Attack Vectors

As previously explained, an attacker is able to leak sensitive user data by including a script from a different domain and observing the results of the execution. In this section we outline different situations in which sensitive data is accessible to an attacker after the included script has been executed.

3.3.1 Global Variables

As noted in the previous section, global variables created by a dynamic script can be accessed by any other script executed on the same Web document. Hence, whenever sensitive user data is assigned to such a global variable inside a script, an attacker can gain access to the corresponding data. In order to do so, he simply includes the script and waits for the global variable to be created. As soon as the value assignment has occurred, the attacker's code can read the sensitive data and leak it back to his backend.

3.3.2 Redefinition of Global APIs

Due to JavaScript's dynamic nature, (almost) any function can be overwritten by an attacker, including a number of globally available APIs. If a dynamic script passes a security-sensitive value to such a function, the attacker may overwrite it beforehand and hence retrieve the secret value. Listing 3 demonstrates how an attacker can, for example, change the behavior of the global function `JSON.stringify`. In order to conduct an attack, the attacker overrides the function first and then includes a dynamic script which passes a sensitive data value to the function. When the user visits the attacker's Web site, his browser retrieves and executes the dynamic script. Rather than invoking the native `JSON.stringify` function, the contained code invokes the attacker-controlled function. In this case, instead of serializing the object, the function sends the user's data back to the attacker's server.

Listing 3 Passing a variable to a global function

```
// Attacker's script overwriting a global function
JSON.stringify = function(data){
  sendToAttackerBackend(data);
}

-------------------------------------------------------
//Within the dynamic script
function myFunction() {
  var myVar = { secret: "secret value"};

  // Calling a predefined global function
  return JSON.stringify(myVar);
}
```

3.3.3 Prototype Tampering

As outlined in the previous section, variables are available in the scope in which they were defined unless the `var` keyword is omitted. Listing 4 shows an example of code making use of this paradigm. The function allocates an array with three secret values using the `var` keyword and therefore, as it seems, protects the array from access by outside code. As discussed in Section 2.2, JavaScript is a prototype-based language. Hence, when requesting a property of an object, the JavaScript interpreter walks up the prototype chain until it finds a matching property. In our example shown in Listing 4, the function `slice` is called on the array named `arr`. By default, an array object does not provide the slice function itself. Therefore, the call is made to the function in the array's prototype, which points to the object `Array.prototype`. In a scenario where the script is included without any malicious intent, the programmer may assume that the call will eventually trigger invocation of the `slice` method for arrays.

This behavior may, however, be changed by an attacker. Listing 5 depicts a small snippet of code that is provided by the attacker. Similar to what we discussed earlier with respect to overwriting global functions, the snippet overwrites the `slice` method in the array's pro-

Listing 4 Variable protected in a closure

```
(function(){
  var arr = ["secret1","secret2","secret3"];
  // intents to slice out first entry
  var x = arr.slice(1);
  ...
})();
```

totype. Since by default all arrays in JavaScript share the same prototype, the call to `slice` in Listing 4 is passed to the attacker-provided function. Since the function is called on the `arr` object, the attacker can use the `this` keyword to gain a reference to the object. Therefore, rather than exhibiting the intended behavior of slicing out a part of the array, the attacker's code now sends the otherwise properly protected information back to the attacker. This attack works for any object that has a globally accessible prototype, i.e., it is feasible on any built-in objects such as Strings or Functions.

Listing 5 Leaking data via the this keyword

```
Array.prototype.slice = function(){
  //leaks ["secret1","secret2","secret3"]
  sendToAttackerBackend(this);
};
```

3.4 Distinction towards CSRF

On first view, the described attack method is related to Cross-site Request Forgery (CSRF) [1], as it follows a similar attack pattern.

In fact, leaking sensitive information via cross-domain script includes belongs to a larger class of Web attacks which function via creating authenticated requests in the context of an authenticated Web user (including CSRF, ClickJacking [12] and reflected Cross-site Scripting [2]).

However, the goal and consequences of the attack differ significantly from other attack variants: CSRF is an attack in which an attacker generates requests to cause state-changing actions in the name of the user. Thereby the attacker is by no means able to read content from a response to a CSRF request. To prevent CSRF developers are advised to conduct state-changing actions only via HTTP POST requests and to protect all these post requests with CSRF tokens.

As opposed to this, dynamic scripts are neither designed to conduct state-changing actions on the server-side nor are these scripts ever fetched via POST requests. Those scripts are stateless and are fetched via GET requests through script tags and, hence, are not classified as a critical endpoint in the context of CSRF, i.e., not contained in the application's CSRF protection surface.

4 Empirical Study

In this section we report on the results of an empirical study designed to gain insights into the prevalence and exploitability of data leakages due to the use of dynamic script generation on the server side. We first discuss the methodology of our study and report on the general prevalence of dynamically generated JavaScript files in the wild. Based on the gathered data, we analyze the underlying purposes of these scripts, discuss the types of security-sensitive data contained in the scripts and highlight who these can be leaked, allowing us specific exploits against a number of sites. We end the section with a discussion of situations in which we could not exploit a dynamic script due to the use of adequate protection measures.

4.1 Methodology

In the following, we cover our research questions, explain our detection methodology and describe our data set.

4.1.1 Research Questions

This study provides an in-depth analysis of dynamic script includes. Before diving into the security aspects of these scripts, we aim at collecting data on this technique in general. Hence, we are first interested in the general prevalence of dynamically generate scripts. More specifically, the goal is to find out how common dynamic script generation is in today's Web and how often these dynamic scripts are dependent on a user's session state. The study sheds light on the purpose of these scripts and the contained data. Finally, we investigate the security aspects by investigating the exploitability and discussing potential countermeasures.

4.1.2 Detecting State-dependent Scripts

As a basis for our empirical study, we needed a means to easily detect state-dependent dynamic scripts. Therefore, we implemented a Chrome browser extension that fulfills two separate tasks:

1. **Collecting scripts:** The first step towards analyzing Web pages for dynamic scripts is the collection of all external script resources included by the Web page. For this purpose, we created a browser extension that collects all included scripts of a page by using a so-called *Mutation Observer* [22]. As soon as a new script node is found, it is immediately passed on to our analysis module.

2. **Detecting dynamic code generation based on authentication credentials:** Whenever the analysis is

invoked, our extension requests the script file twice: once with authentication credentials attached to the request, and once without authentication credentials. After the responses have been received, the extension compares both and if they differ, stores them in a central database for later analysis.

In order to allow for valid credentials to be sent along with the request, a necessary prerequisite are valid session cookies. To obtain these, the user needs to manually log in to the application under investigation beforehand.

The final step in this phase is the manual analysis of the gathered data to precisely determine which scripts have a dynamic nature depending on the user's session state rather than randomness (such as banner rotation scripts).

4.1.3 Data Set

Unlike general vulnerabilities, the detection of potential data leakages through dynamic JavaScript generation requires an active user account (or a similar stateful relationship) at the tested site, so that the scripts are generated in the context of an authenticated Web session.

Since this requires initial manual registration and account set up on sites we want to test, the size and the nature of our data set is limited. We therefore chose the 150 highest ranking (according to Alexa) Web pages matching the following criteria:

1. Account registration and login is freely available for anyone. This excludes, services that have only paid subscription models or require country-dependent prerequisites (such as a mobile phone number).

2. Available in either German, English or a Web site which can be translated using Google Translate. If this is not given, the set up of meaningful user accounts was not feasible.

3. Not a duplicate or localized variant of an already investigated site (e.g. google.com vs. google.co.in)

After manually registering accounts on these sites, we investigated the site employing the methodology and techniques previously explained, thoroughly interacting with the complete functionality of the sites by adding, processing and viewing plausible data within the different Web applications.

4.2 Prevalence of Dynamic Scripts

The first goal of our study was to count the number of Web sites that make use of dynamic script generation. In the course of this study, using our aforementioned methodology, we gathered a total of 9,059 script files spread across 334 domains and their subdomains. Although our data set only consists of 150 different domains, we gathered scripts from such a large number of domains due to the fact that the investigated Web sites include third-party frames pointing to, e.g., advertisement providers. In a first step, we therefore filtered out scripts from all sites not directly related to the domains under investigation.

Out of these, we found that over half of the sites—81 out of the 150 analyzed domains—utilized some form of dynamic script generation. In a subsequent manual examination step we removed dynamic scripts which only exposed changes in apparently random token values (see below for details), resulting in 209 unique scripts on 49 domains, that were dependent on a user's session state. In relation to our initial data set of 150 domains, this shows that the usage of state-dependent dynamic scripts is widespread, namely one third of the investigated domains.

4.3 Purposes of Dynamic Scripts

We analyzed the applications to ascertain the underlying purpose motivating the utilization of the dynamic scripts. In doing so, we found three categories of use cases as well as a few purposes which could not be categorized. Since these were only single use cases specific to one application, we do not outline these any further but instead put them in the *Others* category. The results of our categorization are depicted in Table 1, showing the total amount of domains per category as well as the highest Alexa rank.

The most commonly applied use case was **retrieval of user-specific data**, such as the name, email address or preferences for the logged-in user. This information was used both to greet users on the start page as well as to retrieve user-provided settings and profile data on the corresponding edit pages. We observed that a number of Web applications utilized modal dialogs to present the profile data forms to the user, whereas the HTML code of said form was embedded into the document already and all currently stored values were retrieved by including a dynamic script.

The second category of scripts we found was **service bootstrapping**, i.e., setting up variables necessary for a rich client-side application to work. One example of such a bootstrapping process was observed in a popular free-mail service's file storage system in which the UI was implemented completely in JavaScript. When initially loading the page, the dynamic script we found provided a secret token which was later used by the application to interact with the server using XMLHttpRequests.

Category	# domains	Highest rank
Retrieval of user-specific data	16	7
Service bootstrapping	15	5
Cross-service data sharing	5	8
Others	13	1

Table 1: Amounts and highest Alexa rank of domains with respect to their use case

The third widely witnessed use case was **cross-service data sharing**, which was often applied to allow for single sign-on solutions across multiple services of the same provider or for tracking of users on different domains through a single tracking service. The latter was evidenced by the same script being included across a multitude of domains from different service providers.

4.4 Types of Security Sensitive Data

In a next step, we conducted a manual analysis of the scripts' data that changed its value, depending on the authentication state of the script request. Within our data, we identified four categories of potentially security-critical data:

- **Login state**: The first type of data that could be extracted from dynamic scripts was a user's login state to a certain application. We found that this happened either explicitly, i.e., assign a variable differently if a user is logged in – or implicitly, e.g. in cases where a script did not contain any code if a user was not logged in.

- **Unique identifiers**: The second category we discovered was the leakage of data that uniquely identified the user. Among these values are customer or user IDs as well as email addresses with which a user was registered to a specific application.

- **Personal data**: In this category we classified all those pieces of data which do not necessarily uniquely identify a user, but provide additional information on him, such as his real name, his location or his date of birth.

- **Tokens & Session IDs**: The last category we encountered were tokens and session identifiers for an authenticated user. These tokens potentially provide an attacker with the necessary information to interact with the application in the name of the user.

Table 2 depicts our study's results with respect to the occurrences of each category. Please note, that a given domain may carry more than one script containing security sensitive information and that a given script may fit into more than one of the four categories.

Data	domains	exploitable	highest rank
Login state	49	40	1
Unique Identifiers	34	28	5
Personal data	15	11	11
Tokens & Session IDs	7	4	107

Table 2: Sensitive data contained in dynamic scripts

The following sections give a more detailed insight into these numbers. The final column shows the highest rank of any domain on which we could successfully extract the corresponding data, i.e., on which we could bypass encountered protection mechanisms.

4.5 Exploitation

In the following, we discuss several attacks which leverage the leakage of sensitive user information. After outlining potential attack scenarios, we discuss several concrete examples of attacks we successfully conducted against our own test accounts.

4.5.1 Utilizing Login Oracles

In the previous section, we discussed that 49 domains had scripts which returned somewhat different content if the cookies for the logged in user were removed. In our notion, we call these scripts *login oracles* since they provide an attacker with either explicit or implicit information on whether a user is currently logged into an account on a given website or not. However, out of these domains, nine domains had scripts with unguessable tokens in the URL, therefore these cannot be utilized as login oracles unless the tokens are known, leaving 40 domains with login oracles.

The most prominent script we found to show such a behavior is hosted by Google and is part of the API for Google Plus. This script, which has a seemingly static address, shows differences in three different variables, namely `isLoggedIn`, `isPlusUser` and `useFirstPartyAuthV2` and hence enables an attacker to ascertain a user's login status with Google.

The information obtained from the oracles can be utilized to provide additional bits to fingerprinting approaches [7]. It may however also be used by an attacker to perform a service-specific phishing attack against his victim. Oftentimes, spam emails try to phish user credentials from banks or services the receiving user does not even have an account on. If, however, the attacker knows with certainty that the user currently visiting his website is logged in to, e.g., google.com, he can display a phishing form specifically aimed at users of Google. This attack can also be improved if additional information about the user is known – we will discuss this attack later in this section.

4.5.2 Tracking Users

Out of the 40 domains which provided a login oracle, 28 also provided some pieces of data which uniquely identify a user. Among these features, the most common identifier was the email address used to register for the corresponding service, followed by some form of user ID (such as login name or customer ID). These features can be used to track users even across device platforms, given that they log in to a service leaking this information. The highest-rated service leaking this kind of unique identifier was a top-ranked Chinese search engine. Following that, we found that a highly-frequented page which features a calendar function also contained a script leaking the email address of the currently logged in user. Since the owning company also owns other domains which all use a single sign-on, logging in to any of these sites also enabled the attack.

4.5.3 Personalized Social Engineering

In many applications, we found that email addresses were being leaked to an attacker. This information can be leveraged to construct highly-personalized phishing attacks against users. As Downs et al. [5] discovered, users tend to react on phishing emails in more of the cases if they have a standing business relationship with the sending entity, i.e. have an account on a given site, or the email appears to be for them personally.

Hence, gathering information on sites a user has an account on as well as retrieving additional information such as his name can aid an attacker in a personalized attack. An attacker may choose to abuse this in two ways – first and foremost, trying to send phishing mails to users based on the services they have accounts. However, by learning the email address and hence email provider of the user, an attacker may also try to phish the user's mail account. In our study, we found that 14 different domains leak email addresses and out of these, ten domains also revealed (at least) the first name of the logged in user.

In addition, two domains leaked the date of birth and one script, hosted on a Chinese Web site, even contained the (verified) mobile phone number of the victim. We believe that, especially considering the discoveries by Downs et al., all this information can be leveraged towards creating highly-personalized phishing attacks.

Another form of personalized social engineering attacks enabled by our findings is targeted advertisement. We found that two online shopping platforms utilize a dynamic script which provides the application with the user's wish list. This information can be leveraged by an attacker to either provide targeted advertisements aimed at profiting (e.g. linking to the products on Amazon, using the attacker's affiliate ID) or to sell fake products matching the user's wishes.

Application-Specific Attacks Alongside the theoretical attack scenarios we discussed so far, we found multiple applications with issues related to the analyzed leaking scripts as well as several domains with CSRF flaws. In the following, we discuss these attacks briefly.

Extracting Calendar Entries: One of the most prominent Web sites we could successfully exploit was a mail service which offers a multitude of additional functionality such as management of contacts and a calendar. The latter is implemented mostly in JavaScript and retrieves the necessary bootstrap information when the calendar is loaded. This script, in the form a function call to a custom JavaScript API, provides the application with all of the user's calendars as well as the corresponding entries. This script was not protected against inclusion by third-party hosts and hence, leaks this sensitive information to an attacker. Alongside the calendar's and entries, the script also leaks the e-mail address of the victim, therefore allowing the attacker to associate the appointments to their owner.

Reading Email Senders and Subjects: When logging in to the portal for a big Chinese Web service provider, we found that the main page shows the last five emails for the currently logged in user. Our browser extension determined that this information was provided by an external script, solely using cookies to authenticate the user. The script contained the username, amount of unread emails and additionally the senders and subjects as well as the received dates for the last five emails of the victim. An abbreviated excerpt is shown in Listing 6. Although this attack does not allow for an actual extraction of the content of an email, at the very least contacts and topics of current discussions of the victim are leaked which we believe to be a major privacy issue.

Listing 6 Excerpt of the script leaking mail information

```
var mailinfo = {
  "email": "user@domain.com",
  ...,
  "maillist": [{
    "mid": "0253FE71.....001",
     "mailfrom":"First Last <firstlast@gmail.com>",
    "subject":"Top secret insider information",
    "ctime": "2014-05-02 21:11:46"}]
  ..}
```

Session Hijacking Vulnerabilities: During the course of our study, we found that two German file storage services contained session hijacking vulnerabilitie. Both these services are implemented as a JavaScript application, which utilizes XMLHttpRequest to retrieve directory listings and manage files in the storage. To avoid unauthorized access to the system, both applications require a session key to be present within a cookie as well as in an additional HTTP header. When first visiting the file storage service, the application loads an external script called `userdata.js` which contains the two necessary secrets to access the service: the username and the aforementioned session key. We found that this script is not properly protected against cross-domain data leakage, allowing an attacker to leak the secret information. With this information at hand, we were able to list and access any file in the victim's file storage. Furthermore, it enabled us to invoke arbitrary actions in the name of the user such as creating new files or deleting existing ones.

One minor drawback in this attack is the need for the attacker to know the victim's username in advance, since the dynamic script requires a GET parameter with the username. Regardless, we believe that by either targeted phishing emails or retrieving the email address through another service (as discussed earlier) this attack is still quite feasible.

Circumventing CSRF Protection: One way of preventing cross-domain attacks is the use of CSRF tokens, namely secrets that are either part of the URL (as a GET parameter) or need to be posted in a form and can then be verified by the server. Although CSRF tokens are a well-understood means of preventing these attacks and provide adequate security, the proper implementation is a key factor. In our analysis, we found that two domains contained scripts which leaked just these critical tokens.

The first one was present on a new domain, which required the knowledge of two secrets in order to change profile data of the user – a 25 byte long token as well as the numerical user ID. While browsing the Web site, our extension detected a state-dependent dynamic script that exactly contained these two values. As a consequence, we were able to leak this data and use it to send a properly authenticated profile change request to the corresponding API. As a consequence, we were able to arbitrarily change a user's profile data. Interestingly, one field that was only visible to the user himself contained a stored XSS vulnerability. Hence, we were able to send a Cross-Site Scripting payload within this field to exploit the, otherwise unexploitable, XSS flaw.

Apart from the obvious issues an XSS attack could cause, for a user logged in via the Facebook Social Login, we could retrieve the Facebook API access token and hence interact with the Facebook API in the name of the user, accessing profile information and even make posts in the name of the user.

Similar to the first finding, we found an issue on the highly-ranked domain of a weather service. The application provides an API for changing a user's profile as well as the password, whereas the old password does not need to be entered to set a new one. Nevertheless, the API requires knowledge of the email address of the currently logged in user, thereby employing at least a variant of a CSRF token. Similar to the previously outlined flaw, we found a script that provides information on the user – among which also the email address is contained. Hence, we could successfully automate the attack by first retrieving the necessary token (email) from the leaking script and subsequently sending a password change request to the API. Afterwards, we sent both the email address (which is also used as the login name) and the new password back to our servers, essentially taking over the user's account in a fully automated manner.

4.5.4 Notification of Vulnerable Sites

In order to allow affected pages to fix the vulnerabilities before they can be exploited, we notified the security teams of all domains for which we could successfully craft exploits. To allow for a better understanding of the general vulnerability as well as the specifics of each domain, we created a Web site detailing the problem associated with cross-domain includes of JavaScript and the attack pattern. In addition, we created proof-of-concept exploits for each flaw and shared this information, augmented by a description of the problem and its impact, e.g., the potential to hijack a user's session, with the domains owners.

As of this writing, we received only three replies stating that the flaw was either being dealt with or had been fixed already. However, none of the affected sites agreed to be mentioned in the paper, therefore we opted to anonymize all the vulnerable services we discovered.

4.5.5 Summary of Our Findings

In total, we found that out of the 49 domains which are dependent on the user's login state, 40 lack adequate protection and can therefore be used to deduce if a user is logged into a certain application. On 28 of these domains, dynamic scripts allowed for unique identification of the current user through various means like customer IDs or email addresses.

Additionally and partly overlapping with the aforementioned scripts, we found that personal data (such as the name or location) was contained in scripts on 13 domains. Last but not least, we encountered four domains which allow for extraction of tokens that could in turn be used to control the target application in the name of the victimized user. An overview of these results is depicted in Table 2.

4.6 Non-exploitable Situations

As shown in Table 2, we were not able to leak data from all of the dynamic scripts we found. In general, we identified two different reasons for this: Either the URL of the script was not guessable by an attacker or the Web site utilized referrer checking to avoid the inclusion of resources by third parties. While these mechanisms protected some Web sites from being exploitable, we believe that the corresponding countermeasures were not placed intentionally against the described attack, but were rather in place because of the used application framework (Referrer checking) or because of the application's design (unguessable URLs). In this section, we briefly discuss and analyze these situations.

4.6.1 Unguessable URLs

A prerequisite for the attack described in this paper is that an attacker is able to include a certain script file into his page during a user's visit. For this, the attacker needs to know the exact URL under which a certain dynamic script is available.

Some of the scripts we found required a session ID or another unguessable token to be present in a GET parameter of the URL. As the attacker is in general not able to obtain such a session ID, the script cannot be included by the attacker and hence sensitive data cannot be leaked.

4.6.2 Referrer Checking

Another technique that prevented us from exploiting a script leakage vulnerability was referrer checking. When a browser generates an HTTP request for an embedded script, it adds the Referer header containing the URL of the embedding site. Many Web pages tend to misuse this header as a security feature [31]. By checking the domain of the referrer, a Web site is in theory able to ascertain the origin of the page requesting a resource.

In 2006, however, Johns showed that referrer checking has several pitfalls [17]. As the Referer header was never intended to serve as a security feature, it should not be used as a reliable source of information. So, for example, many proxies and middle boxes remove the Referer header due to privacy concerns. Furthermore, several situations exist in which a browser does not attach a Referer header to a request and as discussed by Kotowicz, an attacker can intentionally remove the header from requests [19].

As a consequence, servers should not rely on the presence of the Referer header. Hence, if a server receives a request for a dynamic script that does not provide a Referer header, it needs to decide whether to allow the request or whether to block it. If the request is allowed, the attacker may force the removal of the referrer as discussed before. On the other hand, if the server blocks the request (strict referrer checking), it might break the application for users behind privacy-aware proxies.

We found several domains that implemented referrer checking. However, of seven pages that conducted such a check, only two conducted strict referrer checking. As a consequence, the other five Web sites were still exploitable by intentionally removing the Referer header. Listing 7 shows the attack we utilized aiming at stripping the Referer header. In this example, we use a data URI assigned to an iframe to embed the leaking script.

Listing 7 Using a data URL within a frame to send a request without a Referer header

```
var url = "data:text/html,"
    + "<script src=’"
    + "http://example.org/dynamic_script.js"
    + "’></script>"

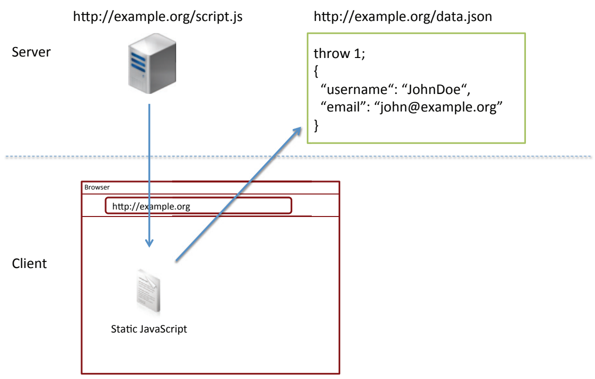
    + "<script>"
    +  "function leakData(){ ... }; "
    +  "leakData();"
    + "</script>";

// create a new iframe
var frame = document.createElement(’iframe’);
// assign the previously created data url
frame.src = url;
body.appendChild(frame);
```

5 Protection Approach

In our study, we observed a surprisingly high number of popular Web sites utilizing the dangerous pattern of using external, dynamically-generated scripts to provide user-specific data to an application. It seems that developers are not aware of the severe consequences this practice has. In order to improve this situation, we provide a secure and functionally-equivalent solution. The main problem of dynamically generated script includes is the incorporation of sensitive user data into files that are not completely protected by the Same-Origin Policy. We discourage this practice and advise developers to strictly separate JavaScript code from sensitive user data.

Figure 2 depicts our design proposal. In this proposal script code is never generated on the fly, but always pulled from a static file. Sensitive and dynamic data values should be kept in a separate file, which cannot be interpreted by the browser as JavaScript. When the static JavaScript gets executed, it sends an XMLHttpRequest to the file containing the data. By default access



```
throw 1;
{
 “username“: “JohnDoe“,
 “email”: “john@example.org”
}
```

Figure 2: Protection scheme

to the response of an XMLHttpRequest is governed by the Same-Origin Policy. Hence, third-party sites cannot request the file within the user's authentication context. As a consequence, attackers cannot access the data contained within this file. By using Cross-Origin Resource Sharing (CORS) [28], Web developers are able to selectively grant access to the file to any third party service that requires access.

While the attacker is able to include and execute the static JavaScript file within his page, the corresponding code will be executed in the origin of the attacker's Web site. Hence, when the script code requests the data file, which resides in the origin of the legitimate Web site, the two origins do not match and hence the Same-Origin Policy protects the file's content from being accessed by the attacker. If, however, the legitimate site requests the data files, the two origins match and thus access is granted.

As the data file does not contain valid JavaScript code, it cannot be included and executed by the attacker via the HTML `script` tag. To completely avoid this risk, Web developers can either include a so-called unparseable cruft to the beginning of file which causes a compile time failure or add valid JavaScript that effectively stops execution during run time, such as an uncatchable exception (cp. Figure 2) [31].

6 Related Work

Conceptually closest to the attacks presented in Section 4.5 is *JSON Hijacking*, an exploitation technique initially presented by Grossman in 2006 [9]. In his attack he utilized a cross-domain script include pointing to a JSON-array resource, which originally was intended as an end-point for an XMLHttpRequest. Via using a non-standard redefinition of JavaScript's object constructor, he was able obtain the content of the user's GMail address book. Grossman reported the issue to Google, where the term Cross-Site Script Inclusion (XSSI) was coined by Christoph Kern. Kern later mentioned the term publicly for the first time in his book from 2007 [18]. Several other authors later on picked up this term to refer to slight variations of the attack [27, 31].

At the same time Chess et al. [3] picked up Grossman's technique, slightly generalized it and coined the term *JavaScript Hijacking*. Unlike the vulnerabilities in this paper, these attacks do not target dynamic JavaScript resources. Instead they use `script`-tags in combination with a non-standard JavaScript quirk (that has been removed from all major browsers in the meantime) to leak data that is encoded in the JSON-array format.

Furthermore, in 2013, Grossman [11] discussed the idea of utilizing resources which are only accessible by users that are logged in to determine the logon status of a user. He also proposed to employ click-jacking attacks on the user to force him to like the attacker's Facebook or Google+ site. In doing so and in comparing the latest addition to his followers, an attacker could thereby deduce the identity of the user currently visiting his website. The idea of determining a user logon status was picked up by Evans [8], who demonstrated a login oracle on `myspace.com` by including a Cascading Style Sheet file from the service which changed certain properties based on whether the user was logged in or not.

In 2015, Takeshi Terada presented another variation of the attack that he called Identifier-based XSSI [27]. Terada used script tags to reference CSV files from third-party domains. A CSV file usually consists of a comma separated list of alphanumeric words. Under certain circumstances this list also represents a syntactically correct list of JavaScript variable declarations. Hence, by referencing such a file the JavaScript engine will create a set of global variables named like the values in the CSV file. By enumerating all globally accessible variables, Terada was able leak the contents of the file.

Other related work has focused on CSS-based history leakage [13, 10, 14]. Analogously to login state leakage, retrieval of a user's history allows an attacker to deduce that a victim has an account on a given site, hence enabling him to start target phishing attacks similar to the ones we outlined in Section 4.5.3.

Another means of utilizing history leakage was discussed in 2010 by Wondracek et al. [30], who proposed a scheme capable of de-anonymizing users based on their group membership in OSNs. To do so, they utilized the stolen history of a user to determine the group sites the user had previously visited. Comparing these to a list of the members of the corresponding groups allowed the authors to determine the user's identity. Recently, for a poster, Jia et al. [16] discussed the notion of utilizing timing side-channels on the browser cache to ascertain a user's geo location.

In 2012, Nikiforakis et al [24] conducted a large-scale analysis of remote JavaScript, focusing mainly on the potential security issues from including third-party code. For W2SP 2011, two groups [20, 15] conducted an analysis of cross-domain policies for Flash, aiming specifically at determining those domains which allow access from any domain. Since Flash attaches the cookies for the *target* domain to said requests, they discussed attack scenarios in which a malicious Flash applet is used to retrieve proprietary information.

In addition to these attacks, Paul Stone demonstrated another means of stealing sensitive information across origin boundaries. To do so, he leveraged a timing side channel, allowing him to leak a framed document pixel by pixel [26].

7 Outlook

The goal of this paper was to conduct an initial study into the usage and potential pitfalls of dynamic scripts in real world applications. Our data set of 150 highly ranked domains gives a good glimpse into the problems caused by such scripts. Nevertheless, we believe that a large-scale study could provide additional key insights into the severity of the issue. To enable such a study, an important problem to solve is the automation of the analysis—starting from fully automated account registration and ranging to meaningful interaction with the application. Therefore, implementing such a generic, yet intelligent crawler and investigating how well it can imitate user interaction is a challenging task we leave for future work. Along with such a broader study, enhancements have to be made to cope with the increased amount of data. As an example, our Chrome extension could use advanced comparisons based on syntactical and semantical differences of the JavaScript code rather than based on content. Since our data set was limited by the fact that our analysis required manual interaction with the investigated applications, the need to automate the secondary analysis steps, i.e., examination of the differences and verification of a vulnerability, did not arise.

Recently, the W3C has proposed a new security mechanism called *Content Security Policy* (CSP), which is a "declarative policy that lets authors of a web application inform the client from where the application expects to load resources" [25]. In its default setting, CSP forbids the usage of inline scripts and hence, programmers are compelled to put the code into external scripts. During our study we noticed that many of these inline scripts are also generated dynamically and incorporate sensitive user data. If all these current inline scripts are naively transformed into dynamic, external script resources, it is highly likely that the attack surface of this paper's attacks will grow considerably.

For instance, Doupé et al. [4] developed a tool called *deDacota* which automatically rewrites applications to adhere to the CSP paradigms by moving all inline script code to external scripts. As our work has shown, these external scripts – if not protected properly – may be included by any third-party application and hence might leak secret data. Therefore, we believe that it is imperative that measures are taken to ensure the secure, yet flexible client-side access to sensitive data and that the changing application landscape caused by CSP adoption is closely monitored. As discussed by Weissbacher et al., however, CSP is not yet widely deployed and significantly lags behind other security measures [29].

Furthermore, in this paper, we exclusively focused on dynamic JavaScript that is pulled into the browser via `script`-tags. This is not necessarily the only method, how server generated script content is communicated. An alternative to `script` tags is to transport the code via XMLHttpRequests bodies, which are subsequently passed to the `eval()` API. In future work, we plan to investigate such XMLHttpRequests endpoints in respect to their susceptibility to attack variants related to this paper's topic.

Finally, as related work has indicated, internal application information, such as the login state of a user, may also be leaked via images or style sheets. In this case, the observed effects of a cross-domain element inclusion manifest themselves through side effects on the DOM level, as opposed to a footprint in the global script object. Hence, a systematical further analysis on other classes of server-side content generation that might enable related attacks would be a coherent extension of our work.

8 Summary & Conclusion

In this paper, we conducted a study into the prevalence of a class of vulnerabilities dubbed Cross-Site Script Inclusion. Whenever a script is generated on the fly and incorporates user-specific data in the process, an attacker is able to include the script to observe its execution behavior. By doing so, the attacker can potentially extract the user-specific data to learn information which he otherwise wouldn't be able to know.

To investigate this class of security vulnerabilities, we developed a browser extension capable of detecting such scripts. Utilizing this extension, we conducted an empirical study of 150 domains in the Alexa Top 500, aimed at gaining insights into prevalence and purpose of these scripts as well as security issues related to the contained sensitive information.

Our analysis showed that out of these 150 domains, 49 domains utilize server-side JavaScript generation. On 40 domains we were able to leak user-specific data leading to attacks such as deanonymizing up to full account hijacking. Our practical experiments show that even high-profile sites are vulnerable to this kind of attacks.

After having demonstrated the severe impact these flaws can incur, we proposed a secure alternative using well-known security concepts, namely the Same-Origin Policy and Cross-Origin Resource Sharing, to thwart the identified security issues.

Acknowledgements

The authors would like to thank the anonymous reviewers for their valued feedback. More over, we want to thank our shepherd Joseph Bonneau for the support in getting our paper ready for publication. This work was in parts supported by the EU Project STREWS (FP7-318097). The support is gratefully acknowledged.

Abstract

Modern web applications are increasingly moving program code to the client in the form of JavaScript. With the growing adoption of HTML5 APIs such as `postMessage`, client-side validation (CSV) vulnerabilities are consequently becoming increasingly important to address as well. However, while detecting and preventing attacks against web applications is a well-studied topic on the server, considerably less work has been performed for the client. Exacerbating this issue is the problem that defenses against CSVs must, in the general case, fundamentally exist in the browser, rendering current server-side defenses inadequate.

In this paper, we present ZigZag, a system for hardening JavaScript-based web applications against client-side validation attacks. ZigZag transparently instruments client-side code to perform dynamic invariant detection on security-sensitive code, generating models that describe how – and with whom – client-side components interact. ZigZag is capable of handling templated JavaScript, avoiding full re-instrumentation when JavaScript programs are structurally similar. Learned invariants are then enforced through a subsequent instrumentation step. Our evaluation demonstrates that ZigZag is capable of automatically hardening client-side code against both known and previously-unknown vulnerabilities. Finally, we show that ZigZag introduces acceptable overhead in many cases, and is compatible with popular websites drawn from the Alexa Top 20 without developer or user intervention.

1 Introduction

Most of the over 2 billion Internet users [1] regularly access the World Wide Web, performing a wide variety of tasks that range from searching for information to the purchase of goods and online banking transactions. Unfortunately, the popularity of web-based services and the fact that the web is used for business transactions has also attracted a large number of malicious actors. These actors compromise both web servers and end-user machines to steal sensitive information, to violate user privacy by spying on browsing habits and accessing confidential data, or simply to turn them into "zombie" hosts as part of a botnet.

As a consequence, significant effort has been invested to either produce more secure web applications, or to defend existing web applications against attacks. Examples of these approaches include applying static and dynamic program analyses to discover vulnerabilities or prove the absence of vulnerabilities in programs [2, 3, 4, 5], language-based approaches to render the introduction of certain classes of vulnerabilities impossible [6, 7, 8], sandboxing of potentially vulnerable code, and signature- and anomaly-based schemes to detect attacks against legacy programs.

However, despite the large amount of research on preventing attacks against web applications, vulnerabilities persist. This is due to a combination of factors, including the difficulty of training developers to make use of more secure development frameworks or sandboxes, as well as the continuing evolution of the web platform itself.

In particular, advances in browser JavaScript engines and the adoption of HTML5 APIs has led to an explosion of highly complex web applications where the majority of application code has been pushed to the client. Client-side JavaScript components from different origins often co-exist within the same browser, and make use of HTML5 APIs such as `postMessage` to interact with each other in highly dynamic ways.

`postMessage` enables applications to communicate with each other purely within the browser, and are not subject to the classical same origin policy (SOP) that defines how code from mutually untrusted principals are separated. While SOP automatically prevents client-side code from distinct origins from interfering with each others' code and data, code that makes use of `postMessage` is expected to define and enforce their own security policy. While this provides much greater flexibility to application developers, it also opens the door for vulnerabilities to be introduced into web applications due to insufficient origin checks or other programming mistakes.

postMessage is but one potential vector for the more general problem of insufficient client-side validation (CSV) vulnerabilities. These vulnerabilities can be exploited by input from untrusted sources – e.g., the cross-window communication interface, referrer data, and others. An important property of these vulnerabilities is that attacks cannot be detected on the server side, and therefore any framework for defending against them at runtime must execute within the browser. Also, in contrast to other popular web attack classes such as Cross-Site Scripting (XSS), CSVs represent application logic flaws that are closely tied to the intended behavior of the application and, consequently, can be difficult to identify and defend against in a generic, automated fashion.

In this paper, we propose ZigZag, a system for hardening JavaScript-based web applications against client-side validation attacks. ZigZag transparently instruments client-side code to perform dynamic invariant detection over live browser executions. From this, it derives models of the normal behavior of client-side code that capture essential properties of how – and with whom – client-side web application components interact, as well as properties related to control flows and data values within the browser. Using these models, ZigZag can then automatically detect deviations from these models that are highly correlated with client-side validation attacks.

We describe an implementation of ZigZag as a proxy, and demonstrate that it can effectively defend against vulnerabilities found in the wild against real web applications without modifications to the browser or application itself aside from automated instrumentation. In addition, we show that ZigZag is efficient, and can be deployed in realistic environments without a significant impact on the user experience.

In summary, this paper makes the following contributions:

- We present a novel in-browser anomaly detection system based on dynamic invariant detection that defends clients against previously unknown client-side validation attacks.
- We present a new technique we term *invariant patching* for extending dynamic invariant detection to server-side JavaScript templates, a very common technique for lightweight parameterization of client-side code.
- We extensively evaluate both the performance and security benefits of ZigZag, and show that it can be effectively deployed in several real scenarios, including as a transparent proxy or through direct application integration by developers.

The rest of the paper is organized as follows. In Section 2, we motivate the need for defending against client-side validation vulnerabilities through the introduction of a running example and define our threat model. In Section 3, we present the high-level design of ZigZag. Sections 4 and 5 describe the details of ZigZag's invariant detection and enforcement. We then evaluate a prototype implementation of ZigZag in Section 6. Finally, Sections 7 and 8 discuss related work and conclude the paper.

2 Motivation and Threat Model

To contextualize ZigZag and motivate the problem of client-slide validation vulnerabilities, we consider a hypothetical webmail service. This application is composed of code and resources belonging both to the application itself as well as advertisements from multiple origins. Since these origins are distinct, the same origin policy applies, and code from each of these origins cannot interfere with the others. This type of origin-based separation is typical for modern web applications.

However, in this example, the webmail component communicates with the advertising network via postMessage to request targeted ads given a profile it has generated for its users. The ad network can respond that it has successfully placed ads, or else request further information in the case that a suitable ad could not be found. Figure 1 shows one side of this communication channel, where the advertising component both registers an onMessage event listener to receive messages from the webmail component, as well as sends responses using the postMessage method. In this case, because the ad network does not verify the origin of the messages it receives, it is vulnerable to a client-side validation attack [9].

To tamper with the ad network, an attacker must be able to invoke postMessage in the same context. This can be achieved by exploiting XSS vulnerabilities from user content, framing the webmail service, or exploiting a logic vulnerability. Hence, the attacker has to send an email to a victim user that contains XSS code, or lure the victim to a site that will frame the webmail service.

Despite the fact that the ad network component is vulnerable, ZigZag prevents successful exploitation of the vulnerability. With ZigZag, the webmail service is used through a transparent proxy that instruments the JavaScript code, augmenting each component with monitoring code. The webmail service then runs in a training phase where execution traces of the JavaScript programs are collected. Collected data points include function pa-

```
// Handle a received message
var receiveMessage = function(e) {
    // Missing check on e.origin!
}

var sendMessage = function(e) {
    // Send data to window ‘w’
    w.postMessage(data, ’*’);
}

// Register for messages
window.addEventListener(”message”, receiveMessage, false);
```

Figure 1: Insecure usage of the `postMessage` API in a hypothetical webmail client-side component.

rameters, caller/callee pairs, and return values. Once enough execution traces have been collected, ZigZag uses invariant detection to establish a model of normal behavior. Next, the original program is extended with enforcement code that detects deviations from the baseline established during training. Execution is compared against this baseline, and violations are treated as attacks.

In this example, ZigZag would recognize that messages received by the ad network must originate from the webmail component’s origin, and would terminate execution if a message is received from another origin – for instance, from the user content origin. Due to the nature of CSV vulnerabilities, this attack would go unnoticed for server-side invariant detection systems such as Swaddler [10] as they focus on more traditional web attacks against server-side code. These attacks can either happen on the client alone, where such systems have no visibility, or when server interaction is triggered through exploitation of a CSV vulnerability. In addition, these requests are indistinguishable from benign user interaction. We stress that this protection requires no changes to the browser or application on the server, and is therefore transparent to both developers and users alike.

We expand upon this example service with more vulnerabilities and learned invariants in following sections.

2.1 Threat model

The threat model we assume for this work is as follows. ZigZag aims to defend benign-but-buggy JavaScript applications against attacks targeting client-side validation vulnerabilities, where CSV vulnerabilities represent bugs in JavaScript programs that allow for unauthorized actions via untrusted input.

The attacker can provide input to JavaScript programs through cross-window communication (e.g., `postMessage`), or window/frame cross-domain properties. This can be performed by operating in an otherwise isolated JavaScript context within the same browser. However, the attacker cannot run arbitrary code in a ZigZag-protected context without first bypassing ZigZag, an eventuality we aim to prevent. In particular, we presume the presence of complementary defenses against XSS-based code injection attacks such as Content Security Policy (CSP) [11] or rigorous template auto-sanitization. Therefore, we assume that attackers cannot directly tamper with ZigZag invariant learning and enforcement by, for instance, overwriting these functions in the JavaScript context without first evading the system.

Because ZigZag depends on a training set to learn dynamic invariants, we assume that the training data is trusted and, in particular, attack-free. This is a general limitation of anomaly-based detection schemes, though one that also has partial solutions [12].

3 System Overview

ZigZag is an in-browser anomaly detection system that defends against client-side validation (CSV) vulnerabilities in JavaScript applications. ZigZag operates by interposing between web servers and browsers in order to transparently instrument JavaScript programs. This instrumentation process proceeds in two phases.

Learning phase. First, ZigZag rewrites programs with monitoring code to collect execution traces of client-side code. These traces are fed to a dynamic invariant detector that extracts likely invariants, or models. The invariants that ZigZag extracts are learned over data such as function parameters, variable types, and function caller and callee pairs.

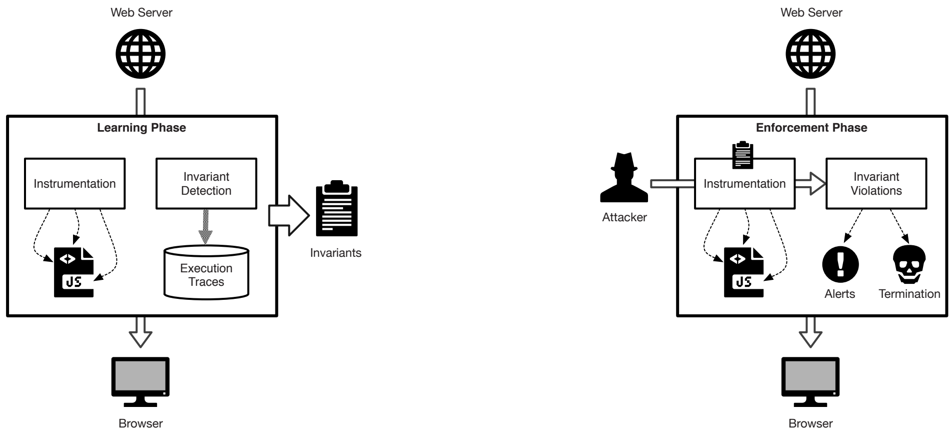
Enforcement phase. In the second phase, the invariants that were learned in the initial phase are used to harden the client-side components of the application. The hardened version of the web application preserves the semantics of the original, but also incorporates runtime checks to enforce that execution does not deviate from what was observed during the initial learning phase. If a deviation is detected, the system assumes that an attack has occurred and execution is either aborted or the violation is reported to the user.

An overview of this system architecture is shown in Figure 2. We note that instrumentation for both the learning phase and enforcement phase is performed *once*, and subsequent accesses of an already instrumented program re-use a cached version of that program.

In the following sections, we describe in detail each phase of ZigZag’s approach to defending against client-side validation vulnerabilities in web applications.

4 Invariant Detection

In this section, we focus on describing the invariants ZigZag learns, why we selected these invariants to enforce, and how we extract these invariants from client-side code.



(a) Learning phase. A JavaScript program is instrumented in order to collect execution traces. Invariant detection is then performed on the trace collection in order to produce a set of likely invariants.

(b) Enforcement phase. Given a JavaScript program and the invariants previously learned, instrumentation is again used to enforce those invariants.

Figure 2: ZigZag overview. Instrumentation is used in both the learning and enforcement phases to produce and enforce likely invariants, respectively. Note that instrumentation is only performed *once* in each case; subsequent loads use a cached instrumented version of the program.

Data Type	Invariants
All	Types
Numbers	Equality, inequality, oneOf
String	Length, equality, oneOf, isJSON, isPrintable, isEmail, isURL, isNumber
Boolean	Equality
Objects	All of the above for object properties
Functions	Calling function, return value

Table 1: Invariants supported by ZigZag.

4.1 Invariant Detection

Dynamic program invariants are statistically-likely assertions established by observing multiple program executions. We capture program state at checkpoints and compare subsets of these states for each individual checkpoint (we define checkpoints in further detail in Section 4.2). The underlying assumption is that invariants should hold not only for the observed executions, but also for future ones.

However, there is no guarantee that invariants will also hold in the future. Therefore, ZigZag only uses invariants which should hold with a high probability. These invariants are later used to decide whether a program execution is to be considered anomalous. By capturing state dynamically, ZigZag has insight into user behavior that purely static systems lack.

ZigZag uses program execution traces to generate Daikon [13] dtrace files. These dtrace files are then generalized into likely invariants with a modified version of Daikon we have developed. Daikon is capable of generating both univariate and multivariate invariants. Univariate invariants describe properties of a single variable; examples of this include the length of a string, the percentage of printable characters in a string, and the parity of a number. Multivariate models, on the other hand, describe relations between two or more variables, for example $x == y$, $x + 5 == y$, or $x < y$.

ZigZag analyzes multivariate relationships within function parameters, return values, and invoking functions. In addition, we extended the invariants provided by Daikon with additional ones, including checks on whether a string is a valid JSON object, URL, or email address.

For example, when used on a website with `postMessage`, ZigZag could learn that the origin attribute of the `onMessage` event is both printable and a URL, or equal to a string. Depending on the number of different origins, the system could also learn the legitimate set of sending origins

$$\text{v0.origin} \in \{o_1, \ldots, o_n\}.$$

As another example, since JavaScript is a dynamically typed language, it has no type annotations in function signatures. This language feature can lead to runtime errors or be exploited by an attacker. By learning likely type invariants over function parameters and return values that are checked during the enforcement phase, ZigZag can (partially) retrofit types into JavaScript programs. For example, this can become security-relevant when developers use numeric values for input, and do not consider other values during input sanitization. We describe an example of parameter injection, and how the attack is thwarted by ZigZag in Section 6.1.

One pitfall of anomaly detection is undertraining. To reduce the impact on our system, we check function coverage before issuing invariants for enforcement. We only allow for enforcement of a particular function after execution traces from four or more training sessions were collected, which was sufficient for the examples we considered. This threshold, however, is configurable and can easily be increased if greater variability is observed during invariant learning.

The full set of invariants supported by ZigZag is shown in Table 1.

4.2 Program Instrumentation

Trace collection and enforcement code is inserted at program points we refer to as *checkpoints*. The finest supported granularity is to insert checkpoints for every statement. However, while this is possible, statement granularity introduces unacceptable overhead with little benefit. The CSV vulnerabilities we have observed in the wild can be detected with a coarser and more efficient level of granularity. Since events such as receiving cross-window communication are handled by functions, function entry and exit points are natural program points to analyze input and return data. Consequently, for our prototype we opted to insert checkpoints at function prologues and epilogues.

During instrumentation, ZigZag performs a lightweight static analysis on the program's abstract syntax tree (AST) to prune the set of checkpoints that must be injected. Functions which contain `eval` sinks, XHR requests, access to the `document` object, and other potentially harmful operations are labeled as important. Only these functions are used in data collection and enforcement mode. As a consequence, large programs that only have few potentially harmful operations will have significantly less overhead as compared to instrumenting the entire program, while at the same time preserving the security of the overall approach. Aside from increased performance, whitelisting functions that are known not to be security-relevant also leads to a reduced risk of false positives.

Each function labeled as important during the static analysis phase is instrumented with pre- and post-function body hooks called `calltrace` and `exittrace`. The original return statement is inlined in the `exittrace` function call and returned by it. These functions access the instrumented function's parameters through the standard `arguments` variable, and either records a program state for invariant detection (learning phase) or checks for an invariant violation (enforcement phase).

```
function x(a, b) {
    // function body
    ...
    return a+b;
}
```

(a) Function body before instrumentation

```
function x(a, b) {
    var callcounter = __calltrace(functionid,
                                  codeid,
                                  sessionid);
    // function body
    ...
    return __exittrace(functionid,
                       callcounter,
                       subexitid,
                       codeid,
                       sessionid,
                       a+b);
}
```

(b) Function body after instrumentation

Figure 3: Function instrumentation example.

ZigZag uses a number of identifiers to label program states at checkpoints. `functionid` uniquely identifies functions within a program, `codeid` labels distinct JavaScript programs, and `sessionid` labels program executions. The variables `functionid` and `codeid` are hardcoded during program instrumentation, while `sessionid` is generated for each request.

The `callcounter` variable is used instead to connect call chains. Every invocation of `calltrace` increments and returns a global `callcounter` to provide a unique identifier such that `calltrace` and `exittrace` invocations can be matched. This is necessary since JavaScript is re-entrant, and therefore multiple threads of execution can invoke a function and yield before returning, potentially resulting in out-of-order pre- and post-function hook invocations.

ZigZag can not only instrument the code initially loaded by a site, but also code dynamically downloaded during execution. JavaScript programs can potentially modify themselves at runtime, since a program can generate code for its own execution. We address this by wrapping `eval` invocations, script tag insertion, and writes to the DOM. Our wrapper sends the new program code to the proxy and calls the original function with the instrumented program. This technique has been shown to be effective in prior work [14].

In our prototype implementation, each of these calls incurs a roundtrip to the server, where such code is treated the same way as non-`eval` code. As a possible optimization, the instrumented version of previously observed data passed to `eval` could be inlined with the enclosing (instrumented) program, removing the need for subsequent separate roundtrips. Furthermore, we often observed `eval` to be used for JSON deserialization. If such a use case is detected, instrumentation could be bypassed entirely. However, we did not find it necessary to implement these features in our research prototype.

The `calltrace` and `exittrace` functions reside in the same scope since they must be callable from all functions. An example of uninstrumented and instrumented code is shown in Figures 3a and 3b, respectively.

5 Invariant Enforcement

Given a set of invariants collected during the learning phase, ZigZag then instruments JavaScript programs to enforce these invariants. Since templated JavaScript is a prevalent technique on the modern web for lightweight parameterization of client-side code, we then present a technique for adapting invariants to handle this case. Finally, we discuss possible deployment scenarios and limitations of the system.

Daikon supports invariant output for several languages, including C++, Java, and Perl. However, it does not support JavaScript by default. Groeneveld et al. implemented extensions to Daikon to support invariant analysis using Daikon [15]. However, we found that their implementation was not capable of generating JavaScript for all of the invariants ZigZag must support, and therefore we wrote our own implementation.

In our implementation, the `calltrace` and `exittrace` functions perform a call to an enforcement function generated for each function labeled important during the static analysis step. `calltrace` examines the function input state, while `exittrace` examines the return value of the original function. These functions are generated automatically by ZigZag for each important function. Based on the invoking program point, assertions corresponding to learned invariants are executed. Should an assertion be violated, a course of action is taken depending on the system configuration. Options include terminating execution by navigating away from the current site, or alternatively reporting to the user that a violation occurred and continuing execution. Figure 4 shows a possible instance of the `calltrace` function, abbreviated for clarity.

5.1 Program Generalization

Modern web applications often make use of lightweight templates on the server, and sometimes within the browser as well. These templates usually take the form of a program snippet or function that largely retains the same structure with respect to the AST, but during instantiation placeholders in the template are substituted with concrete data – for instance, a timestamp or user identifier. This is often done for performance, or to reduce code duplication on the server. As an example, consider the templated version of the webmail example shown in Figure 5.

```
__calltrace = function(functionid, codeid, sessionid) {
    // Enforcement
    var v0 = arguments.callee.caller.caller.arguments[0];
    var v1 = ...

    if ( functionid === 0 ) {
        __assert(typeof(v0) === ’number’ && v0 > 5);
        __assert(typeof(v1) === ’string’ && v1 === ”x”);
        ...
    } else if ( functionid === 1 ) {
        ...
    }
    ...
    return __incCallCounter();
}
```

Figure 4: Example of invariant enforcement over a function’s input state.

```
// Server-side JavaScript template
var state = {
    user: {{username}},
    session: {{sessionid}}
};

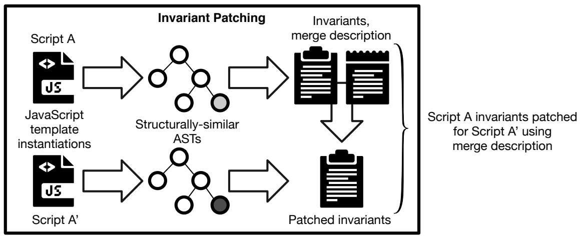
// Client-side JavaScript code after template instantiation
var state = {
    user: ”UserX”,
    session: 0
};
```

Figure 5: Example of a JavaScript template.

Due to the cost of instrumentation and the prevalence of this technique, this mix of code and data poses a fundamental problem for ZigZag since a templated program causes – in the worst case – instrumentation on every resource load. Additionally, each template instantiation would represent a singleton training set, leading to artificial undertraining. Therefore, it was necessary to develop a technique for both recognizing when templated JavaScript is present and, in that case, to generalize invariants from a previously instrumented template instantiation to keep ZigZag tractable for real applications.

ZigZag handles this issue by using efficient structural comparisons to identify cases where templated code is in use, and then performing *invariant patching* to account for the differences between template instantiations in a cached instrumented version of the program.

Structural comparison. ZigZag defines two programs as structurally similar and, therefore, candidates for generalization if they differ only in values assigned to either primitive variables such as strings or integers, or as members of an array or object. Objects play a special role as in template instantiation properties can be omitted or ordered non-deterministically. As a result ASTs are not equal in all cases, only similar. Determining whether this



Invariant Patching
Script A

Script A'
Patched invariants

Figure 6: Invariant patching overview. If ZigZag detects that two JavaScript programs are structurally isomorphic aside from constant assignments, a merge description is generated that allows for efficient patching of previously-generated invariants. This scheme allows ZigZag to avoid re-instrumentation of templated JavaScript on each load.

is the case could be performed by pairwise AST equality that ignores constant values in assignments and normalizes objects. However, this straightforward approach does not scale when a large number of programs have been instrumented.

Therefore, we devised a string equality-based technique. From an AST, ZigZag extracts a string-based summary that encodes a normalized AST that ignores constant assignments. In particular, normalization strips all constant assignments of primitive data types encountered in the program. Also, assignments to object properties that have primitive data types are removed. Objects, however, cannot be removed completely as they can contain functions which are important for program structure. Removing primitive types is important as many websites generate programs that depend on the user state – e.g., setting `{logged_in: 1}` or omitting that property depending on whether a user is logged in or not. Removing the assignment allows ZigZag to correctly handle cases such as these.

Furthermore, normalization orders any remaining object properties such as functions or enclosed objects, in order to avoid comparison issues due to non-deterministic property orderings. Finally, the structural summary is the hash of the reduced, normalized program.

As an optimization, if the AST contains no function definitions, ZigZag skips instrumentation and serves the original program. This check is performed as part of structural summary generation, and is possible since ZigZag performs function-level instrumentation.

Code that is not enclosed by a function will not be considered. Such code cannot be addressed through event handlers and is not accessible through `postMessage`. However, calls to `eval` would invoke a wrapped function, which is instrumented and included in enforcement rules.

Fast program merging. The first observed program is handled as every other JavaScript program because ZigZag cannot tell from one observation whether a program represents a template instantiation. However, once ZigZag has observed two structurally similar programs, it transparently generates a *merge description* and *invariant patches* for the second and future instances.

The merge description represents an abstract version of the observed template instantiation that can be patched into a functional equivalent of new instantiations. To generate a merge description, ZigZag traverses the full AST of structurally similar programs pairwise to extract differences between the instantiations. Matching AST nodes are preserved as-is, while differences are replaced with placeholders for later substitution. Next, ZigZag compiles the merge description with our modified version of the Closure compiler [16] to add instrumentation code and optimize.

The merge description is then used every time the templated resource is subsequently accessed. The ASTs of the current and original template instantiations are compared to extract the current constant assignments, and the merge description is then patched with these values for both the program body as well as any invariants to be enforced. By doing so, we bypass repeated, possibly expensive, compilations of the code.

5.2 Deployment Models

We note that several scenarios for ZigZag deployment are possible. First, application developers or providers could perform instrumentation on-site, protecting all users of the application against CSV vulnerabilities. Since no prior knowledge is necessary in order to apply ZigZag to an application, this approach is feasible even for third parties. And, in this case there is no overhead incurred due to re-instrumentation on each resource load.

On the other hand, it is also possible to deploy ZigZag as a proxy. In this scenario, network administrators could transparently protect their users by rewriting all web applications at the network gateway. Or, individual users could tunnel their web traffic through a personal proxy, while sharing generated invariants within a trusted crowd.

5.3 Limitations

ZigZag's goal is to defend against attackers that desire to achieve code execution within an origin, or act on behalf of the victim. The system was not designed to be stealthy or protect its own integrity if an attacker manages to gain JavaScript code execution in the same origin. If attackers were able to perform arbitrary JavaScript commands, any kind of in-program defense would be futile without support from the browser.

Therefore, we presume (as discussed in Section 2.1) the presence of complementary measures to defend against XSS-based code injection. Examples of such techniques that could be applied today include Content Security Policy (CSP), or any of the number of template auto-sanitization frameworks that prevent code injection in web applications [17, 18, 6].

Another important limitation to keep in mind is that anomaly detection relies on a benign training set of sufficient size to represent the range of runtime behaviors that could occur. If the training set contains attacks, the resulting invariants might be prone to false negatives. We believe that access to, or the ability to generate, benign training data is a reasonable assumption in most cases. For instance, traces could be generated from end-to-end tests used during application development, or might be collected during early beta testing using a population of well-behaving users. However, in absence of absolute ground truth, solutions to sanitize training data exist. For instance, Cretu et al. present an approach that can sanitize polluted training data sets [12].

If the training set is too small, false positives could occur. To limit the impact of undertraining, we only generate invariants for functions if we have more than four sessions, which we found to be sufficient for the test cases we evaluated. We note that the training threshold is configurable, however, and can easily be increased if greater variability is observed at invariant checkpoints. Undertraining, however, is not a limitation specific to ZigZag, but rather a limitation of anomaly detection in general.

With respect to templated JavaScript, while ZigZag can detect templates of previously observed programs by generalizing, entirely new program code can not be enforced without previous training.

In cases where multiple users share programs instrumented by ZigZag, users might have legitimate privacy concerns with respect to sensitive data leaking into invariants generated for enforcement. This can be addressed in large part by avoiding use of the oneOf invariant, or by heuristically detecting whether an invariant applies to data that originates from password fields or other sensitive input and selectively disabling the oneOf invariant. Alternatively, oneOf invariants could be hashed to avoid leaking user data in the enforcement code.

6 Evaluation

To evaluate ZigZag, we implemented a prototype of the approach using the proxy deployment scenario. We wrote Squid [19] ICAP modules to interpose on HTTP(S) traffic, and modified the Google Closure compiler [16] to instrument JavaScript code.

```
// Dispatches received messages to appropriate function
if (e.data.action == ’markasread’) {
    markEmailAsRead(e.data);
}

// Communication with the server to mark emails as read
function markEmailAsRead(data) {
    var xhr = new XMLHttpRequest();
    xhr.open(’POST’, serverurl, true);
    xhr.send(’markasread=’ + data.markemail);
}

// Communication with the ad network iframe
function sendAds(e) {
    adWindow.postMessage({
        ’topic’: ’ads’,
        ’action’: ’showads’,
        ’content’: ’{JSON␣string}’
    }, ”*”);
}
```

Figure 7: Vulnerable webmail component.

```
// Receive JSON object from webmail component
function showAds(data) {
    var received = eval(’(’ + data.content + ’)’);
    // Work with JSON object...
}
```

Figure 8: Vulnerable ad network component.

Our evaluation first investigates the security benefits that ZigZag can be expected to provide to potentially vulnerable JavaScript-based web applications. Second, we evaluate ZigZag's suitability for real-world deployment by measuring its performance overhead over microbenchmarks and real applications.

6.1 Synthetic Applications

Webmail service. We evaluated ZigZag on the hypothetical webmail system first introduced in Section 2. This application is composed of three components, each isolated in iframes with different origins that contain multiple vulnerabilities. These iframes communicate with each other using `postMessage` on `window.top.frames`.

We simulate a situation in which an attacker is able to control one of the iframes, and wants to inject malicious code into the other origins or steal personal information. The source code snippets are described in Figures 7 and 8.

From the source code listings, it is evident that the webmail component is vulnerable to parameter injection through the `markemail` property. For instance, injecting the value `1&deleteuser=1` could allow an attacker to delete a victim's profile. Also, the ad network uses an `eval` construct for JSON deserialization. While highly discouraged, this technique is still commonly used in the wild and can be trivially exploited by sending code instead of a JSON object.

We first used the vulnerable application through the ZigZag proxy in a learning phase consisting of 30 sessions over the course of half an hour. From this, ZigZag extracted statistically likely invariants from the resulting execution traces. ZigZag then entered the enforcement phase. Using the site in a benign fashion, we verified that no invariants were violated in normal usage.

For the webmail component, and specifically the function handling the XMLHttpRequest, ZigZag generated the following invariants.

1. The function is only called by one parent function
2. `v0.topic === 'control'`
3. `v0.action === 'markasread'`
4. `typeof(v0.markemail) === 'number' && v0.markemail >= 0`
5. `typeof(v0.topic) === typeof(v0.action) && v0.topic < v0.action`

For the ad network, ZigZag generated the following invariants.

1. The function is only called by one parent function
2. `v0.topic === 'ads'`
3. `v0.action === 'showads'`
4. `v0.content is JSON`
5. `v0.content` is printable
6. `typeof(v0.topic) === typeof(v0.action) && v0.topic < v0.action`
7. `typeof(v0.topic) === typeof(v0.content) && v0.topic < v0.content`
8. `typeof(v0.action) === typeof(v0.content) && v0.action < v0.content`

Next, we attempted to exploit the webmail component by injecting malicious parameters into the `markemail` property. This attack generated an invariant violation since the injected parameter was not a number greater than or equal to zero.

Finally, we attempted to exploit the vulnerable ad network component by sending JavaScript code instead of a JSON object to the `eval` sink. However, this also generated an invariant violation, since ZigZag learned that `data.content` should always be a JSON object – i.e., it should not contain executable code.

URL fragments. Before `postMessage` became a standard for cross-origin communication in the browser, URL fragments were used as a workaround. The URL fragment portion of a URL starts after a hash sign. A distinct difference between URL fragments and the rest of the URL is that changes to the fragment will not trigger a reload of the document. Furthermore, while SOP generally denies iframes of different origin mutual access to resources, the document location can nevertheless be accessed. The combination of these two properties allows for a channel of communication between iframes of different origins.

We evaluated ZigZag on a demo program that communicates via URL fragments. The program expects as input an email address and uses it without proper sanitization in `document.write`. Another iframe could send unexpected data to be written to the DOM. The code is described in Figure 9.

```
function getFragment ( ) {
    return window.location.hash.substring(1);
}

function fetchEmailAddress() {
    var email = getFragment();
    document.write("Welcome␣" + email);
    // ...
}
```

Figure 9: Vulnerable fragment handling.

After the training phase, we generated the following invariants for the `getFragment` function.

1. The function is only called by one parent function
2. The return value is an email address
3. The return value is printable

6.2 Real-World Case Studies

In our next experiment, we tested ZigZag on four real-world applications that contained different types of vulnerabilities. These vulnerabilities are a combination of previously documented bugs as well as newly discovered vulnerabilities.[1]

These applications are representative of different, previously-identified classes of CSV vulnerabilities. In particular, Son et al. [9] examined the prevalence of CSV vulnerabilities in the Alexa Top 10K websites, found 84 examples, and classified them. The aim of this experiment is to demonstrate that the invariants ZigZag generates can prevent exploitation of these known classes of vulnerabilities.

For each of the following case studies, we first trained ZigZag by manually browsing the application with one user for five minutes, starting with a fresh browser state four times. Next, we switched ZigZag to the enforcement phase and attempted to exploit the applications. We consider the test successful if the attacks are detected with no false alarms. In each case, we list the relevant invariants responsible for attack prevention.

Janrain. A code snippet used by `janrain.com` for user management is vulnerable to a CSV attack. The application checks the format of the string, but does not check the origin of messages. Therefore, by iframing the site, an attacker can execute arbitrary code if the message has a specific format, such as `capture:x;alert(3):`. This is due to the fact that the function that acts as a message receiver will, under certain conditions, call a handler that evaluates part of the untrusted message string

[1] For each vulnerability we discovered, we notified the respective website owners.

as code. Both functions were identified as important by ZigZag's lightweight static analysis. We note that this vulnerability was previously reported in the literature [9]. As of writing, ten out of the 13 listed sites remain vulnerable, including `wholefoodsmarket.com` and `ladygaga.com`.

For the event handler, ZigZag generated the following invariants.

1. The function is only invoked from the global scope or as an event handler
2. `typeof(v0) === 'object' && v0.origin === 'https://dpsg.janraincapture.com'`
3. `v0.data === 's1' || v0.data === 's2'`[2]
4. `v0.data` is printable

For the function that is called by the event handler, ZigZag generated the following invariants.

1. The function is only called by the receiver function
2. `v0 === 's1' || v0 === 's2'`[3]

The attack is thwarted by restricting the receiver origin, only allowing two types of messages to be received, and furthermore restricting control-flow to the dangerous sink.

playforex.ru. This application contains an incorrect origin check that only tests whether the message origin *contains* the expected origin (using `indexOf`), not whether the origin equals or is a subdomain of the allowed origin. Therefore, any origin containing the string "playforex.ru" such as "playforex.ru.attacker.com" would be able to iframe the site and evaluate arbitrary code in that context. We reported the bug and it was promptly fixed. However, this is not an isolated case. Related work [9] has shown that such a flawed origin check was used by 71 hosts in the top 10,000 websites.

ZigZag generated the following relevant invariants.

1. The function is only invoked from the global scope or as an event handler
2. `typeof(v0) === 'object'`
   `&& v0.origin === 'http://playforex.ru'`
3. `v0.data === "$('#right_buttons').hide();"`
   `|| v0.data === 'calculator()'`

ZigZag detected that the `onMessage` event handler only receives two types of messages, which manipulate the UI to hide buttons or show a calculator. By only accepting these two types of messages, arbitrary execution can be prevented.

Yves Rocher. This application does not perform an origin check on received messages, and all received code is executed in an `eval` sink. The bug has been reported to the website owners. 43 out of the top 10,000 websites had previously been shown to be exploitable with the same technique. ZigZag generated the following relevant invariant.

1. `v0.origin === 'http://static.ak.facebook.com' || v0.origin === 'https://s-static.ak.facebook.com'`

From our manual analysis, this program snippet is only intended to communicate with Facebook, and therefore the learned invariant above is correct in the sense that it prevents exploitation while preserving intended functionality.

adition.com. This application is part of a European ad network. It used a `new Function` statement to parse untrusted JSON data, which is highly discouraged as it is equivalent to an `eval`. In addition, no origin check is performed. This vulnerability allows attackers that are able to send messages in the context of the site to replace ads without having full JavaScript execution.

ZigZag learned that only valid JSON data is received by the function, which would prevent the attack based on the content of received messages. This is different than the Yves Rocher example, as data could be transferred from different origins while still securing the site. The bug was reported and fixed.

Summary. These are four attacks against CSV vulnerabilities representative of the wider population. `postMessage` receivers are used on 2,245 hosts out of the top 10,000 websites. Such code is often included through third-party libraries that can be changed without the knowledge of website owners.

6.3 Performance Overhead

Instrumentation via a proxy incurs performance overhead in terms of latency in displaying the website in the browser. We quantify this overhead in a series of experiments to evaluate the time required for instrumentation, the worst-case runtime overhead due to instrumentation, and the increase in page load latency for real web applications incurred by the entire system.

Instrumentation overhead. We tested the instrumentation time of standalone files to measure ZigZag's impact on load times. As samples, we selected a range of popular JavaScript programs and libraries: Mozilla pdf.js, an in-browser pdf renderer; jQuery, a popular client-side scripting library; and, d3.js, a library for data visualization. Where available, we used compressed, production versions of the libraries. As Mozilla pdf.js is not minified by default, we applied the yui compressor for simple minification before instrumenting.

[2] s1 and s2 were long strings, which we omitted for brevity.

[3] s1 and s2 were long strings, which we omitted for brevity.

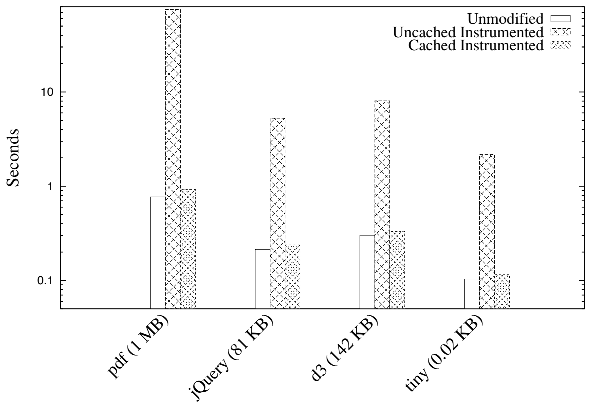

Figure 10: Instrumentation overhead for individual files. While the initial instrumentation can take a significant amount of time for large files, subsequent instrumentations have close to no overhead.

The worker file is at 1.5 MB uncompressed and represents an atypically large file. Additionally, we instrumented a simple function that returns the value of `document.cookie`. We performed 10 runs for cold and warm testing each. For cold runs, the database was reset after every run.

Figure 10 shows that while the initial instrumentation can be time-consuming for larger files, subsequent calls will incur low overhead.

Microbenchmark. To measure small-scale runtime enforcement overhead, we created a microbenchmark consisting of a repeated `postMessage` invocation where one iframe (A) sends a message to another iframe (B), and B responds to A. Specifically, A sends a message object containing a property `process` set to the constant 20. B calculates the Fibonacci number for `process`, and responds with another object that contains the result.

We trained ZigZag on this simple program and then enabled enforcement mode. Next, we ran the program in both uninstrumented and instrumented forms. The subject of measurement was the elapsed time between sending a message from A to B and reception of the response from B to A. We used the high resolution timer API `window.performance.now` to measure the round trip time, and ran the test 100 times each. The results of this benchmark are shown in Table 2.

ZigZag learned and enforced the following invariants for the receiving side.

1. The function is only invoked from the global scope or as an event handler
2. `typeof(v0) === 'object' &&`
   `v0.origin === 'http://example.com'`
3. `v0.data.process === 20`
4. `typeof(v0) === typeof(v0.data)`
5. `typeof(v0.timeStamp) === typeof(v0.data.process) && v0.timeStamp > v0.data.process`

	Uninstrumented	Instrumented
Average Runtime	3.11 ms	3.77 ms
Standard Deviation	1.80	0.54
Confidence (0.05)	0.11	0.35

Table 2: Microbenchmark overhead.

For the message receiver that calculates the response, ZigZag learned and enforced the following invariants.

1. The function is only invoked from the global scope or as an event handler
2. `typeof(v0) === 'object'`
   `&& v0.origin === 'http://example.com'`
3. `typeof(v0.data.process) === 'number'`
   `&& v0.data.process === 20`
4. `typeof(v0.timestamp) === typeof(v0.data.process)`

Finally, for the receiver of the response, ZigZag learned and enforced the following invariants.

1. The function is only invoked from the global scope or as an event handler
2. `typeof(v0) === 'object' &&`
   `v0.origin === 'http://example.com'`
3. `v0.data.response === 6765`
4. `typeof(v0) === typeof(v0.data)`
5. `typeof(v0.timeStamp) === typeof(v0.data.response) && v0.timeStamp > v0.data.response`

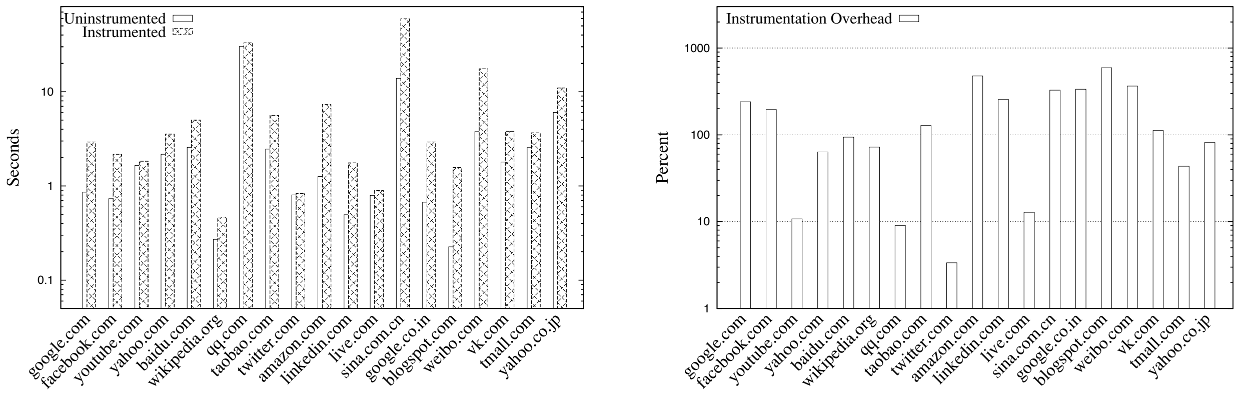
The above invariants represent a tight bound on the allowable data types and values sent across between each origin.

End-to-end benchmark. To quantify ZigZag's impact on the end-to-end user experience, we measured page load times on the Alexa Top 20. First, we manually inspected the usability of the sites and established a training set for enforcement mode. To do so, we browsed the target websites for half an hour each.

We used Chrome to load the site and measure the elapsed time from the initial request to the `window.load` event, when the DOM completed loading (including all sub-frames).[4] The browser was unmodified, with only one extension to display page load time.

Uninstrumented sites are loaded through the same HTTP(S) proxy ZigZag resides on, but the program text

[4] We note, however, that websites can become usable before that event fires.



(a) Absolute load times for uninstrumented and instrumented programs.

(b) Overhead due to instrumentation.

Figure 11: End-to-end performance benchmark on the Alexa 20 most popular websites (excluding hao123.com as it is incompatible with our prototype). A site is considered to be done loading content when the `window.load` event is fired, indicating that the entire contents of the DOM has finished loading.

is not modified. Instrumented programs are loaded from a ZigZag cache that has been previously filled with instrumented code and merge descriptions. However, we do not cache original web content, which is freshly loaded every time.

The performance overhead in absolute and relative terms is depicted in Figure 11. We excluded `hao123.com` from the measurement as it was incompatible with our prototype.[5] On average, load times took 4.8 seconds, representing an overhead of 180.16%, with median values of 2.01 seconds and an overhead of 112.10%. We found server-side templated JavaScript to be popular with the top-ranked websites. In particular, `amazon.com` served 15 such templates, and only 6 out of 19 serve no such templates.

`sina.com.cn` is an obvious outlier, with an absolute average overhead of 45 seconds. With 115 inlined JavaScript snippets and 112 referenced JavaScript files, this is also the strongest user of inline script. Furthermore, we noticed that the site fires the `DOMContentLoaded` event in less than 6 seconds. Hence, the website appears to become usable quickly even though not all sub-resources have finished loading.

In percentages, the highest overhead of 593.36% is introduced for `blogspot.com`, which forwards to Google. This site has the shortest uninstrumented loading time (0.226 seconds) in our data set, hence an absolute overhead will have the strongest implications on relative overhead. That is, in relative numbers, it seems higher than the actual impact on end-users.

We note that we measure the load event, which means that all elements (including ads) have been loaded. Websites typically become usable before that event is fired. Our research prototype could be further optimized to reduce the impact of our technique for performance-critical web applications, for example by porting our ICAP Python code, including parsing libraries, to an ECAP C module. However, generally speaking we believe that trading off some performance for improved security would be acceptable for high assurance web applications and security-conscious users.

6.4 Program Generalization

As discussed in Section 3, ZigZag supports structural similarity matching and invariant patching for templated JavaScript to avoid singleton training sets and excessive instrumentation when templated code is used. We measured the prevalence of templated JavaScript in the Alexa Top 50, and found 185 instances of such code. In addition, the median value per site was three. Without generalization and invariant patching, ZigZag would not have generated useful invariants and, furthermore, would perform significantly worse due to unnecessary re-instrumentation on template instantiations.

6.5 Compatibility

To check that ZigZag is compatible with real web applications, we ran ZigZag on several complex, benign JavaScript applications. Since ZigZag relies on user in-

[5] We discovered, as others have before, that `hao123.com` does not interact well with Squid. We attempted to work around the problem by adjusting Squid's configuration as suggested by Internet forum posts, but this did not succeed. Due to time constraints, we did not expend further effort in dealing with this particular site.

teraction and the functionality of a complex web application is not easily quantifiable, we added manual quantitative testing to augment automated tests. The testers were familiar with the websites before using the instrumented version, and we performed live instrumentation using the proxy-based prototype.

For YouTube and Vimeo, the testers browsed the sites and watched multiple videos, including pausing, resuming, and restarting at different positions. Facebook was tested by scrolling through several timelines and using the chat functionality in a group setting. The testers also posted to a timeline and deleted posts. For Google Docs, the testers created and edited a document, closed it, and re-opened it. For d3.js, the testers opened several of the example visualizations and verified that they ran correctly. Finally, the testers sent and received emails with Gmail and live.com.

In all cases, no enforcement violations were detected when running the instrumented version of these web applications.

7 Related Work

In this section, we discuss ZigZag in the context of related work.

Client-side validation vulnerabilities. CSV vulnerabilities were first highlighted by Saxena et al. [3]. In their work, the authors propose FLAX, a framework for CSV vulnerability discovery that combines dynamic taint analysis and fuzzing into taint-enhanced blackbox fuzzing. The system operates in two steps. JavaScript programs are first translated into a simplified intermediate language called JASIL. Then, the JavaScript application under test is executed to dynamically identify all data flows from untrusted sources to critical sinks such as cookie writes, `eval`, or `XMLHttpRequest` invocations. This flow information is processed into small executable programs called acceptor slices. These programs accept the same inputs as the original program but are reduced in size. Second, the acceptor slices are fuzzed using an input-aware technique to find inputs to the original program that can be used to exploit a bug. A program is considered to be vulnerable when a data flow from an untrusted source to a critical sink can be established.

Later, the same authors improved FLAX by replacing the dynamic taint analysis component with a dynamic symbolic execution framework [4]. Again, the goal of the static analysis is to find unchecked data flows from inputs to critical sinks. This method provides no completeness and can hence miss vulnerabilities.

The main difference between ZigZag and FLAX is that FLAX focuses on detecting vulnerabilities in applications, while ZigZag is intended to defend unknown vulnerabilities against attacks.

DOM-based XSS. Cross-site scripting (XSS) is often classified as either stored, reflected, or DOM-based XSS [20]. In this last type of XSS, attacks can be performed entirely on the client-side such that no malicious data is ever sent to the server. Programs become vulnerable to such attacks through unsafe handling of DOM properties that are not controlled by the server; examples include URL fragments or the referrer.

As a defense, browser manufacturers employ client-side filtering, where the state-of-the-art is represented by the Chrome XSS Auditor. However, the auditor has shortcomings in regards to DOM-based XSS. Stock et al. [21] have demonstrated filter evasion with a 73% success rate and proposed a filter with runtime taint tracking.

DexterJS [22] rewrites insecure string interpolation in JavaScript programs into safe equivalents to prevent DOM-based XSS. The system executes programs with dynamic taint analysis to identify vulnerable program points and verifies them by generating exploits. DexterJS then infers benign DOM templates to create patches that can mitigate such exploits.

JavaScript code instrumentation. Proxy-based instrumentation frameworks have been proposed before [23, 14]. JavaScript can be considered as self-modifying code since a running program can generate input code for its own execution. This renders complete instrumentation prior to execution impossible since writes to code cannot be covered. Hence, programs must be instrumented before execution and all subsequent writes to program code must be processed by separate instrumentation steps.

Anomaly detection. Anomaly detection has found wide application in security research. For instance, Daikon [13] is a system that can infer likely invariants. The system applies machine learning to make observations at runtime. Daikon supports multiple programming languages, but can also be used over arbitrary data as CSV files. In ZigZag, we extended Daikon with new invariants specific to JavaScript applications for runtime enforcement.

DIDUCE [24] is a tool that instruments Java bytecode and builds hypotheses during execution. When violations to these hypotheses occur, they can either be relaxed or raise an alert. The program can be used to help in tracking down bugs in programs semi-automatically.

ClearView [25] uses a modified version of DAIKON to create patches for high-availability binaries based on learned invariants. The focus of the system is to detect and prevent memory corruption through changing the program code at runtime. However, the embedded monitors do not extend to detecting errors in program logic.

Attacks on the workflow of PHP applications have been addressed by Swaddler [10]. Not all attacks on systems produce requests or, more generally, external behavior that can be detected as anomalous. These attacks can be detected by instrumenting the execution environment and generating models that are representative of benign runs. Swaddler can be operated in three modes: training, detection, and prevention. To model program execution, profiles for each basic block are generated, using univariate and multivariate models. During training, probability values are assigned to each profile by storing the most anomalous score for benign data, a level of "normality" is established. In detection and prevention mode, an anomaly score is calculated based on the probability of the execution data being normal using a preset threshold. Violations are assumed to be attacks. The results suggest that anomaly detection on internal application state allows a finer level of attack detection than exclusively analyzing external behavior.

While Swaddler focuses on the server component of web applications, ZigZag characterizes client-side behavior. ZigZag can protect against cross-domain attacks within browsers that Swaddler has no visibility into. Swaddler invokes detection for every basic block, while we use a dynamic level of granularity based on the types of sinks in the program, resulting in a dramatic reduction in enforcement overhead.

Client-side policy enforcement. ICESHIELD [26] is a policy enforcement tool for rules based on manual analysis. By adding JavaScript code before all other content, ICESHIELD is invoked by the browser before other code is executed. Through ECMAScript 5 features, DOM properties are frozen to maintain the integrity of the detection code. ICESHIELD protects users from drive-by downloads and exploit websites. In contrast, ZigZag performs online invariant detection and prevents previously unknown attacks.

ConScript [27] allows developers to create fine-grained security policies that specify the actions a script is allowed to perform and what data it is allowed to access or modify. Conscript can generate rules from static analysis performed on the server as well as by inspecting dynamic behavior on the client. However, it requires modifications to the JavaScript engine, which ZigZag aims to avoid.

The dynamic nature of JavaScript renders a purely static approach infeasible. Chugh et al. propose a staged approach [28] where they perform an initial analysis of the program given a list of disallowed flow policies, and then add residual policy enforcement code to program points that dynamically load code. The analysis of dynamically loaded code can be performed at runtime. These policies can enforce integrity and confidentiality properties, where policies are a list of tuples of disallowed flows (from, to).

Content Security Policy (CSP) [29, 11] is a framework for restricting JavaScript execution directly in the browser. CSP can be effective at preventing significant classes of code injection in web applications if applied correctly (e.g., without the use of `unsafe-inline` and `unsafe-eval`) and if appropriate rules are enforced. However, CSP does not defend against general CSV attacks, and therefore we view it and other systems with similar goals as complementary to ZigZag. In particular, CSP could be highly useful to prevent code injection and thereby protect the integrity of ZigZag in the browser.

Web standards. Although Barth et al. [30] made the HTML5 postMessage API more secure, analysis of websites suggests that it is nevertheless used in an insecure manner. Authentication weaknesses of popular websites have been discussed by Son et al. [9]. They showed that 84 of the top 10,000 websites were vulnerable to CSV attacks, and moreover these sites often employ broken origin authentication or no authentication at all. Their proposed defenses rely on modifying either the websites or the browser.

In ZigZag, we aim for a fine-grained, automated, annotation-free approach that dynamically secures applications against unknown CSV attacks in an unmodified browser.

8 Conclusion

Most websites rely on JavaScript to improve the user experience on the web. With new HTML5 communication primitives such as `postMessage`, inter-application communication in the browser is possible. However, these new APIs are not subject to the same origin policy and, through software bugs such as broken or missing input validation, applications can be vulnerable to attacks against these client-side validation (CSV) vulnerabilities. As these attacks occur on the client, server-side security measures are ineffective in detecting and preventing them.

In this paper, we present ZigZag, an approach to automatically defend benign-but-buggy JavaScript applications against CSV attacks. Our method leverages dynamic analysis and anomaly detection techniques to learn and enforce statistically-likely, security-relevant invariants. Based on these invariants, ZigZag generates assertions that are enforced at runtime. ZigZag's design inherently protects against unknown vulnerabilities as it enforces learned, benign behavior. Runtime enforcement is carried out only on the client-side code, and does not require modifications to the browser.

ZigZag can be deployed by either the website operator or a third party. Website owners can secure their JavaScript applications by replacing their programs with a version hardened by ZigZag, thereby protecting all users of the application. Third parties, on the other hand, can deploy ZigZag using a proxy that automatically hardens any website visited using it. This usage model of ZigZag protects all users of the proxy, regardless of the web application.

We evaluated ZigZag using a number of real-world web applications, including complex examples such as online word processors and video portals. Our evaluation shows that ZigZag can successfully instrument complex applications and prevent attacks while not impairing the functionality of the tested web applications. Furthermore, it does not incur an unreasonable performance overhead and, thus, is suitable for real-world usage.

Anatomization and Protection of Mobile Apps' Location Privacy Threats

Kassem Fawaz, Huan Feng, and Kang G. Shin
The University of Michigan

Abstract

Mobile users are becoming increasingly aware of the privacy threats resulting from apps' access of their location. Few of the solutions proposed thus far to mitigate these threats have been deployed as they require either app or platform modifications. Mobile operating systems (OSes) also provide users with location access controls. In this paper, we analyze the efficacy of these controls in combating the location-privacy threats. For this analysis, we conducted the first location measurement campaign of its kind, analyzing more than 1000 free apps from Google Play and collecting detailed usage of location by more than 400 location-aware apps and 70 Advertisement and Analytics (A&A) libraries from more than 100 participants over a period ranging from 1 week to 1 year. Surprisingly, 70% of the apps and the A&A libraries pose considerable profiling threats even when they sporadically access the user's location. Existing OS controls are found ineffective and inefficient in mitigating these threats, thus calling for a finer-grained location access control. To meet this need, we propose `LP-Doctor`, a light-weight user-level tool that allows Android users to effectively utilize the OS's location access controls while maintaining the required app's functionality as our user-study (with 227 participants) shows.

1 Introduction

Mobile users are increasingly aware of the privacy threats caused by apps' access of their location [12, 42]. According to recent studies [14, 17, 42], users are also taking measures against these threats ranging from changing the way they run apps to disabling location services all together on their mobile devices. How to mitigate location-privacy threats has also been researched for some time. Researchers have proposed and even implemented location-privacy protection mechanisms (LPPMs) for mobile devices [2, 6, 12, 20, 30]. However, few of them have been deployed as they require app or system-level modifications, both of which are unappealing/unrealistic to the ordinary users.

Faced with location-privacy threats, users are left only with whatever controls the apps and OSes provide. Some, but not all, apps allow the users to control their location access. OSes have been improving on this front. iOS includes a new permission to authorize location access in the background, or when the app is not actively used. Also, iOS, Windows OS, and Blackberry (Android to follow suit) utilize per-app location-access permissions. The user authorizes location access at the very first time an app accesses his location and has the option to change this decision for every subsequent app invocation. We want to answer two important questions related to this: *(i) are these controls effective in protecting the user's location privacy and (ii) if not, how can they be improved at the user level without modifying any app or the underlying OS?*

To answer these questions, we must understand the location-privacy threats posed by mobile apps. This consists of understanding the apps' location-access patterns and their usage patterns. For this, we instrumented and analyzed the top 1165 downloaded free apps (that require location-access permissions) from Google Play to study their location-access patterns. We also studied the behavior of Advertisement and Analytics (A&A) libraries, such as Flurry, embedded in the apps that might access location. We analyzed only those apps/libraries that access location through Android's official location APIs. While some apps/libraries might circumvent the OS in accessing location, it is an orthogonal problem to that addressed in this paper.

We then analyzed the users' app-usage patterns by utilizing three independent datasets. First, we collected and analyzed app-tagged location traces through a 10-month data collection campaign (Jan. 2013—Nov. 2013) for 24 Android smartphone users. Second, we recruited 95 Android users through PhoneLab [31], a smartphone measurement testbed at New York State University at Buffalo, for 4 months. Finally, we utilized the dataset from Livelab at Rice University [34] that contains app-usage and location traces for 34 iPhone users for over a year.

Utimately, we were able to evaluate the privacy threats posed by 425 apps and 77 third-party libraries. 70% of the apps are found to have the potential of posing profiling threats that have not yet been adequately studied or addressed before [15, 16, 25, 41]. Moreover, the A&A libraries pose significant profiling threats on more than 80% of the users as they aggregate location information from multiple apps. Most of the users are unaware of these threats as they can't keep track of exposure of their location information. The issue becomes more problematic in the case of A&A libraries where users are oblivious to which apps these libraries are packed in and whether they are receiving location updates.

Given the nature of the threats, we studied the effectiveness of the existing OS controls. We found that these controls are capable of thwarting only a fraction of the underlying privacy threats, especially tracking threats. As for profiling, the user only has the options of either blocking or allowing location access. These two options come at either of the two extremes of the privacy–utility spectrum: the user either enjoys full privacy with no utility, or full utility with no privacy. As for A&A libraries, location accesses from a majority of the apps must be blocked to thwart the location-privacy threats caused by these libraries.

The main problem arises from the user's inability to exercise fine-grained control on when an app should receive a location update. The interface provided by existing controls makes it hard for the user to enforce location-access control on a per visited place/session basis. Even if the user can dynamically change the control of location access, he cannot estimate the privacy threats at runtime. The location-privacy threat is a function of the current location along with previously released locations. This makes it difficult to estimate the threat for apps and even harder for A&A libraries.

To fill this gap, we propose `LP-Doctor`, a user-level app, to protect the location privacy of smartphone users, which offers three salient features. First, `LP-Doctor` evaluates the privacy threat that the app might pose before launching it. If launching the app from the current location poses a threat, then it acts to protect the user's privacy. It also warns the user of the potential threat in a non-intrusive manner. Second, `LP-Doctor` is a *user-level* app and does not require any modification to the underlying OS or other apps. It acts as a control knob for the underlying OS tools. Third, `LP-Doctor` lets the user control, for each app, the privacy–utility tradeoff by adjusting the protection level while running the app.

We implemented `LP-Doctor` as an Android app that can be downloaded from Google Play. The privacy protection that `LP-Doctor` provides comes at a minimal performance overhead. We recruited 227 participants through Amazon Mechanical Turk and asked them to download and use `LP-Doctor` from Google Play. The overwhelming majority of the participants reported little effect on the quality of service and user experience. More than 77% of the participants indicated that they would install `LP-Doctor` to protect their location privacy.

In summary, we make the following main contributions:

- The first location data collection campaign of its kind to measure, analyze, and model location-privacy threats from the apps' perspectives (Sections 3–6);
- Evaluation of the effectiveness of OS's location privacy controls by anatomizing the location-privacy threats posed by the apps (Sections 7–8);
- Design, implementation and evaluation of a novel user-level app, `LP-Doctor`, based on our analysis to fill the gaps in existing controls and improve their effectiveness (Section 9).

2 Related Work

App-Based Studies: To the best of our knowledge, this is the first attempt to quantify and model location privacy from the apps' perspective. Researchers already concluded that many mobile apps and A&A libraries leak location information about the users to the cloud [5, 23, 38]. These efforts are complimentary to ours; we study the quantity and quality of location information that the apps and libraries locally gather while assuming that they may leak this information outside the device.

Analysis of Location Privacy: Influenced by existing location datasets (vehicular traces, cellular traces, etc.), most of the existing studies view location privacy in smartphones as if there were only one app *continuously* accessing a user's location [7, 11, 25, 26, 29, 33, 41]. Researchers also proposed mechanisms [28, 29, 32] (their effectiveness analyzed by Shokri *et al.* [36]) to protect against the resulting tracking-privacy threats. Such mechanisms have shown to be ineffective in thwarting the profiling threats [41] which are more prevalent as we will show later.

Researchers started considering sporadic location-access patterns as a source of location-privacy threat that calls for a different treatment than the continuous case [4]. Still, existing studies focus mostly on the tracking threat [3, 35]. The only exception to this is the work by Freudiger *et al.* [15]. They assessed the erosion of the user's privacy from sporadic location accesses as the portion of the PoIs identified after downsampling the continuous location trace. In this paper, we propose a formal metric to model the profiling threats. Also, we show that an app's location-access behavior can't be modeled as simply downsampling the user's mobility.

Location-Privacy Protection Proposals: Several solutions have been proposed to protect mobile users' location privacy. MockDroid [6] allows for blocking apps' location access to protect the user's location privacy. LP-Guardian [12] is another system aiming at protecting the user's location privacy by incorporating a myriad of mechanisms. Both systems require platform modifications, hindering their deployment. Other mechanisms, such as Caché [2] and the work by Micinski *et al.* [30], provide apps with coarsened locations but require modifications to the apps. Koi [20] proposed a location privacy enhancing system that utilizes a cloud service, but requires developers to use a different API to access location. Apps on Google Play such as PlaceMask and Fake GPS Location Spoofer rely on the user to manually feed apps with fake locations, which reduce their usability.

Finally, researchers have proposed improved permission models for Android [1, 24]. In their models, the users are aware of how much the apps access their location and have the choice to enable/disable location access for each app (AppOps provided such functionality in Android 4.3). LP-Doctor improves on these in three ways. First, it provides a privacy model that maps each app's location access to a privacy metric. This model includes more information than just the number of location accesses by the app. Second, LP-Doctor makes some decisions on behalf of the users to avoid interrupting their tasks and to make privacy protection more usable. Third, LP-Doctor employs *per-session* location-access granularity which achieves a better privacy–utility tradeoff.

3 Background and Data Collection

To study the efficacy of location-access controls of different mobile OSes, we had to first analyze location-privacy threats from the apps' perspectives. This includes studying how different apps collect the user's location. We conduct a data collection campaign to achieve this using the Android platform. Our results, however, can be generalized to other mobile platforms like iOS.

3.1 Location-Access Controls

Each mobile platform provides users with a set of location-access controls to mitigate possible location-privacy threats. Android (prior to Android M) provides a one-time permission model that allows users to authorize location access. Once the user approves the permission list (Fig. 1–left) for the app, it is installed and the permissions can't be revoked. It also provides a global location knob (Fig. 1–right) to control location services. The user can't exercise per-app location-access control.

Figure 2: iOS's location settings (left) and prompts (right).

Other platforms, such as Blackberry OS and iOS, provide finer-grained location permissions. Each app has a settings menu (Fig. 2–left) that indicates the resources it is allowed to access, including location. The user can at any point of time revoke resource access by any app. The first time an app accesses location, the OS prompts the user to authorize location access for the app in the current and future sessions (Fig. 2–right). Also, Google, starting from Android M, will provide a similar permission model (an evolution of the previously deployed AppOps in Android 4.3) to control access of location and other resources. At present, iOS provides the users with an additional option to authorize location access in the background to prevent apps from tracking users.

In the rest of this paper, we study the following controls: (1) one-time location permissions, (2) authorization of location access in the background, and (3) finer-grained per-app permissions.

3.2 System Model

We study location-privacy threats through apps and A&A libraries that access the user's location. These apps and libraries then provide the service, and keep the location records indexed by a user ID, such as MAC address, Android ID, IMEI, etc.

We assume that the app/library communicates all of the user's location samples to the service provider.[1] This allows us to model the location-privacy threats caused by apps/libraries in the worst-case scenario. The app is the only means by which the service provider can collect the user's location updates. We don't consider cases where the service provider obtains the user's location via side channels other than the official API, e.g., an app reads the nearby access points and sends them to a localization service, such as skyhook.

We preclude system and browsing apps from our study for the following reasons. System apps are part of the OS that already has access to the user's location all the time. Hence, analyzing their privacy implications isn't very informative. As for the browsing apps, the location sink might be a visited website as well as the browser itself. We decided not to monitor the user's web history during the data collection for privacy concerns. Also, app-usage patterns differ from browsing patterns. The conclusions derived for the former don't necessarily translate to those for the latter.

3.3 App and A&A libraries Analysis

In February 2014, we downloaded the top 100 apps of each of Google Play's 27 app categories. We were left with 2588 unique apps, of which 1165 apps request location permissions. We then instrumented Android to intercept every location access invoked by both the app and the packed A&A libraries.

The main goal of this analysis was to unravel the situations in which an app accesses location and whether it feeds a packed A&A library. In Android, the app could be running in the foreground, cached in the background, or as a service. Using a real device, we ran every app in foreground, moved it to background, and checked if it forked a service, while recording its location requests.

Apps running in the foreground can access location spontaneously or in response to some UI event. So, we ran every app in two modes. In the first mode, the app runs for a predefined period of time and then closes, while in the second, we manually interact with each app to trigger the location-based functionality. Finally, we analyzed the functionality of every app and the required location granularity to achieve this functionality.

3.4 Data Collection

As will be evident in Section 4, the app-usage pattern is instrumental in determining the underlying location-privacy threats. We collected the app-usage data using an app that we developed and published on Google Play. Our study was deemed as not-requiring an IRB oversight by the IRB at our institution; all the data we collected is anonymous. Also, we clustered the participants' location on the device to extract their visited places. We define the "place" as a center location with a radius of 50m and a minimum visit time of 5 min. Then, we logged place IDs instead of absolute location samples to further protect the participants' privacy.

PhoneLab: PhoneLab [31] is a testbed, deployed at the NY State University at Buffalo, composed of 288 smartphone users. PhoneLab aims to free the researchers from recruiting participants by providing a diverse set of participants, which leads to stronger conclusions.

We recruited 95 participants to download and run our app for the period between February 2014 and June 2014. We collected detailed usage information for 625 apps, of which 218 had location permissions and were also part of the apps inspected in the app-analysis stage.

Our Institution: The second set consists of 24 participants whom we recruited through personal relations and class announcements. We launched this study from January 2013 till November 2013, with the participation period per user varying between 1 week and 10 months. From this set, we collected usage data of 256 location-aware apps.

We also collected location access patterns of some apps from a subset of the participants. We handed 11 participants Galaxy Nexus devices with an instrumented Android (4.1.2) that recorded app-tagged location accesses. We measured how frequently do ordinary users invoke location-based functionality of apps that don't spontaneously access location (e.g., Whatsapp).

LiveLab: Finally, we utilize the Livelab dataset [34] from Rice University. This dataset contains the app usage and mobility records for 34 iPhone users over the course of a year (2010). We post-processed this dataset to map app-usage records to the location where the apps were invoked. We only considered those apps that overlapped with our Android dataset (35 apps).

4 Location-Access Patterns

We address the location-access patterns by analyzing how different apps collect location information while running in foreground and background. The former represents the state where the user actively interacts with the app, while the latter represents the case where the app runs in the background either as cached by Android or as a persistent service.

As evident from Table 1, 74% of the apps solely access location when running in the foreground, while only 3% continuously access the user's location in the back-

[1] We refer to both the app developers and A&A agencies as the service provider.

Table 1: Location-access patterns for smartphone apps according to Android location permissions

	Fore. (%)	Cached (%)	Back. (%)	None (%)	Gran. Coarse (%)
Coarse	71	6	1	22	100
Fine	74	14	4	12	48

Table 2: Location-access patterns for A&A libraries

Total	No Location Access	App Feeds Location	Auto Location Access		
			Coarse	Fine	Both
77	22	17	3	2	33

ground. Around 70% of the apps accessing location in the foreground spontaneously perform such access preceding any user interaction. Examples of these apps include Angry Birds, Yelp, Airbnb, etc.

Android caches the app when the user exits it; depending on the app's behavior it might still access location; only 12% of the apps access the user's location when they are cached. Interestingly, for 14% of the apps, we didn't find any evidence that they access location in any state.

We also analyzed the location-based functionality of every app and the required location granularity to achieve such functionality. We focused on two location granularity levels: *fine* and *coarse*. A fine location sample is one with block-level granularity or higher, while coarse location is that with zipcode-level granularity or lower. We manually interacted with each app to assess the change in its functionality while feeding it locations with different granularity. We show the percentage of the apps that can accommodate coarse location without noticeable loss of app functionality in Table 1 under the column titled *Gran. Coarse*. One can notice that apps abuse the location permissions: 48% of the apps requesting fine location permissions can accommodate locations with coarser granularity without loss of functionality.

Finally, we analyzed the packed A&A libraries in these apps. We were able to identify 77 of such libraries packed in these apps. Table 2 shows basic statistics about these libraries. Most (more than 70%) libraries require location access where some are fed location from the apps (22%). The rest of the libraries automatically access location where 3 of them require coarse location permissions, 2 require fine permissions, and the rest don't specify a permission. Also, these libraries are included within more than one location-aware app giving them the ability to track the user's location beyond what a single app can do. For example, of 1165 analyzed apps, Google Ads is packed within 499 apps, Flurry within 325 apps, Medialets within 35 apps, etc.

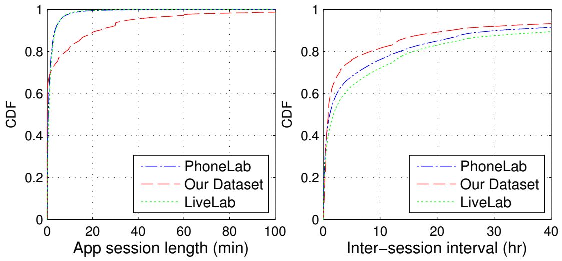

Figure 3: The distribution of app session lengths (left) and inter-session intervals (right) for the three datasets.

5 App-Usage Patterns

As apps mostly access users' location in the foreground, the app-usage patterns (the way that users invoke different apps) help determine how much location information each app collects. Apps are shown to sporadically sample the user's location based on two facts. First, an app session is equivalent to the place visited during the session. Second, apps' inter-session intervals follow a Pareto-law distribution.

For foreground apps, we define a session as a single app invocation—the period of time in which a user runs the app then exits it. The session lengths are not long enough to cover more than one place the user visits, where 80% of these app sessions are shorter than 10 minutes (the left plot of Fig. 3). We confirmed this from our PhoneLab dataset; 98% of the app sessions started and ended at the same place.

This allows for collapsing an app session into one location-access event. It doesn't matter what frequency the app polls the user's location with. As long as the app requests the user's location at least once, while it is running in the foreground, it will infer that the user visited that location. We thus ignore the location-access frequency of foreground apps, and instead focus on the app-usage patterns.

We define the inter-session time as the interval separating different invocations (sessions) of the same app by the same user. The right plot of Fig. 3 shows the distribution of the inter-session intervals for the three datasets. More than 50% of the app sessions were separated by at least one hour.

We also found that the inter-session intervals follow a Pareto-law distribution rather than a uniform distribution. This indicates that apps don't sample the user's location uniformly, indicating that existing models for apps' location access don't match their actual behavior.

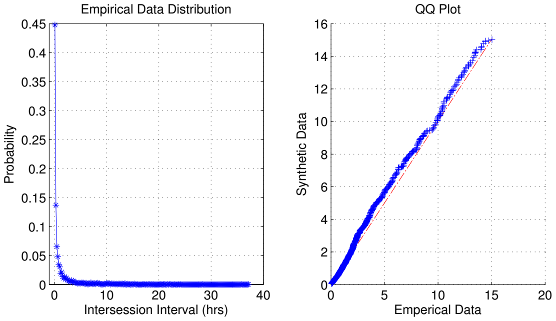

Figure 4: The distribution of the inter-session times for Facebook in Livelab dataset (left), and the QQ plot of this distribution versus a Pareto law distribution (right).

Fig. 4 shows the distribution of the inter-session intervals of a user running Facebook. It is evident that the distribution of the inter-session intervals decays linearly with respect to the increase of inter-session intervals. We observed a similar trend with all other apps. This suggests that the data decays according to a Pareto law (QQ plot in Fig. 4). We followed the guidelines outlined by Clauset *et al.* [10] to fit the data to the truncated Pareto distribution. Three parameters (L, H, and α) define the truncated Pareto law distribution:

$$p_X(x) \begin{cases} \frac{(-\alpha-1)L^{-\alpha-1}x^{\alpha}}{1-\left(\frac{L}{H}\right)^{-\alpha-1}} & \text{if } L \leq x \leq H \\ 0 & \text{otherwise.} \end{cases}$$

After fitting the data, more than 97% of the app-usage models are found to have α between -1 and -1.5. According to Vagna *et al.* [40], Pareto law fits different human activity models with α between -1 and -2.

6 Privacy Model

Here we model the privacy threats caused by mobile apps'/libraries' access of the user's location.

6.1 Preliminaries

Below we describe the models of user mobility, app-usage, and adversaries that we will use throughout the paper.

User Mobility Model: We assume there is a region (e.g., city) of interest which includes set of places that the user can visit. So, a domain of interest is represented by the set Pl of all the places available in that domain: $Pl = \{pl_1, pl_2, pl_3 \ldots\}$. Under this model, the user visits a set of places, $U_{Pl} \subseteq Pl$, as part of his daily life, spends time at pl_i running some apps and then moves to another place pl_j. We alternatively refer to these places as the user's *Points of Interest* (PoIs).

We associate every place pl_i with a visit probability of p_i, reflecting the portion of time the user spends at pl_i. The user's *mobility profiles* are defined as the set, U_{pl}, of places he visited and the probability, p_i, of visit to each place. The mobility profile is unique to each user since a different user visits a different set of places with a different probability distribution [41].

App-Usage Model: In Section 5, we showed that each app session is equivalent to an observation of the user's visit to a place. The app accumulates observations of the set of places that the user visits. The app will eventually observe that a user visited a certain place pl_i for c_{pl_i} times. So, we view the app as a random process that samples the user's entire location trace and outputs a histogram of places of dimension $|U_{Pl}|$. Each bin in the histogram is the number of times, c_{pl_i}, the app observes the user at that specific place. The total number of visits is represented as $N = \sum_{i=1}^{|U_{Pl}|} c_{pl_i}$.

The histogram represents the app's view of the user's mobility. Most apps don't continuously monitor user's mobility as they don't access location in the background. As such, they can't track users; the most these apps can get from a user is the histogram of the places he visited, which constitutes the source of location-privacy threats in this case.

Adversary Model: The adversary in our model is not necessarily a malicious entity seeking to steal the user's private information. It is rather a curious entity with possession of the user's location trace. The adversary will process and analyze these traces to infer more information about the user that allows for a more personalized service. This is referred to as *authentic apps* [39]. The objective of our analysis is to study the effect of the ordinary apps collecting location on the user's privacy.

Apps accessing location in the foreground can't track the user (Section 8). So, the adversary seeks to profile the user based on locations he visited. We use the term *profiling* to represent the process of inferring more information about the user through the collected location data. The profiling can take place at multiple levels, ranging from identifying preferences all the way to revealing the user's identity. Instead of modeling the adversary's profiling methods/attacks, we quantify the amount of information that location data provides the adversary with. The intuition behind our analysis of the profiling threat is that the more descriptive the app's histogram of the actual user's mobility pattern, the higher the threat is.

6.2 Privacy Metrics

Table 3 summarizes the set of metrics that we utilize to quantify the privacy threats that each app poses from its location access. The simplest metric is the fraction of the users' PoIs the app can identify [15]. We evaluate this

Table 3: The metrics used for evaluating the location privacy threats.

Metric	Description
PoI_{total}	Fraction of the user's PoIs
PoI_{part}	Fraction of the user's infrequently visited PoIs
$Prof_{cont}$	Distance between the user's histogram and mobility profile
$Prof_{bin}$	χ^2 test of the user's histogram fitting the mobility profile

metric by looking at the apps' actual collected location traces, rather than a downsampled location trace. We will henceforth refer to this metric as PoI_{total}.

We also consider a variant of the metric (referred to as PoI_{part}) as the portion of the sensitive PoIs that the apps might identify. We define the sensitive PoIs as those that have a very low probability of being visited. These PoIs will exhibit abnormalities in the user's behavior. Research results in psychology [19, 21] indicated that people regard deviant (abnormal) behavior as being more private and sensitive. Places that an individual might visit that are not part of his regular patterns might leak a lot of information and are thus more sensitive in nature.

The histogram, as we mentioned before, is a sample of the user's mobility pattern. The second aspect of the profiling is quantifying how descriptive of the user's mobility pattern (original distribution) the app's histogram (sample) is.

For the purpose of our analysis and the privacy-preserving tool we propose later, we need two types of metrics. The first is a *continuous* metric, $Prof_{cont}$, that quantifies the profiling threat as the distance between the original distribution (mobility profile) and the sample (app's histogram). The second is a *binary* metric, $Prof_{bin}$, that indicates whether a threat exists or not.

For $Prof_{cont}$, we use the KL-divergence [27] as a measure of the difference (in bits) between the histogram (H) and the user's mobility pattern. The K-L divergence is given by $D_{\mathrm{KL}}(H\|p) = \sum_{i=1}^{|U_{Pl}|} H(i) \ln \frac{H(i)}{p_i}$, where $H(i)$ is the probability of the user visiting place pl_i based on the histogram, while p_i is the probability of the user visiting that place based on his mobility profile. The lower (higher) the value of $Prof_{cont}$, the higher (lower) the threat will be since the distance between the histogram and mobility pattern will be smaller (larger).

$Prof_{cont}$ is not useful in identifying histograms that pose privacy threats. There is no intuitive way by which a threshold can separate values that pose threats and those not posing any threat. So, we need a criterion indicating whether or not a threat exists based on the app's histogram. We use Pearson's Chi-square goodness of fit test to meet this need. This test indicates if the observed sample differs from the original (theoretical) distribution. Specifically, it checks if the null hypothesis of the sample originating from an original distribution can be accepted or not.

The test statistic, in our context, is $\chi^2 = \sum_{i=1}^{|U_{Pl}|} \frac{(c_{pl_i} - E_i)^2}{E_i}$ where $E_i = N.p_i$ is the expected number of visits to the place pl_i. The statistic converges to a Chi-squared distribution with $|U_{Pl}| - 1$ degrees of freedom when the null hypothesis holds. The test yields a p-value which if smaller than the significance level (α) then the null hypothesis can be rejected ($Prof_{bin} = 0$—no threat), else $Prof_{bin} = 1$, where null hypothesis can't be rejected, indicating the existence of a threat. In Sections 7 and 8, we employ the widely-used value of 0.05 as the significance level.

A&A libraries: can aggregate location information from the different apps in which they are packed and allowed to access location. We can thus view the histogram pertaining to an A&A library as the aggregate of the histograms of the apps in which the library is packed. We evaluate the same metrics for the aggregated histogram.

For the case of PoI_{total} and PoI_{part} metric, the aggregate histogram will be representative of the threat posed by the libraries. As for $Prof_{cont}$ and $Prof_{bin}$, we consider the aggregate histogram as well as the individual apps' histograms. The threat per library is the highest of that of the aggregate and individual histograms. The privacy threat posed by the library is at least as bad as that of any app that packs it in.

7 Anatomy

We now present the major findings from our measurement campaign. We analyze the location trace of each app and user, and hence, every data point in the subsequent plots belongs to an app–user combination. We constructed each app's histogram by overlaying its location-access pattern on its usage data for every user.

Privacy Threat Distribution: Fig. 5 shows the distributions of PoI_{total}, PoI_{part}, and $Prof_{cont}$ for both the apps and A&A libraries. As to PoI_{total}, most of the apps can identify at least 10% of the user's PoIs; while for 20% of the app–user combinations, apps were able to identify most of the user's PoIs. Apps can't identify all of the user's PoIs for two reasons: (1) not all apps access the user's location every time, as highlighted in Section 4, and (2) users don't run their apps from every place they visit. On the other hand, A&A libraries can identify more of the user's PoIs, with most of the libraries identifying at least 20% of the user's PoIs. Moreover, as the middle plots of Fig. 5 indicate, around 30% of the apps were able to identify some of the user's sensitive (less frequently visited) PoIs. More importantly, A&A libraries were able to identify more of the user's sensitive PoIs,

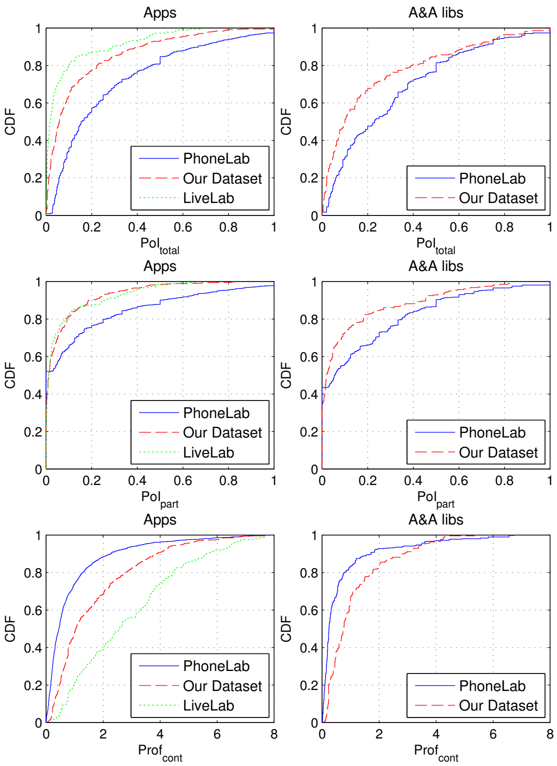

Figure 5: The distributions of PoI_{total} (top), PoI_{part} (middle), and $Prof_{cont}$ (bottom) for the apps (left) and A&A libraries (right) from our datasets.

indicating the level of privacy threats they pose.

The two bottom plots of Fig. 5 show the distributions of the profiling metric $Prof_{cont}$ for the foreground apps in the three datasets. The lower the value of the metric, the higher the privacy threat is. There are two takeaways from these two plots. First, apps do pose significant privacy threats; the distance between the apps' histogram and the user's mobility pattern is less than 1 bit in 40% of the app–user combinations for the three datasets. The second observation has to do with the threat posed by A&A libraries. It is clear from the comparison of the left and right plots that these libraries pose considerably higher threats. In more than 80% of user–library combinations, the distance between the observed histograms and the user's mobility profile is less than 1 bit.

Apps tend to even pose higher identification threats. As evident from Fig. 5, some apps can identify a relatively minor portion of the user's mobility which might not be sufficient to fully profile the user. Nevertheless, the portion of PoIs tend to be those users frequently visit (e.g., home and work) which may suffice to identify them [18, 25, 41]. This might not be a serious issue for those apps, such as Facebook, that can learn the user's home and work from other methods. Other apps

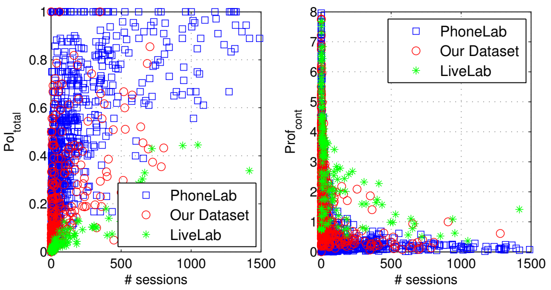

Figure 6: The distribution of PoI_{total} (left) and $Prof_{cont}$ (right) vs. the number of app sessions.

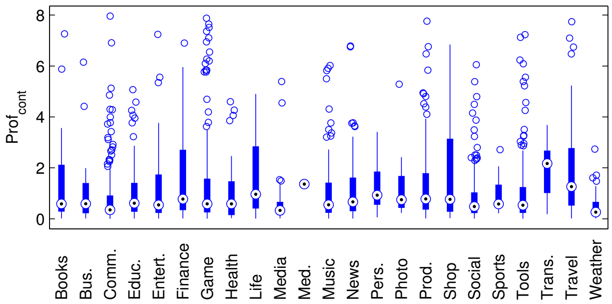

Figure 7: The distribution of $Prof_{cont}$ vs. app categories.

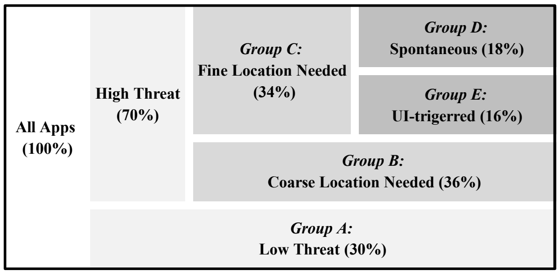
and libraries (e.g., Angry Birds), however, might infer the user's identity even when he anonymously uses them (without providing an identity or login information).

Fig. 5 also confirms our intuition in studying the location traces from the apps' perspective. If apps were to uniformly sample the user's mobility as has been assumed in literature, $Prof_{cont}$ should be mostly close to 0 (indicating no difference between the histogram and the mobility pattern), which is not the case.

Privacy Threats and App-Usage: We also evaluated the posed privacy threats vs. the app-usage rate as shown in Fig. 6. As evident from the plots, there is little correlation between the amount of posed threats and the app-usage rate. Apps that are used more frequently, do not necessarily pose higher threats, as user mobility, the app's location-access pattern, and the user's app-usage pattern affect the privacy threat.

With lower usage rates, both PoI_{total} and $Prof_{cont}$ vary significantly. Users with little diversity in their mobility pattern are likely to visit the same places more frequently. Even the same user could invoke apps differently; he uses some apps mostly at unfamiliar places (navigation apps), while using other apps more ubiquitously (gaming apps), thus enabling the apps to identify more of his PoIs.

Finally, we studied the distribution of the threat in relation to app categories. Fig. 7 shows that the threat level is fairly distributed across different app categories and



All Apps (100%)
High Threat (70%)
Group C: Fine Location Needed (34%)
Group D: Spontaneous (18%)
Group E: UI-trigerred (16%)
Group B: Coarse Location Needed (36%)
Group A: Low Threat (30%)

Figure 8: App categorization according to threat levels, location requirements, and location-access patterns.

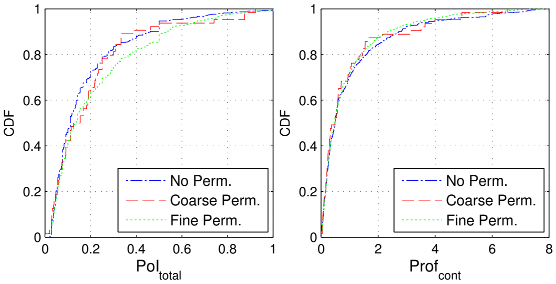


Figure 9: The distribution of PoI_{total} (left) and $Prof_{cont}$ (right) for PhoneLab apps with different permissions.

the same category. This confirms, again, that privacy threats result from multiple sources and are a function of both apps and users. Some app categories, however, pose lower threats on average. For example, transportation apps (including navigation apps) pose lower threats as users tend to use from unfamiliar places.

Threat Layout: Given the three datasets, we were able to analyze the profiling threats as posed by 425 location-aware apps (Fig. 8). For this part, we use $Prof_{bin}$ metric to decide which apps pose privacy threats and those which don't. As apps pose different threats depending on the users, we counted an app as posing a threat if it poses a privacy threat to at least one user. Only a minority of the apps (30%) pose negligible threats.

The rest of the apps pose a varying degree of profiling threat. We analyzed their functionality: 52% of such apps don't require location with high granularity to provide location-based functionality. For these apps, a zipcode- or city-level granularity would be more than enough (weather apps, games). This leaves us with 34% of the apps that require block-level or higher location granularity to provide usable functionality. These apps either spontaneously access location (18%) or in response to a UI event (16%).

8 OS Controls

Having presented an anatomy for the location-privacy threats posed by mobile apps, we are now ready to evaluate the effectiveness of existing OSes' location access controls in thwarting these threats.

Global Location Permissions: Android's location permissions attempt to serve two purposes: notification and control. They notify the user that the app he is about to install can access his location. Also, permissions aim to control the granularity by which apps access location. Apps with coarse-grained location permission can only access location with both low granularity and frequency.

Fig. 9 compares the profiling threats (PoI_{total} and $Prof_{cont}$) posed by apps with fine location permissions and those with coarse location permissions. It also plots the distribution of the privacy metrics for apps without location permissions assuming that they accessed location when running. While this might seems oblivious at a first glance, we aim to compare the location-based usage of apps with different location permissions. This allows us to study if the location permissions are effective as a notification mechanism so that users use apps from different places depending on the location permissions.

The apps with fine-grained location permissions exhibited very similar usage pattern to those apps without location access. The users ran the app from the same places regardless of whether they have location permissions or not. We conclude that this notification mechanism does little to alert users on potential privacy threats and has no effect on the app-usage behavior. Similar observations have also been made by others [17].

Almost a half of the apps (Table 1) that request fine-grained location permissions are found to be able to achieve the location-based functionality with coarser-granularity location. This suggests that apps abuse location permissions. If used appropriately, permissions can be effective in thwarting the threats resulting from apps' abuse of location access (∼40% of the apps — Group B — according to Fig. 8).

Background Location Access: Background location access is critical when it comes to tracking individuals. It enables comprehensive access to the user's mobility information including PoIs and frequent routes. Recently, iOS 8 introduced a new location permission that allows users to authorize location access in the background for apps on their devices.

This permission strikes a balance between privacy and QoS. We showed in Section 4 that apps rarely access location in the background. Thus, this option affects a very low portion of the user's apps, but is effective in terms of privacy protection, especially in thwarting tracking threats. We evaluated the tracking threat in terms of tracking time per day [12, 22] for the three datasets for foreground location access.

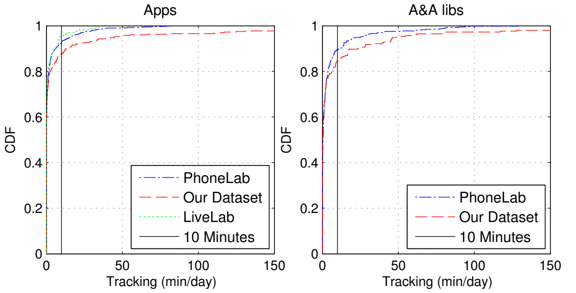

Figure 10: The distribution of the tracking threat posed by the foreground apps (left) and A&A libraries (right).

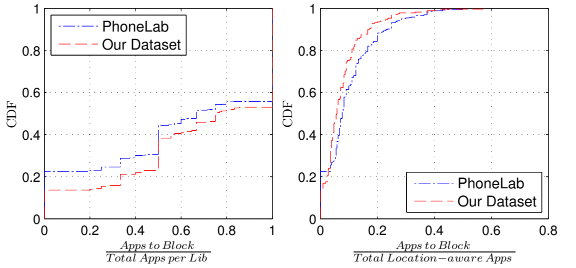

Figure 11: The fraction of the user's apps that must be blocked from accessing location to protect against privacy threats posed by A&A libraries.

Fig. 10 (left) shows that in 90% of the app–user combinations, blocking background location access will limit the location exposure to less than 10 minutes a day (from foreground location access). The third-party libraries tend to pose slightly higher tracking threats than apps (Fig. 10 – right).

Per-app Location Permissions: To improve over static permissions, iOS enables the user to allow/disallow location access on a per-app basis. The users gain two advantages from this model: (i) location access can be blocked for a subset, but not all, of the apps, and (ii) the apps retain some functionality even when the location access is blocked.

Even if the user trusts an app with location access, the app can still profile him through the places he visited (Groups D and E in Fig. 8). To combat these threats, the user has to either allow location access to fully exploit the app and lose privacy, or gain his privacy while losing the location-based app functionality. Currently, mobile platforms offer no middle ground to balance privacy and QoS requirements.

In Section 7, we showed that A&A libraries pose significant threats that users are completely unaware of as they access location from more than one app. The user can't identify which apps he must disallow to access location in order to mitigate threats from third-party libraries. Fig. 11 shows the portion of the user's apps that must be disbarred from accessing location to thwart threats from packed A&A libraries. It turns out (left plot of Fig. 11) that in order to protect the user from privacy threats posed by a single library, at least 50–70% of the apps carrying the library must be disbarred from accessing location. This amounts to blocking location for more than 10% of the apps installed on the device.

In conclusion, a static permission model suffers serious limitations, blocking location access in the background is effective in mitigating the tracking threat but not the profiling one, and per-app controls exhibit an unbalanced tradeoff between privacy and QoS. Also, they are ineffective against the threats caused by A&A libraries. Thus, a finer-grained location access control is required, allowing control for each app session depending on the context. Per-session location access control allows users to leverage better and more space in the privacy–QoS spectrum.

9 LP-Doctor

Users can't utilize the existing controls to achieve per-session location-access controls for two reasons. First, these controls are coarse-grained (providing only per-app controls at best). For finer-level controls, the user has to manually modify the location settings before launching each app, which is quite cumbersome and annoying. Second, even if the user can easily change these settings, making an informed decision is a different story. Therefore, we propose `LP-Doctor` that helps users utilize the existing OS controls to provide location-access control on a per-session basis.

9.1 Design

`LP-Doctor` trusts the underlying OS and its associated apps; it targets user-level apps accessing location while running in the foreground, as we found that most apps don't access location in the background. `LP-Doctor` focuses on the apps with fine location permissions as they could pose higher threats. `LP-Doctor` automatically coarsens location for apps requesting coarse location permissions to ensure a commensurate privacy-protection level.

The main operation of `LP-Doctor` consists of two parts. The first involves the user-transparent operations described below, while the second includes the interactions with the user described in Section 9.2.

We bundled `LP-Doctor` with CyanogenMod's app launcher.[2] It runs as a background service, intercepts app-launch events, decides on the appropriate actions, performs these actions, and then instructs the app to launch. Fig. 12 shows the high-level execution flow of

[2] Source code: `https://github.com/kmfawaz/LP-Doctor`.

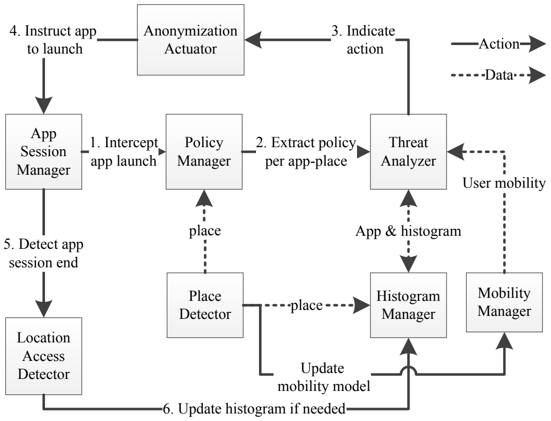

Figure 12: The execution flow of LP-Doctor when a location-aware app launches.

LP-Doctor. Next, we elaborate on LP-Doctor's components and their interactions.

App Session Manager: is responsible for monitoring app launch and exit events. LP-Doctor needs to intercept app-launch events to anonymize location.

Fortunately, Android (recently iOS as well) allow for developing custom app launchers. Users can download and install these launchers from the app store which will, in turn, be responsible for listening to the user's events and executing the apps. We instrumented CyanogenMod's app launcher (available as open source and under Apache 2 license) to intercept app launch events.

Particularly, before the app launcher instructs the app to execute, we stop the execution, save the state, and send an intent to LP-Doctor's background service (step 1 in Fig. 12). LP-Doctor takes a set of actions and sends an intent to the app launcher, signaling the app can launch (steps 2 and 3 in Fig. 12). The app launcher then restores the saved state and proceeds with execution of the app (step 4 in Fig. 12). In Section 9.4, we will report the additional delay incurred by this operation.

In the background, LP-Doctor frequently polls (once every 10s) the current foreground app to detect if the app is still running. For this purpose, it uses getRecentTasks on older versions of Android and AppUsageStats class for Android L. When an app is no longer running in the foreground, LP-Doctor executes a set of maintenance operations to be described later (steps 5 and 6 in Fig. 12).

Policy Manager: fetches the privacy policy for the currently visited place and the launched app as shown in Fig. 13.

At installation time, the user specifies a privacy policy to be applied for the app. We call this the *per-app policy* which specifies three possible actions: *block*, *allow*, and *protect*. If the per-app policy indicates privacy protection, LP-Doctor asks the user to specify a per-place policy for the app. The per-place policy indicates the policy that LP-Doctor must follow when the app launches from a particular place. The policy manager passes the app's policy and the current place to the threat analyzer.

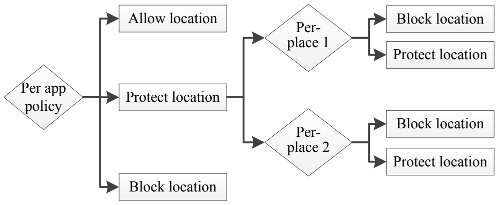

Figure 13: The policy hierarchy of LP-Doctor.

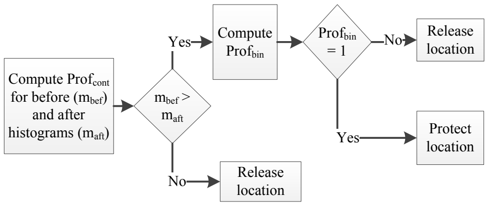

Figure 14: The threat analyzer's decision diagram.

Place Detector & Mobility Manager: The place detector monitors the user's actual location, and applies online clustering to extract the spatio-temporal clusters which represent places that the users visit. Whenever the user changes the place he is visiting, the place detector module instructs the mobility manager to update the mobility profile of the user as defined in Section 6.

Histogram Manager: maintains the histogram of the places visited as observed by each app. It stores the histograms in an SQLite table that contains the mapping of each app–place combination to a number of observations. The threat analyzer module consults the histogram manager to obtain two histograms whenever an app is about to launch. The first is the current histogram of the app (based on previous app events) which we refer to as the "before" histogram. While the second one is the potential histogram if the app were to access location from the currently visiting place; we call this histogram as the "after" one.

Threat Analyzer: decides on the course of action regarding apps associated with a *protect* policy. It basically performs the decision diagram depicted in Fig. 14 to decide whether to release the location or add noise.

The threat analyzer determines whether the "after" histogram leaks more information than the old one through computing $Prof_{cont}$ for each histogram. If $Prof_{cont}$ increases LP-Doctor decides to release the location to the app. On the other hand, if $Prof_{cont}$ decreases, LP-Doctor uses $Prof_{bin}$ to decide if the "after" histogram fits the user's mobility pattern and whether to release or anonymize location.

$Prof_{bin}$ depends on the significance level, α, as we specified in Section 6. In LP-Doctor, α is a function of the privacy level chosen by the user. LP-Doctor recognizes three privacy levels: low, medium, and high. Low privacy corresponds to $\alpha = 0.1$; medium privacy corresponds to $\alpha = 0.05$; and high privacy protection corresponds to the most conservative $\alpha = 0.01$.

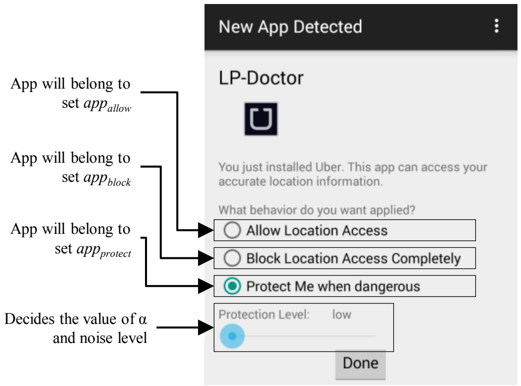
The procedure depicted in Fig. 14 won't hide places that the user seldom visits but are sensitive to him. The per-place policies allow the user to set a privacy policy for each visited place, effectively allowing him to control the places he wants revealed to the service providers. Also, LP-Doctor can be extended to support other privacy criteria that try to achieve optimal privacy by perturbing location data [9,37].

Anonymization Actuator: receives an action to perform from the threat analyzer. If the action is to protect the current location, the actuator computes a fake location by adding Laplacian noise [3] to ensure location indistinguishability. The privacy level determines the amount of noise to be added on top of the current location. One the other hand, if the action is to block, the actuator computes the fake location of $< 0,0 >$.

As specified by Andrés *et al.* [3], repetitive engagement of Laplacian noise mechanism at the same location leaks information about the location. To counter this threat, LP-Doctor computes the anonymized location once per location and protection-level combination, and saves it. When the user visits the same location again, LP-Doctor employs the same anonymized location that was previously computed to prevent LP-Doctor from recomputing a fake location for the same place.

After computing/fetching the fake location, the actuator module will engage the mock location provider. The mock location provider is an Android developer feature to modify the location provided to the app from Android. It requires no change in the OS or the app. The actuator then displays a non-intrusive notification to the user, and signals the session manager to start the app.

End-of-Session Maintenance: When the app finishes execution, the actuator disengages the mock location provider, if engaged. The location-access detector will then detect if the app accessed location to update the app's histogram accordingly. The location access detector performs a "dumpsys location" to exactly detect if the app accessed location or not while running. If it did access location, the location-access detector module updates the app's histogram (increment the number of visits from the current location). It is worth noting that LP-Doctor treats sessions of the same app within 1 min as the same app session.



New App Detected

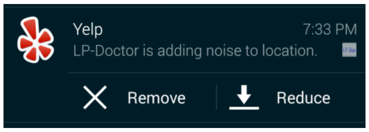
9.2 User Interactions

LP-Doctor interacts with the user to communicate privacy-protection status. It also enables him to populate the privacy profiles for different apps and places. As will be evident below, the main philosophy guiding LP-Doctor's design is to minimize the user interactions, especially intrusive ones. We satisfy two design principles proposed by Felt *et al.* [13] that should guide the design of a permission granting UI. The first principle is to conserve user attention by not issuing excessively repetitive prompts. The second is to avoid interrupting the user's primary tasks.

Bootstrapping Menu: The first communication instance with LP-Doctor takes place upon its installation. LP-Doctor will ask the user to set general configuration options. These options include (1) alerting the user when visiting a new location to set the per-place policies and (2) invoking protection for A&A libraries. The menu will also instruct the user to enable the mock location provider and grant the app "DUMP" permissions through ADB. This interaction takes place only once per LP-Doctor's lifetime.

Installation Menu: LP-Doctor prompts the user when a new (non-system and location-aware) app is installed. The menu enables the user to set the per-app profiles. Fig. 15 shows the displayed menu when an app ("uber" in this case) has finished installation. The user can choose one of three options which populates three app sets: app_{allow}, app_{block}, and $app_{protect}$.

Logically, this menu resembles the per-app location settings for iOS, except that it provides users with an additional option of privacy protection. The protection option acts as a middle-ground between completely allowing and blocking location access to the app. The user will interact with this menu; only once per app, and only for non-system apps that requests the fine location permission. Based on our PhoneLab dataset, we estimate



Yelp 7:33 PM

LP-Doctor is adding noise to location.

Figure 16: LP-Doctor's notification when adding noise.

that the user will be issued this menu on average for one app he installs per five installed apps on the device.

Per-Place Prompts: LP-Doctor relies on the user to decide its actions in different visited places, if he agrees to get prompted when visiting new places. Specifically, whenever the user visits a new place, LP-Doctor prompts him to decide on actions to perform when running apps that the user chose to protect. We call these *per-place policies* (Fig. 13).

The per-place policies apply for apps belonging to the set $app_{protect}$. The user has the option to specify whether to block location access completely, or apply protection. Applying protection will proceed to execute the operations of the threat analyzer as defined in Fig. 14. LP-Doctor allows the user to modify the policies for each app–place combination.

LP-Doctor issues this prompt only when the user launched an app of the set $app_{protect}$ from a new location. From our PhoneLab dataset, we estimate that such a prompt will be issued to the user at most once a week.

Notifications: As specified earlier, the threat actuator displays a non-intrusive notification (Fig. 16) to the user to inform him about the action being taken.

If the action is to allow location access (because the policy dictates so or there is no threat), LP-Doctor notifies the user that there is no action being taken. The user has the option to invoke privacy protection for the current app session. If the user instructs LP-Doctor to add noise for a single app over two consecutive sessions from the same place, LP-Doctor will create a per-place policy for the app and move it to the $app_{protect}$ set if it were part of app_{allow}.

On the other hand, if LP-Doctor decides to add noise to location or block it, it will notify the user of it (Fig. 16). The notification includes two actions that the user can make: remove or reduce noise. If the user overrides LP-Doctor's actions for two consecutive sessions of an app from the same place, LP-Doctor remembers the decision for future reuse.

LP-Doctor leverages the user's behavior to learn the protection level that achieves a favorable privacy–utility tradeoff. Since the mapping between the chosen privacy and noise levels is independent of the running app, the functionality of certain apps might be affected. LP-Doctor allows the user to fine-tune this noise level and then remembers his preference for future reuse.

Reducing the noise level will involve recomputing the fake location with a lower noise value (if no such location has been computed before). One could show that leak of information (from lowering noise level successively) will be capped by that corresponding to the fake location with the lowest noise level released to the service provider.

Using our own and PhoneLab's datasets, we estimate LP-Doctor's need to issue such non-intrusive notification (indicating protection taking place) for only 12% of the sessions on average for each app.

9.3 Limitations

The user-level nature of LP-Doctor introduces some limitations related to certain classes of apps. First, LP-Doctor, like other mechanisms, is inapplicable to apps that require accurate location access such as navigation apps for elongated period of times.

Second, LP-Doctor can't protect the user against apps utilizing unofficial location sources such as "WeChat." Such apps might scan for nearby WiFi access points and then use scan results to compute location. LP-Doctor can't anonymize location fed to such apps, though it can warn the user of the privacy threat incurred if the user is to invoke the location-based functionality. Also, it can offer the user the option to turn off the WiFi on the device to prevent accurate localization by the app when running.

Finally, LP-Doctor doesn't apply privacy protection to the apps continuously accessing location while running in the background. Constantly invoking the mock location provider affects the usability of apps that require fresh and accurate location when running. Fortunately, we found that the majority of the apps don't access location in the background (Section 4). Nevertheless, this still highlights the need for OS support to control apps' location access in the background (like the one that iOS currently provides).

9.4 Evaluation

We now evaluate and report LP-Doctor's overhead on performance, Quality of Service (QoS), and usability.

9.4.1 Performance

LP-Doctor performs a set of operations which delay the app launching. We evaluate this delay on two devices: Samsung Galaxy S4 running Android 4.2.2, and Samsung Galaxy S5 running Android 4.4.4. We recorded the delay in launching a set of apps while running LP-Doctor. We partitioned those apps into two sets. The first (set 1) includes the apps which LP-Doctor doesn't target, while the second (set 2) includes non-system apps that request fine location permissions.

Fig. 17 plots the delay distribution for both devices and for the two app sets. Clearly, apps that belong to the

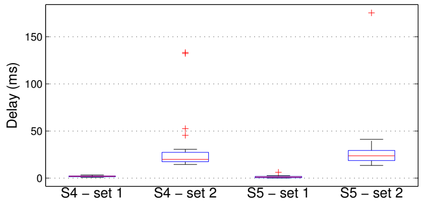


Figure 17: The app launch delay caused by LP-Doctor.

first set experience very minimal delay, varying between 1 and 3ms. The second set of apps experience longer delays without exceeding 50ms for both devices. We also tested LP-Doctor's impact on the battery by recording the battery depletion time when LP-Doctor was running in the background and when it was not. We found that LP-Doctor has less than 10% energy overhead (measured as the difference in battery depletion time). Besides, LP-Doctor runs the same logic as our PhoneLab survey app in the background which 95 users ran over 4 months and reported no performance or battery issues.

9.4.2 User Study

To evaluate the usability of LP-Doctor and its effect on QoS, we conducted a user study over Amazon Mechanical Turk. We designed two Human Intelligence Tasks (HITs), each evaluating a different representative testing scenario of LP-Doctor.

Apps that provide location-based services (LBSes) fall into several categories. On one dimension, an app can *pull* information to the user based on the current location, or it can *push* the user's current location to other users. On another dimension, the app can access the user's location *continuously* or *sporadically* to provide the LBS. One can then categorize apps as: *pull-sporadic* (e.g., weather, Yelp, etc.), *pull-continuous* (e.g., Google Now), *push-sporadic* (e.g., geo-tagging, Facebook check-in, etc.), or *push-continuous* (e.g., Google Latitude). As LP-Doctor isn't effective against apps continuously accessing the user's location (which are a minority to start with), we focus on studying the user's experience of LP-Doctor while using **Yelp**, as a representative example of *pull-sporadic* apps, and **Facebook**, as representative example of *push-sporadic* apps.

We recruited 120 participants for the Yelp HIT and another 122 for the Facebook HIT[3]; we had 227 unique participants in total. On average, each participant completed the HIT in 20min and was compensated $3 for his response. We didn't ask the users for any personal information and nor did LP-Doctor . We limited the study to Android users.

Of the participants: 28% were females vs. 72% males; 32% had high school education, 47% with BS degree or equivalent; and 37% are older than 30 years. Also, 52% of the participants reported that they have taken steps to mitigate privacy threats. Interestingly, 93% of the participants didn't have mock locations enabled on their devices indicating the participants are not tech-savvy.

We constructed the study with a set of connected tasks. In every task, the online form displays a set of instructions/questions that the participant user must follow/answer. After successfully completing the task, LP-Doctor displays a special code that the participant must input to proceed to the next task. In what follows, we describe the various tasks that we asked users to perform and how they responded.

Installing and configuring LP-Doctor: The participants' first task was to download LP-Doctor from Google Play and enable mock locations. We asked the users to rate how difficult it was to enable mock locations on the scale of 1 (easy) to 5 (difficult). 83% of the participants answered with a value of 1 or 2 implying that LP-Doctor is easy to install.

Installation menu: In their second task, the participants interacted with the installation menu (Fig. 15). The users had to install (re-install if already installed) either Yelp or Facebook. Just when either app completes installation, LP-Doctor presents the user with the menu to input the privacy options. The participants reported a positive experience with this menu; 83% reported it was easy to use (rated 1 or 2 on a scale of 1 (easy) to 5 (hard)); 86% said it was informative; 83% thought it provides them with more control than Android's permission; 79% answered it is useful (rated 1 or 2 on a scale of 1 (useful) to 5 (useless)); and 74% would like to have such menu appearing whenever they install a location-aware app (12% answered with not sure).

Impact on QoS: The survey version of LP-Doctor adds noise on top of the user's location regardless of his previous choice. This allowed us to test the impact of adding noise (Laplacian with 1000m radius) to the location accessed by either Yelp or Facebook. We didn't ask the participants to assess the effect of location anonymization on the QoS directly. Rather, we asked the Yelp respondents to report their satisfaction with the list of restaurants returned by the app. While we asked the Facebook respondents to indicate whether the list of places to check-in from is relevant to them. The participants in the first HIT indicated that Yelp ran normally (82%), the restaurant search results were relevant (73%), the user experience didn't change (76%), and Yelp need not access the user's accurate location (67%).

The Facebook HIT participants exhibited similar results: Facebook ran normally (80%), the list of places to check-in was relevant (60%), user experience didn't change (80%), and Facebook need not access the user's

[3] https://kabru.eecs.umich.edu/wordpress/wp-content/uploads/lp-doctor-survey-fb.pdf

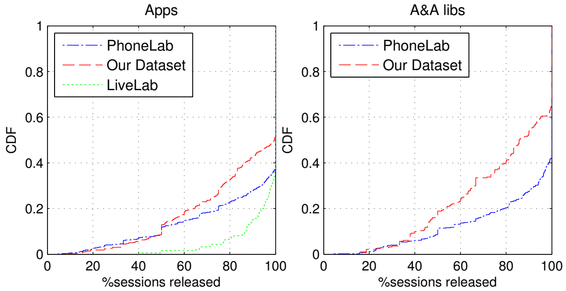

Figure 18: The distribution of percentage of sessions where apps maintain QoS for apps (left) and A&A libraries (right).

accurate location (80%).

Fig. 18 shows the percentage of sessions (for all app–user combinations) that won't experience any noise addition according to our datasets. It is obvious that the percentage of sessions with potential loss in QoS (when LP-Doctor adds noise) is minimal (less than 20%, a bit higher if the user opts for A&A libraries protection). Our user study shows that more than 70% of the users won't experience loss in QoS in these sessions. For those users who do face loss in QoS, LP-Doctor provides them with the option of adjusting the noise level at runtime through the notifications.

Notifications: In the final task, we asked the participants to test the noise reduction feature that allows for a personalized privacy–utility trade-off. After they reduced the noise level, they would invoke the location-based feature in both Yelp and Facebook and check if the results were improved. Indeed, most of the participants who reported loss in QoS reported the Yelp's search results (64%) and Facebook's check-in places (70%) improved after reducing the noise.

The participants also indicated the the noise reduction feature is easy to use (75%). 86% of the participants won't mind having this feature whenever they launch a location-aware app.

Post-study questions: As we couldn't control the per-place prompts given our study design, we asked the participants for their opinion about being prompted when visiting new places (per-place prompts). Only 54% answered they would prefer prompted, 37% answered negatively, and the rest answered "I am not sure." These responses are consistent with our design decision; the user has to approve per-place prompts when initially configuring LP-Doctor as they are not automatically enabled.

Also, 82% of the participants felt comfortable that Facebook (80%) and Yelp (85%) didn't access their accurate location. Finally, 77% of the participants answered "Yes" when asked about installing LP-Doctor or other tool to protect their location privacy. Only 11% answered "No" and the rest answered with "I am not sure." This result comes at an improvement over the 52% who initially said they took steps in the past to address location-privacy threat.

In summary, we conducted one of the few studies (e.g., [8]) that evaluate a location-privacy protection mechanism in the wild. We showed that location-privacy protection is feasible in practice where a balance between QoS, usability, and privacy could be achieved.

10 Conclusion

In this paper, we posed a question about the effectiveness of OS-based location-access controls and whether they can be improved. To answer this question, we conducted a location-collection campaign that considers location-privacy threats from the perspective of mobile apps. From this campaign, we observed, modeled, and categorized profiling as being the prominent privacy threat from location access for both apps and A&A libraries. We concluded that controlling location access per session is needed to balance between loss in QoS and privacy protection. As existing OS controls don't readily provide such functionality, we proposed LP-Doctor, a user-level tool that helps the user better utilize existing OS-based location-access controls. LP-Doctor is shown to be able to mitigate privacy threats from both apps and A&A libraries with little effect on usability and QoS. In future, we would like to test LP-Doctor in the wild and use it to explore the dynamics that affect users' decisions to install a location-privacy protection mechanism.

11 Acknowledgments

We would like to thank the anonymous reviewers and the shepherd, Reza Shokri, for constructive suggestions. The work reported in this paper was supported in part by the NSF under Grants 0905143 and 1114837, and the ARO under W811NF-12-1-0530.

LinkDroid: Reducing Unregulated Aggregation of App Usage Behaviors

Huan Feng, Kassem Fawaz, and Kang G. Shin
Department of Electrical Engineering and Computer Science
The University of Michigan
{*huanfeng, kmfawaz, kgshin*}*@umich.edu*

Abstract

Usage behaviors of different smartphone apps capture different views of an individual's life, and are largely independent of each other. However, in the current mobile app ecosystem, a curious party can covertly link and aggregate usage behaviors of the same user across different apps. We refer to this as *unregulated aggregation* of app-usage behaviors. In this paper, we present a fresh perspective of unregulated aggregation, focusing on monitoring, characterizing and reducing the underlying linkability across apps. The cornerstone of our study is the *Dynamic Linkability Graph* (DLG) which tracks app-level linkability during runtime. We observed how DLG evolves on real-world users and identified real-world evidence of apps abusing IPCs and OS-level identifying information to establish linkability. Based on these observations, we propose a linkability-aware extension to current mobile operating systems, called `LinkDroid`, which provides runtime monitoring and mediation of linkability across different apps. `LinkDroid` is a client-side solution and compatible with the existing smartphone ecosystem. It helps end-users "sense" this emerging threat and provides them intuitive opt-out options.

1 Introduction

Mobile users run apps for various purposes, and exhibit very different or even unrelated behaviors in running different apps. For example, a user may expose his chatting history to WhatsApp, mobility traces to Maps, and political interests to CNN. Information about a single user, therefore, is scattered across different apps and each app acquires only a partial view of the user. Ideally, these views should remain as 'isolated islands of information' confined within each of the different apps. In practice, however, once the users' behavioral information is at the hands of the apps, it may be shared or leaked in an arbitrary way without the users' control or consent. This makes it possible for a curious adversary to aggregate usage behaviors of the same user across multiple apps without his knowledge and consent, which we refer to as *unregulated aggregation* of app-usage behaviors.

In the current mobile ecosystem, many parties are interested in conducting unregulated aggregation, including:

- *Advertising Agencies* embed ad libraries in different apps, establishing an explicit channel of cross-app usage aggregation. For example, Grindr is a geosocial app geared towards gay users, and BabyBump is a social network for expecting parents. Both apps include the same advertising library, MoPub, which can aggregate their information and recommend related ads, such as on gay parenting books. However, users may not want this type of unsolicited aggregation, especially across sensitive aspects of their lives.
- *Surveillance Agencies* monitor all aspects of the population for various precautionary purposes, some of which may cross the 'red line' of individuals' privacy. It has been widely publicized that NSA and GCHQ are conducting public surveillance by aggregating information leaked via mobile apps, including popular ones such as Angry Birds [3]. A recent study [26] shows that a similar adversary is able to attribute up to 50% of the mobile traffic to the "monitored" users, and extract detailed personal interests, such as political views and sexual orientations.
- *IT Companies* in the mobile industry frequently acquire other app companies, harvesting vast user base and data. Yahoo alone acquired more than 10 mobile app companies in 2013, with Facebook and Google following closely behind [1]. These acquisitions allow an IT company to link and aggregate behaviors of the same user from multiple apps without the user's consent. Moreover, if the acquiring com-

pany (such as Facebook) already knows the users' real identities, usage behaviors of all the apps it acquires become identifiable.

These scenarios of unregulated aggregation are realistic, financially motivated, and are only becoming more prevalent in the foreseeable future. In spite of this grave privacy threat, the process of unregulated aggregation is unobservable and works as a black box — no one knows what information has actually been aggregated and what really happens in the cloud. Users, therefore, are largely unaware of this threat and have no opt-out options. Existing proposals disallow apps from collecting user behaviors and shift part of the app logic (e.g., personalization) to the mobile OS or trusted cloud providers [7, 17]. This, albeit effective, is against the incentive of app developers and requires construction of a new ecosystem. Therefore, there is an urgent need for a practical solution that is compatible with the existing mobile ecosystem.

In this paper, we propose a new way of addressing the unregulated aggregation problem by monitoring, characterizing and reducing the underlying linkability across apps. Two apps are *linkable* if they can associate their usage behaviors of the same user. This linkability is the prerequisite of conducting unregulated aggregation and represents an upper-bound of the potential threat. Researchers studied linkability under domain-specific scenarios, such as on movie reviews [19] and social networks [16]. In contrast, we focus on the linkability that is ubiquitous in the mobile ecosystem and introduced by domain-independent factors, such as device IDs, account numbers, location and inter-app communications. Specifically, we model mobile apps on the same device as a *Dynamic Linkability Graph* (DLG) which monitors apps' access to OS-level identifying information and cross-app communication channels. DLG quantifies the potential threat of unregulated aggregation and allows us to monitor the linkability across apps during runtime.

We implemented DLG as an Android extension and observed how it evolved on 13 users during a period of 47 days. The results reveal an alarming view of the app-level linkability in the wild. Two random apps (installed by the same user) are linkable with a probability of 0.81. Specifically, 86% of the apps a user installed are directly linkable to the Facebook app, namely, his real identity. In particular, we found that apps frequently abuse OS-level information and inter-process communication (IPC) channels in unexpected ways, establishing the linkability that is unrelated to app functionalities. For example, we found that many of the apps requesting account information collect all of the user's accounts even when they only need one to function correctly. We also noticed that some advertising agencies, such as Admob and Facebook, use IPCs to share user identifiers with other apps, completely bypassing system permissions and controls. Furthermore, we identified cases when different apps write and read the same persistent file in shared storage to exchange user identifiers. The end-users should be promptly warned about these unexpected behaviors to reduce unnecessary linkability.

Based on the above observations, we propose `LinkDroid`, a linkability-aware extension to Android which provides runtime monitoring and mediation of the linkability across apps. `LinkDroid` introduces a new dimension to privacy protection on smartphones. Instead of checking whether some app behavior poses direct privacy threat, `LinkDroid` warns users about how it implicitly affects the linkability across apps. Practicality is a main driver for the design of `LinkDroid`. It extends the widely-deployed (both runtime and install-time) permission model on the mobile OS that end-users are already familiar with. Specifically, `LinkDroid` provides the following privacy-enhancing features:

- **Install-Time Obfuscation:** `LinkDroid` obfuscates device-specific identifiers that have no influence on most app functionalities, such as IMEI, Android ID, etc. We perform this during install-time to maintain the consistency of these identifiers within each app.
- **Runtime Linkability Monitoring:** When an app tries to perform a certain action that introduces additional linkability, users will receive a just-in-time prompt and an intuitive risk indicator. Users can then exercise runtime access control and choose any of the opt-out options provided by `LinkDroid`.
- **Unlinkable Mode:** The user can start an app in unlinkable mode. This will create a new instance of the app which is unlinkable with other apps. All actions that may establish a direct association with other apps will be denied by default. This way, users can enjoy finer-grained privacy protection, unlinking only a set of app sessions.

We evaluated `LinkDroid` on the same set of 13 users as in our measurement and found that `LinkDroid` reduces the cross-app linkability substantially with little loss of app performance. The probability of two random apps being linkable is reduced from 0.81 to 0.21, and the percentage of apps that are directly linkable to Facebook drops from 86% to 18%. On average, a user only needs to handle 1.06 prompts per day in the 47-day experiments and the performance overhead is marginal.

This paper makes the following contributions:

1. Introduction of a novel perspective of defending against unregulated aggregation by addressing the underlying linkability across apps (Section 2).

2. Proposal of the Dynamic Linkability Graph (DLG) which enables runtime monitoring of cross-app linkability (Section 3).

3. Identification of real-world evidence of how apps abuse IPCs and OS-level information to establish linkability across apps (Section 4).

4. Addition of a new dimension to access control based on the runtime linkability, and development of a practical countermeasure, `LinkDroid`, to defend against unregulated aggregation (Section 5).

2 Privacy Threats: A New Perspective

In this section, we will first introduce our threat model of unregulated aggregation and then propose a novel perspective of addressing it by monitoring, characterizing and reducing the linkability across apps. We will also summarize the explicit/implicit sources of linkability in the current mobile app ecosystem.

2.1 Threat Model

In this paper, we target unregulated aggregation across app-usage behaviors, i.e., when an adversary aggregates usage behaviors across multiple functionally-independent apps without users' knowledge or consent. In our threat model, an adversary can be any party that collects information from multiple apps or controls multiple apps, such as a widely-adopted advertising agency, an IT company in charge of multiple authentic apps, or a set of malicious colluding apps. We assume the mobile operating system and network operators are trustworthy and will not collude with the adversary.

2.2 Linkability: A New Perspective

There are many parties interested in conducting unregulated aggregation across apps. In practice, however, this process is unobservable and works as a black box — no one knows what information an adversary has collected and whether it has been aggregated in the cloud. Existing studies propose to disable mobile apps from collecting usage behaviors and shift part of the app logic to trusted cloud providers or mobile OS [7, 17]. These solutions, albeit effective, require building a new ecosystem and greatly restrict functionalities of the apps. Here, we address unregulated aggregation from a very different angle by monitoring, characterizing and reducing the underlying linkability across mobile apps. Two apps are *linkable* if they can associate usage behaviors of the same user. This linkability is the prerequisite of conducting unregulated aggregation, and represents an "upper-bound" of the potential threat. In the current mobile app ecosystem, there are various sources of linkability that an adversary can exploit. Researchers have studied linkability under several domain-specific scenarios, such as movie reviews [19] and social networks [16]. Here, we focus on the linkability that is ubiquitous and domain-independent. Specifically, we group its contributing sources into the following two fundamental categories.

Type	*2013-3*	*2013-10*	*2014-8*	*2015-1*
Android ID	80%	84%	87%	91%
IMEI	61%	64%	65%	68%
MAC	28%	42%	51%	55%
Account	24%	29%	32%	35%
Contacts	21%	26%	33%	37%

Table 1: Apps are increasingly interested in requesting persistent and consistent identifying information during the past few years.

OS-Level Information The mobile OS provides apps ubiquitous access to various system information, many of which can be used as consistent user identifiers across apps. These identifiers can be *device-specific*, such as MAC address and IMEI, *user-specific*, such as phone number or account number, or *context-based*, such as location or IP clusters. We conducted a longitudinal measurement study from March 2013 to January 2015, on the top 100 free Android apps in each category. We excluded the apps that are rarely downloaded, and considered only those with more than 1 million downloads. We found that apps are getting increasingly interested in requesting persistent and consistent identifying information, as shown in Table 1. By January 2015, 96% of top free apps request both the Internet access and at least one persistent identifying information. These identifying vectors, either explicit or implicit, allow two apps to link their knowledge of the same user at a remote side without even trying to bypass on-device isolation of the mobile OS.

Inter-Process Communications The mobile OS provides explicit Inter-Process Communication (IPC) channels, allowing apps to communicate with each other and perform certain tasks, such as export a location from Browser and open it with Maps. Since there is no existing control on IPC, colluding apps can exchange identifying information of the user and establish linkability covertly, without the user's knowledge. They can even synchronize and agree on a randomly-generated sequence as a custom user identifier, without accessing any system resource or permission. This problem gets more complex since apps can also conduct IPC implicitly by reading and writing shared persistent storage (SD card

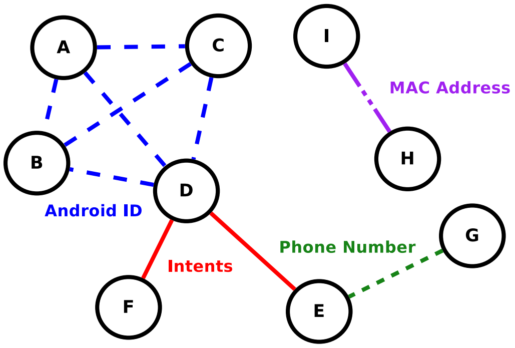

Figure 1: An illustrative example of DLG. Edges of different types represent linkability introduced by different sources.

and databases). As we will show in Section 4, these exploitations are not hypothetical and have already been utilized by real-world apps.

3 Dynamic Linkability Graph

The cornerstone of our work is the Dynamic Linkability Graph (DLG). It enables us to monitor app-level linkability during runtime and quantify the linkability introduced by different contributing sources. In what follows, we will elaborate on the definition of DLG, the linkability sources it considers, and describe how it can be implemented as an extension of Android.

3.1 Basic Concepts

We model linkability across different apps on the same device as an undirected graph, which is called the *Dynamic Linkability Graph* (DLG). Nodes in DLG represent apps and edges represent linkability introduced by different contributing sources. DLG monitors the linkability during runtime by tracking the apps' access to various OS-level information and IPC channels. An edge exists between two apps if they accessed the same identifying information or engaged in an IPC. Fig. 15 presents an illustrative example of DLG.

DLG presents a comprehensive view of the linkability across all installed apps. An individual adversary, however, may only observe a subgraph of the DLG. For example, an advertising agency only controls those apps (nodes) that incorporate the same advertising library; an IT corporate only controls those apps (nodes) it has already acquired. In the rest of the paper, we focus on the generalized case (the entire DLG) instead of considering each adversary individually (subgraphs of DLG).

3.2 Definitions and Metrics

Linkable Two apps a and b are *linkable* if there is a path between them. In Fig. 15, app A and F are linkable, app A and H are not linkable.

Gap is defined as the number of nodes (excluding the end nodes) on the shortest path between two linkable apps a and b. It represents how many additional apps an adversary needs to control in order to link information across a and b. For example, in Fig. 15, $gap_{A,D} = 0$, $gap_{A,E} = 1$, $gap_{A,G} = 2$.

Linking Ratio (LR) of an app is defined as the number of apps it is linkable to, divided by the number of all installed apps. LR ranges from 0 to 1 and characterizes to what extent an app is linkable to others. In DLG, LR equals to the size of the *Largest Connected Component* (LCC) this app resides in, excluding itself, divided by the size of the entire graph, also excluding itself:

$$LR_a = \frac{size(LCC_a) - 1}{size(DLG) - 1}$$

Linking Effort (LE) of an app is defined as the *Linking Effort* (LE) of an app as the average *gap* between it and all the apps it is linkable to. LE_a characterizes the difficulty in establishing linkability with a. $LE_a = 0$ means that to link information from app a and any random app it is linkable to, an adversary does not need additional information from a third app.

$$LE_a = \sum_{\substack{b \in LCC_a \\ b \neq a}} \frac{gap_{a,b}}{size(LCC_a) - 1}$$

LR and LE describe two orthogonal views of the DLG. In general, LR represents the quantity of links, describing the percentage of all installed apps that are linkable to a certain app, whereas LE characterizes the quality of links, describing the average amount of effort an adversary needs to make to link a certain app with other apps. In Fig. 15, $LR_A = 6/8$, $LR_H = 1/8$; $LE_A = \frac{0+0+0+1+1+2}{7-1} = 4/6, LE_H = 0$.

GLR and GLE Both LR and LE are defined for a single app, and we also need two similar definitions for the entire graph. So, we introduce *Global Linking Ratio* (GLR) and *Global Linking Effort* (GLE). *GLR* represents the probability of two randomly selected apps being linkable, while *GLE* represents the number of apps an adversary needs to control to link two random apps.

$$GLR = \sum_a \frac{LR_a}{size(DLG)}$$

$$GLE = \frac{1}{\sum_a size(LCC_a) - 1} \sum_b \sum_{\substack{c \in LCC_b \\ c \neq b}} gap_{b,c}$$

In graph theory, *GLE* is also known as the *Characteristic Path Length* (CPL) of a graph, which is widely used in Social Network Analysis (SNA) to characterize whether the network is easily negotiable or not.

3.3 Sources of Linkability

DLG maintains a dynamic view of app-level linkability by monitoring runtime behaviors of the apps. Specifically, it keeps track of apps' access to *device-specific* identifiers (IMEI, Android ID, MAC), *user-specific* identifiers (Phone Number, Accounts, Subscriber ID, ICC Serial Number), and *context-based* information (IP, Nearby APs, Location). It also monitors explicit IPC channels (Intent, Service Binding) and implicit IPC channel (Indirect RW, i.e., reading and writing the same file or database). This is not an exhaustive list but covers most standard and widely-used aggregating channels. Table 2 presents a list of all the contributing sources we consider and the details of each source will be elaborated in Section 3.4.

The criterion of two apps being linkable differs depending on the linkability source. For consistent identifiers that are obviously unique — Android ID, IMEI, Phone Number, MAC, Subscriber ID, Account, ICC Serial Number — two apps are linkable if they both accessed the same type of identifier. For pair-wise IPCs — intents, service bindings, and indirect RW — the two communicating parties involved are linkable. For implicit and fuzzy information, such as location, nearby APs, and IP, there are well-known ways to establish linkability as well. User-specific location clusters (Points of Interests, or PoIs) is already known to be able to uniquely identify a user [11, 15, 29]. Therefore, an adversary can link different apps by checking whether the location information they collected reveal the same PoIs. Here, the PoIs are extracted using a lightweight algorithm as used in [5, 10]. We select the top 2 PoIs as the linking standard, which typically correspond to home and work addresses. Similarly, the consistency and persistence of a user's PoIs are also reflected on its AP clusters and frequently-used IP addresses. This property allows us to establish linkability across apps using these fuzzy contextual information.

3.4 DLG: A Mobile OS Extension

DLG gives us the capability to construct cross-app linkability from runtime behaviors of the apps. Here, we introduce how it can be implemented as an extension to current mobile operating systems, using Android as an illustrative example. We also considered other implementation options, such as user-level interception (Aurasium [28]) or dynamic OS instrumentation (Xposed Framework [27]). The former is insecure since the extension resides in the attacker's address space and the latter is not comprehensive because it cannot handle the native code of an app. However, the developer can always implement a useful subset of DLG using one of these more deployable techniques.

Category	*Type*	*Source*
OS-level Info.	Device	IMEI Android ID MAC
	Personal	Phone # Account Subscriber ID ICC Serial #
	Contextual	IP Nearby APs Location (PoIs)
IPC Channel	Explicit	Intent Service Binding
	Implicit	Indirect RW

Table 2: DLG considers the linkability introduced by 10 types of OS-level information and 3 IPC channels.

Android Basics Android is a Linux-based mobile OS developed by Google. By default, each app is assigned a different Linux uid and lives in its own sandbox. Inter-Process Communications (IPCs) are provided across different sandboxes, based on the Binder protocol which is inherently a lightweight RPC (Remote Procedure Call) mechanism. There are four different types of components in an Android app: Activity, Service, Content Provider, and Broadcast Receiver. Each component represents a different way to interact with the underlying system: Activity corresponds to a single screen supporting user interactions; Service runs in the background to perform long-running operations and processing; Content Provider is responsible for managing and querying of persistent data such as database; and Broadcast Receiver listens to system-wide broadcasts and filters those it is interested in. Next, we describe how we instrument the Android framework to monitor app's interactions with the system and each other via these components.

Implementation Details In order to construct a DLG in Android, we need to track apps' access to various OS-

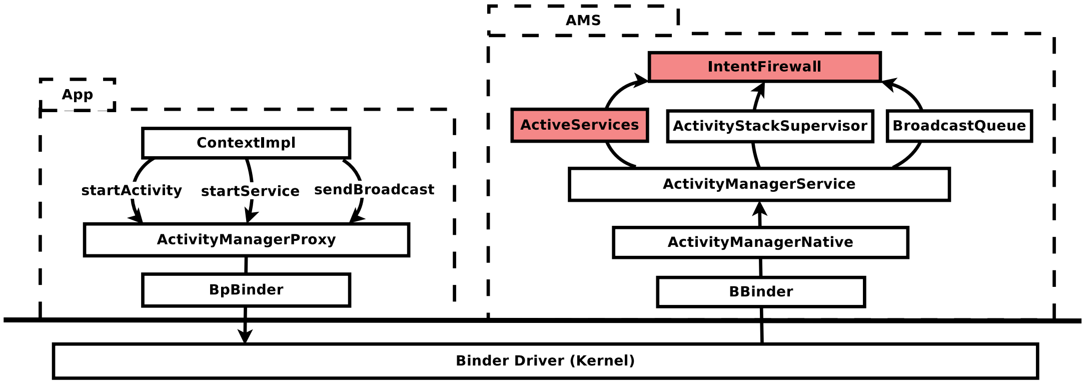

Figure 3: We extend the centralized intent filter in Android (`com.android.server.firewall.IntentFirewall`) to intercept all the intents across apps.

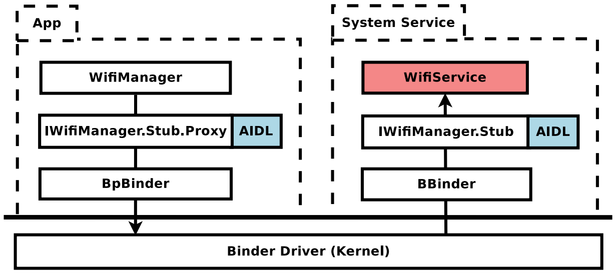

Figure 2: We instrument system services (red shaded region) to record which app accessed which identifier using Wi-Fi service as an example.

level information as well as IPCs between apps. Next, we describe how we achieve this by instrumenting different components of the Android framework.

Apps access most identifying information, such as IMEI and MAC, by interacting with different system services. These system services are parts of the Android framework and have clear interfaces defined in AIDL (Android Interface Definition Language). By instrumenting the public functions in each service that return persistent identifiers, we can have a timestamped record of which app accessed what type of identifying information via which service. Fig. 2 gives a detailed view of where to instrument using the Wi-Fi service as an example.

On the other hand, apps access some identifying information, such as Android ID, by querying system content providers. Android framework has a universal choke point for all access to remote content providers — the server-side stub class `ContentProvider.Transport`. By instrumenting this class, we know which database (uri) an app is accessing and with what parameters and actions. Fig. 4 illustrates how an app accesses remote Content Provider and explains which part to modify in order to log the information we need.

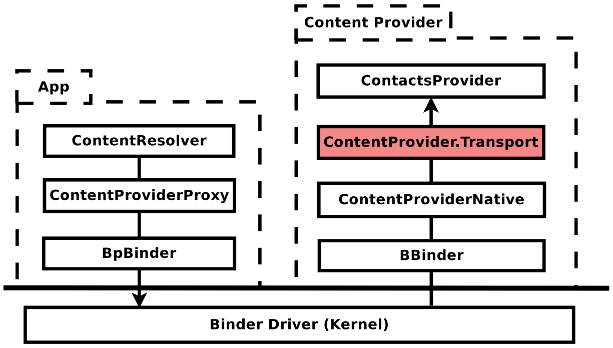

Figure 4: We instrument Content Provider (shaded region) to record which app accessed which database with what parameters.

Apps can launch IPCs explicitly, using Intents. Intent is an abstract description of an operation to be performed. It can either be sent to a specific target (app component), or broadcast to the entire system. Android has a centralized filter which enforces system-wide policies for all Intents. We extend this filter (`com.android.server.firewall.IntentFirewall`) to record and intercept all Intent communications across apps (see Fig. 3). In addition to Intents, Android also allows an app to communicate explicitly with another app by binding to one of the services it exports. Once the binding is established, the two apps can communicate under a client-server model. We instrument `com.android.server.am.ActiveServices` in the Activity Manager to monitor all the attempts to establish service bindings across apps.

Apps can also conduct IPCs implicitly by exploiting shared persistent storage. For example, two apps can write and read the same file in the SD card to exchange identifying information. Therefore, we need to monitor read and write access to persistent storage. External storage in Android are wrapped by a FUSE (Filesystem in

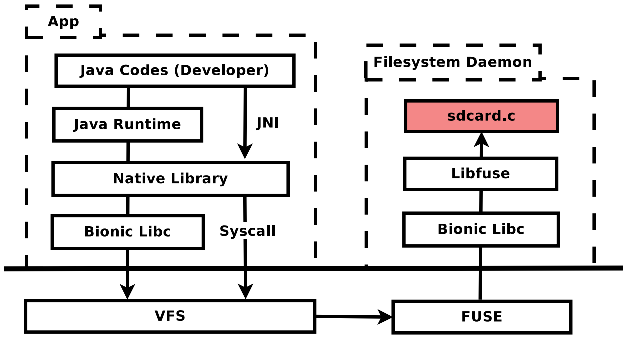

Figure 5: We customize the FUSE daemon under `/system/core/sdcard/sdcard.c` to intercept apps' access to shared external storage.

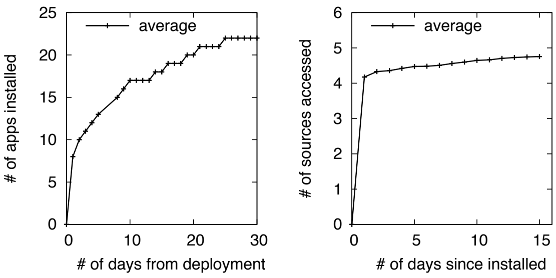

Figure 6: For an average user, more than 80% of the apps are installed in the first two weeks after deployment; each app accesses most of the linkability sources it's interested in during the first day of its installation.

Userspace) daemon which enables user-level permission control. By modifying this daemon, we can track which app reads or writes which files (see Fig. 5). This allows us to implement a Read-Write monitor which captures implicit communications via reading a file which has previously been written by another app. Besides external storage, our Read-Write monitor also considers similar indirect communications via system Content Providers.

We described how to monitor all formal ways an app can interact with system components (Services, Content Providers) and other apps (Intents, service bindings, and indirect RW). This methodology is fundamental and can be extended to cover other potential linkability sources (beyond our list) as long as a clear definition is given. By placing hooks at the aforementioned locations in the system framework, we get all the information needed to construct a DLG. For our measurement study, we simply log and upload these statistics to a remote server for analysis. In our countermeasure solutions, these are used locally to derive dynamic defense decisions.

4 Linkability in Real World

In this section, we study app-level linkability in the real world. We first present an overview of linkability, showing the current threats we're facing. Then, we go through the linkability sources and analyze to what extent each of the sources is contributing to the linkability. Finally, we shed light on how these sources can be or have been exploited for reasons unrelated to app functionalities. This paves the way for us to develop a practical countermeasure.

4.1 Deployment and Settings

We prototyped DLG on Cyanogenmod 11 (based on Android 4.4.1) and installed the extended OS on 7 Samsung Galaxy IV devices and 6 Nexus V devices. We recruited 13 participants from the students and staff in our institution, spanning over 8 different academic departments. Of the 13 participants, 6 of the participants are females and 7 are males. Before using our experimental devices, 7 of them were Android users and 6 were iPhone users. Participants are asked to operate their devices normally without any extra requirement. They are given the option to temporarily turn off our extension if they want more privacy when performing certain tasks. Logs are uploaded once per hour when the device is connected to Wi-Fi. We exclude built-in system apps (since the mobile OS is assumed to be benign in our threat model) and consider only third-party apps that are installed by the users themselves. Note that our study is limited in its size and the results may not generalize.

4.2 Data and Findings

We observed a total of 215 unique apps during a 47-day period for 13 users. On average, each user installed 26 apps and each app accessed 4.8 different linkability sources. We noticed that more than 80% of the apps are installed within the first two weeks after deployment, and apps would access most of the linkability sources they are interested in during the first day of their installation (see Fig. 6). This suggests that a relative short-term (a few weeks) measurement would be enough to capture a representative view of the problem.

Overview: Our measurement indicates an alarming view of the threat: two random apps are linkable with a probability of 0.81, and an adversary only needs to control 2.2 apps (0.2 additional app), on average, to link them. This means that an adversary in the current ecosystem can aggregate information from most apps without additional efforts (i.e., controlling a third app). Specifically, we found that 86% of the apps a user installed on his device are directly linkable to the Facebook app, namely, his real identity. This means almost all the activ-

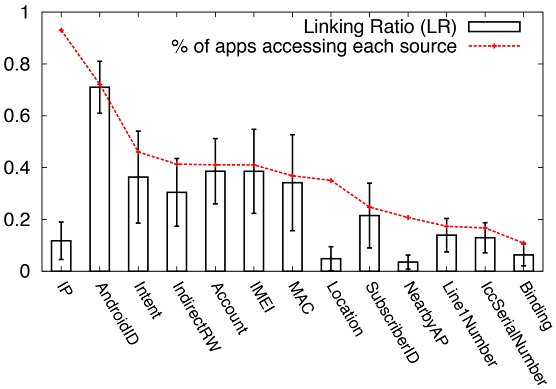

Figure 7: The percentage of apps accessing each source, and the linkability (LR) an app can get by exploiting each source.

ities a user exhibited using mobile apps are identifiable, and can be linked to the real person.

Breakdown by Source: This vast linkability is contributed by various sources in the mobile ecosystem. Here, we report the percentage of apps accessing each source and the linkability (LR) an app can acquire by exploiting each source. The results are provided in Fig. 7. We observed that except for device identifiers, many other sources contributed to the linkability substantially. For example, an app can be linked to 39% of all installed apps (LR=0.39) using only account information, and 36% (LR=0.36) using only Intents. The linkability an app can get from a source is roughly equal to the percentage of apps that accessed that source, except for the case of contextual information: IP, Location and Nearby APs. This is because the contextual information an app collected does not always contain effectively identifying information. For example, Yelp is mostly used at infrequent locations to find nearby restaurants, but is rarely used at consistent PoIs, such as home or office. This renders location information useless in establishing linkability with Yelp.

The effort required to aggregate two apps also differs for different linkability sources, as shown in Fig. 8. Device identifiers have *LE=0*, meaning that any two apps accessing the same device identifier can be directly aggregated without requiring control of an additional third app. Linking apps using IPC channels, such as Intents and Indirect RW, requires the adversary to control an average of 0.6 additional app as the connecting nodes. This indicates that, from an adversary's perspective, exploiting consistent identifiers is easier than building pair-wise associations.

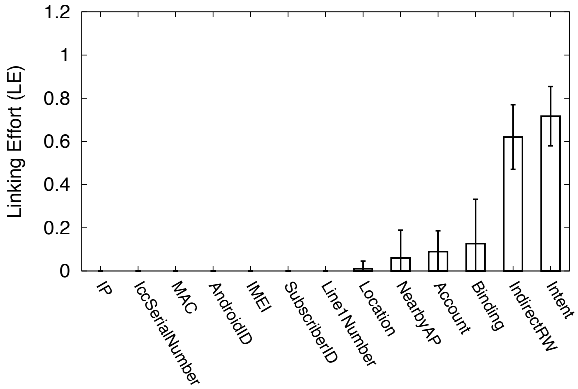

Figure 8: The (average) Linking Efforts (LE) of all the apps that are linkable due to a certain linkability source.

Category	*GLR*	*GLE*	$LR_{Facebook}$
Device	0.52 (0.13)	0.03 (0.03)	0.68 (0.12)
Personal	0.30 (0.10)	0.30 (0.11)	0.54 (0.11)
Contextual	0.20 (0.13)	0.33 (0.20)	0.44 (0.25)
IPC	0.32 (0.13)	0.78 (0.06)	0.59 (0.15)

Table 3: Linkability contributed by different categories of sources.

Breakdown by Category: We group the linkability sources into four categories — device, personal, contextual, and IPC — and study the linkability contributed by each category (see Table 3). As expected, device-specific information introduces substantial linkability and allows the adversary to conduct across-app aggregation effortlessly. Surprisingly, the other three categories of linkability sources also introduce considerable linkability. In particular, only using fuzzy contextual information, an adversary can link more than 40% of the installed apps to Facebook, the user's real identity. This suggests the naive solution of anonymizing device ids is not enough, and hence a comprehensive solution is needed to make a trade-off between app functionality and privacy.

4.3 Functional Analysis

Device identifiers (IMEI, Android ID, MAC) introduce vast amount of linkability. We manually went through 162 mobile apps that request these device-specific identifiers, but could rarely identify any explicit functionality that requires accessing the actual identifier. In fact, for the majority of these apps, their functionalities are device-independent, and therefore independent of device IDs. This indicates that device-specific identifier can be obfuscated across apps without noticeable loss of app functionality. The only requirement for device ID is that it should be unique to each device.

As to personal information (Account Number, Phone

Figure 9: Real-world example of indirect RW: an app (fm.qingting.qradio) writes user identifiers to an xml file in SD card which was later read by three other apps. This file contains the IMEI (DID) and SubscriberID (SI) of the user.

Number, Installed Apps, etc.), we also observed many unexpected accesses that resulted in unnecessary linkability. We found that many apps that request account information collected all user accounts even when they only needed one to function correctly; many apps request access to phone number even when it is unrelated to their app functionalities. Since the legitimacy of a request depends both on the user's functional needs and the specific app context, end-users should be prompted about the access and make the final decision.

The linkability introduced by contextual information (Location, Nearby AP) also requires better regulation. Many apps request permission for precise location, but not all of them actually need it to function properly. In many scenarios, apps only require coarse-grained location information and shouldn't reveal any identifying points of interest (PoIs). Nearby AP information, which is only expected to be used by Wi-Fi tools/managing apps, is also abused for other purposes. We noticed that many apps frequently collect Nearby AP information to build an internal mapping between locations and access points (APs). For example, we found that even if we turn off all system location services, WeChat (an instant messaging app) can still infer the user's location only with Nearby AP information. To reduce the linkability introduced by these unexpected usages, the users should have finer-grained control on when and how the contextual information can be used.

Moreover, we found that IPC channels can be exploited in various ways to establish linkability across apps. Apps can establish linkabililty using Intents, sharing and aggregating app-specific information. For instance, we observed that WeChat receives Intents from three different apps right after their installations, reporting their existence on the same device. Apps can also establish linkability with each other via service binding. For example, both AdMob and Facebook allow an app to bind to its service and exchanging the user identifier, completely bypassing the system permissions and controls. Apps can also establish linkabililty through Indirect RW, by writing and reading the same persistent file. Fig. 9 shows a real-world example: an app (fm.qingting.qradio) writes user identifiers to an xml file in the SD card which was later read by three other apps. The end-user should be promptly warned about these unexpected communications across apps to reduce unnecessary linkability.

5 LinkDroid: A Practical Countermeasure

Based on our observation and findings on linkability across real-world apps, we propose a practical countermeasure, `LinkDroid`, on top of DLG. We first introduce the basic design principle of `LinkDroid` and its three major privacy-enhancing features: *install-time obfuscation*, *runtime linkability monitoring*, and *unlinkable mode support*. We then evaluate the effectiveness of `LinkDroid` with the same set of participants as in our measurement study.

5.1 Design Overview

`LinkDroid` is designed with practicality in mind. Numerous extensions, paradigms and ecosystems have been proposed for mobile privacy, but access control (runtime for iOS and install-time for Android) is the only deployed mechanism. `LinkDroid` adds a new dimension to access control on smartphone devices. Unlike existing approaches that check if some app behavior poses direct privacy threats, `LinkDroid` warns users about how it implicitly builds the linkability across apps. This helps users reduce unnecessary links introduced by abusing OS-level information and IPCs, which happens frequently in reality as our measurement study indicated.

As shown in Fig. 10, `LinkDroid` provides runtime monitoring and mediation of linkability by

- monitoring and intercepting app behaviors that may introduce linkability (including interactions with various system services, content providers, shared external storage and other apps);
- querying a standalone linkability service to get the user's decision regarding this app behavior;
- prompting the user about the potential risk if the user has not yet made a decision, getting his decision and updating the linkability graph (DLG).

We have already described in Section 3.4 how to instrument the Android framework to build the monitoring components (corresponding to boxes A, B, C, D in Fig. 10). In this section, we focus on how the linkability service operates.

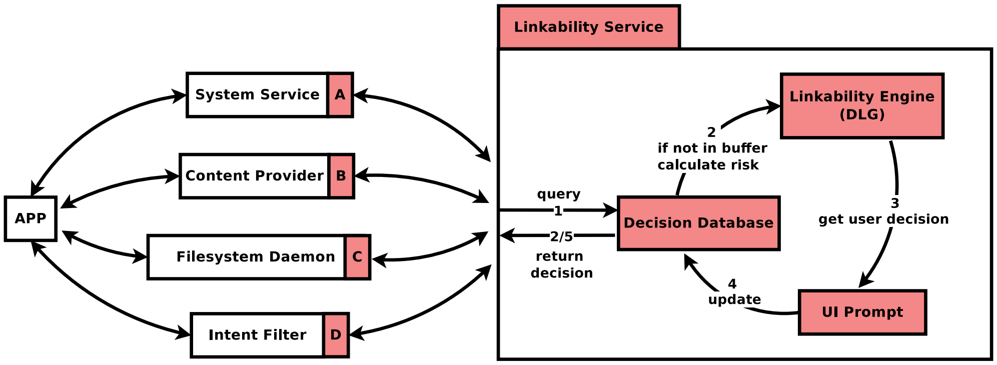

Figure 10: An overview of `LinkDroid`. Shaded areas (red) represent the parts we need to extend/add in Android. (We already explained how to extend A, B, C and D in Section 3.4.)

5.2 Install-Time Obfuscation

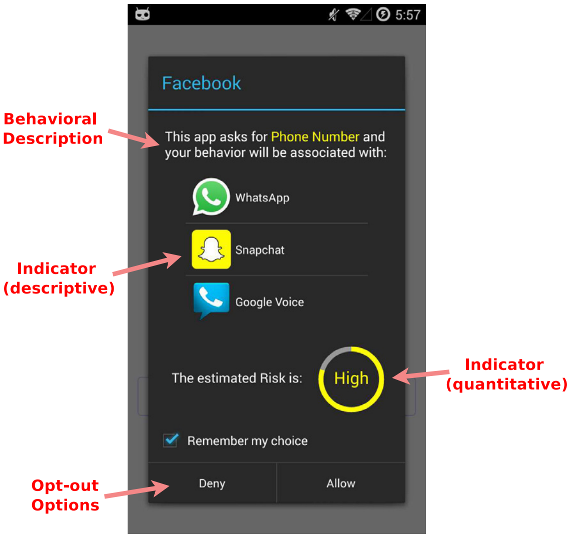
As mentioned earlier, app functionalities are largely independent of device identifiers. This allows us to obfuscate these identifiers and cut off many unnecessary edges in the DLG. In our case, the list of device identifiers includes IMEI, Android ID and MAC. Every time an app gets installed, the linkability service receives the app's uid and then generates a random mask code for it. The mask code together with the types of obfuscated device identifiers will be pushed into the decision database. This way, when an app a tries to fetch the device identifier of a certain type t, it will only get a hash of the real identifier salted with the app-specific mask code:

$$ID_t^a = hash(ID_t + mask_a).$$

Note that we do this at install-time instead of during each session because we still want to guarantee the relative consistency of the device identifiers within each app. Otherwise, it will let the app think the user is switching to a different device and trigger some security/verification mechanisms. The user can always cancel this default obfuscation in the privacy manager (Fig. 12) if he finds it necessary to reveal real device identifiers to certain apps.

5.3 Runtime Linkability Monitoring

Except for device-specific identifiers, obfuscating other sources of linkability is likely to interfere with the app functionalities. Whether there is a functional interference or not is highly user-specific and context-dependent. To make a useful trade-off, the user should be involved in this decision-making process. Here, `LinkDroid` provides just-in-time prompts before an edge creates in the DLG. Specifically, if the linkability service could not find an existing decision regarding some app behavior, it will issue the user a prompt, informing him: 1) what app behavior triggers the prompt; 2) what's the quantitative risk of allowing this behavior; and 3) what're the opt-out options. Fig. 11 gives an illustrative example of the UI of the prompt.



This app asks for Phone Number and your behavior will be associated with:

The estimated Risk is: High

☑ Remember my choice

Figure 11: The UI prompt of `LinkDroid`'s runtime access control, consisting of a behavioral description, descriptive and quantitative risk indicators, and opt-out options.

Description of App Behavior Before the user can make a decision, he first needs to know what app behavior triggers the prompt. Basically, we report two types of description: access to OS-level information and cross-app communications. To help the user understand the situation, we use a high-level descriptive language instead of the exact technical terms. For example, when an app tries to access Subscriber ID or IccSerialNumber, we report that "App X asks for sim-card information." When an app tries to send Intents to other apps, we report "App X tries to share content with App Y". During our experiments with real users (introduced later in the evaluation), 11 out of the 13 participants find these descriptions clear

and informative.

Risk Indicator LinkDroid reports two types of risk indicators to users: one is descriptive and the other is quantitative. The descriptive indicator tells what apps will be directly linkable to an app if the user allows its current behavior. By 'directly linkable,' we mean without requiring a third app as the connecting nodes. The quantitative indicator, on the other hand, reflects the influence on the overall linkability of the running app, including those apps that are not directly linkable to it. Here, the overall linkability is reported as a combination of the linking ratio (LR) and linking effort (LE):

$$L_a = LR_a \times e^{-LE_a}.$$

The quantitative risk indicator is defined as ΔL_a. A user will be warned of a larger risk if the total number of linkable apps significantly increases, or the average linking effort decreases substantially. We transform the quantitative risk linearly into a scale of 4 and report the risk as Low, Medium, High, and Severe.

Opt-out Options In each prompt, the user has at least two options: Allow or Deny. If the user chooses Deny, LinkDroid will obfuscate the information this app tries to get or shut down the communication channel this app requests. For some types of identifying information, such as Accounts and Location, we provide finer-grained trade-offs. For Location, the user can select from zip-code level (1km) or city-level (10km) precision; for Accounts, the user can choose which specific account he wants to share instead of exposing all his accounts. LinkDroid also allows the user to set up a VPN (Virtual Private Network) service to anonymize network identifiers. When the user switches from a cellular network to Wi-Fi, LinkDroid will automatically initialize the VPN service to hide the user's public IP. This may incur additional energy consumption and latency (see Section 5.5). All choices made by the user will be stored in the decision database for future reuse. We provide a centralized privacy manager such that the user can review and change all previously made decisions (see Fig. 12).

5.4 Unlinkable Mode

Once a link is established in DLG, it cannot be removed. This is because once a piece of identifying information is accessed or a communication channel is established, it can never be revoked. However, the user may sometimes want to perform privacy-preserving tasks which have no interference with the links that have already been introduced. For example, when the user wants to write an anonymous post in Reddit, he doesn't want it to be linkable with any of his previous posts as well as other apps. LinkDroid provides an unlinkable mode to meet such a need. The user can start an app in unlinkable mode by pressing its icon for long in the app launcher. A new uid as well as isolated storage will be allocated to this unlinkable app instance. By default, access to all OS-level identifying information and inter-app communications will be denied. This way, LinkDroid creates the illusion that this app has just been installed on a brand-new device. The unlinkable mode allows LinkDroid to provide finer-grained (session-level) control, unlinking only a certain set of app sessions.

5.5 Evaluation

We evaluate LinkDroid in terms of its overheads in usability and performance, as well as its effectiveness in reducing linkability. We replay the traces of the 13 participants of our measurement study (see Section 4), prompt them about the privacy threat and ask for their decisions. This gives us the exact picture of the same set of users using LinkDroid during the same period of time. We instruct the user to make a decision in the most conservative way: the user will Deny a request only when he believes the prompted app behavior is not applicable to any useful scenario; otherwise, he will Accept the request.

The overhead of LinkDroid mainly comes from two parts: the usability burden of dealing with UI prompts and the performance degradation of querying the linkability service. Our experimental results show that, on average, each user was prompted only 1.06 times per day during the 47-day period. The performance degradation

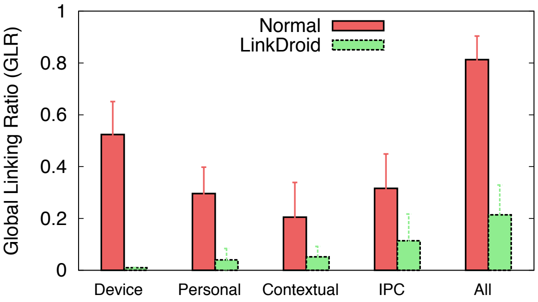

Figure 13: The Global Linking Ratio (GLR) of different categories of sources before and after using LinkDroid.

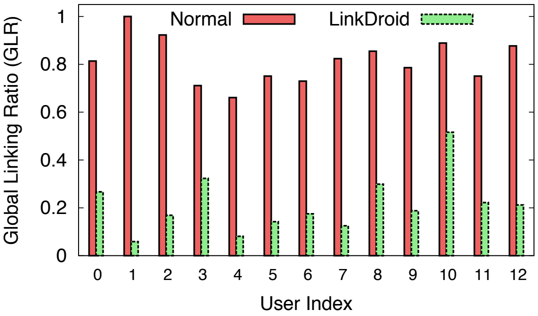

Figure 14: The Global Linking Ratio (GLR) of different users before and after using LinkDroid.

introduced by the linkability service is also marginal. It only occurs when apps access certain OS-level information or conduct cross-app IPCs. These sensitive operations happened rather infrequently — once every 12.7 seconds during our experiments. These results suggest that LinkDroid has limited impact on system performance and usability.

We found that after applying LinkDroid, the Global Linking Ratio (GLR) dropped from 81% to 21%. Fig. 13 shows the breakdown of linkability drop in different categories of sources. The majority of the remaining linkability comes from inter-app communications, most of which are genuine from the user's perspective. Not only fewer apps are linkable, LinkDroid also makes it harder for an adversary to aggregate information from two linkable apps. The Global Linking Effort (GLE) increases significantly after applying LinkDroid: from 0.22 to 0.68. Specifically, the percentage of apps that are directly linkable to Facebook dropped from 86% to 18%. Fig. 15 gives an illustrative example of how DLG changes after applying LinkDroid. We also noticed that that the effectiveness of LinkDroid differs across users, as shown in Fig. 14. In general, LinkDroid is more effective for the users who have diverse mobility patterns, are cautious about sharing information across apps and/or maintain different accounts for different services.

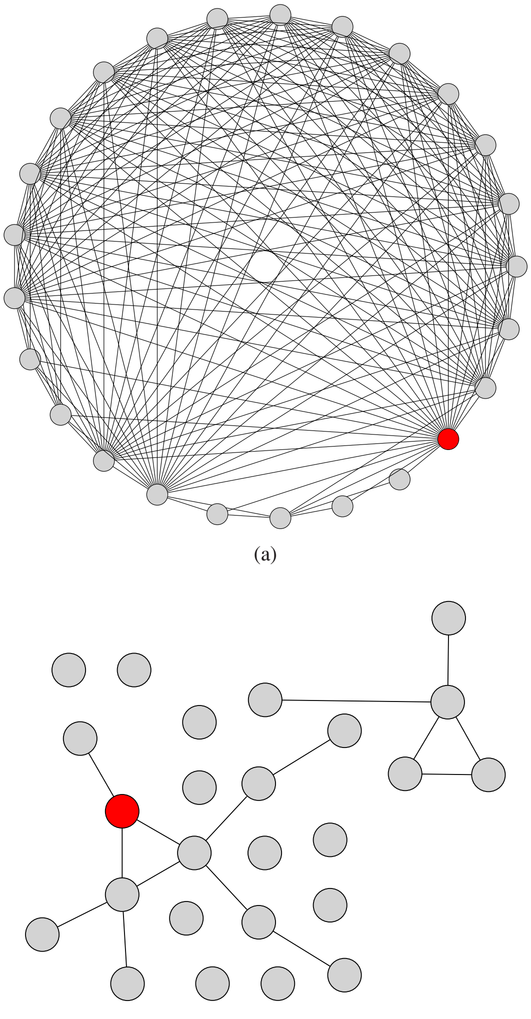

Figure 15: DLG of a representative user before (a) and after (b) applying LinkDroid. Red circle represents the Facebook app.

LinkDroid takes VPN as a plug-in solution to obfuscate network identifiers. The potential drawback of using VPN is its influence on device energy consumption and network latency. We measured the device energy consumption of using VPN on a Samsung Galaxy 4 device, with Monsoon Power Monitor. Specifically, we tested two network-intensive workloads: online videos and browsing. We observed a 5% increase in energy consumption for the first workload, and no observable difference for the second. To measure the network latency, we measured the ping time (average of 10 trials) to Alexa Top 20 domains and found a 13% increase (17ms). These results indicate that the overhead of using VPN on smartphone device is noticeable but not significant. Seven of 13 participants in our evaluation were willing to use VPN services to achieve better privacy.

We interviewed the 13 participants after the experiments. Questions are designed on a scale of 1 to 5 and a score of 4 or higher is regarded as "agree." Eleven of the participants find the UI prompt informative and clear and nine are willing to use LinkDroid on a daily basis to inform them about the risk and provide opt-out options. However, these responses might not be representative due to the limited size and diversity of the participants. We also noticed that users care a lot about the linkability of sensitive apps, such as Snapchat and Facebook. Some participants clearly state that they do not want any app to be associated with the Facebook app, except for very necessary occasions. This also supports the rationale behind the design of LinkDroid's unlinkable mode.

6 Related Work

There have been other proposals [7,17] which also address the privacy threats of information aggregation by mobile apps. They shift the responsibility of information personalization and aggregation from mobile apps to the mobile OS or trusted cloud providers, requiring re-development of mobile apps and extensive modifications on the entire mobile ecosystem. In contrast, LinkDroid is a client-side solution which is compatible with existing ecosystem — it focuses on characterizing the threat in current mobile ecosystem and making a practical trade-off, instead of proposing new computation (advertising) paradigm.

Existing studies investigated linkability under several domain-specific scenarios. Arvind *et al.* [19] showed that a user's profile in Netflix can be effectively linked to his in IMDB, using long-tailed (unpopular) movies. Sebastian *et al.* [16] described how to link the profiles of the same user in different social networks using friends topologies. This type of linkability is restricted to a small scope, and may only exist across different apps in the same domain. Here, we focus on the linkability that are domain-independent and ubiquitous to all apps, regardless of the type and semantics of each app.

The capability of advertising agency on conducting profiling and aggregation has been extensively studied [12,23]. Various countermeasures have been proposed, such as enforcing finer-grained isolation between ad library and the app [21,22], or adopting a privacy-preserving advertising paradigm [4]. However, unlike LinkDroid, they only consider a very specific and restricted scenario — advertising library — which involves few functional trade-offs. LinkDroid, instead, introduces a general linkability model, considers various sources of linkability and suits a diverse set of adversaries.

There have also been numerous studies on information access control on smartphone [6,8,9,13,14,20,24]. Many of these studies have already proposed to provide apps with fake identifiers and other types of sensitive information [13,20,27]. These studies focus on the explicit privacy concern of accessing and leaking sensitive user information, by malicious mobile apps or third-party libraries. Our work addresses information access control from a very different perspective, investigating the implicit linkability introduced by accessing various OS-level information and IPC channels.

Many modern browsers provide a private (incognito) mode. These are used to defend against local attackers, such as users sharing the same computer, from stealing cookies or browse history from each other [2]. This is inherently different from LinkDroid's *unlinkable mode* which targets unregulated aggregation by remote attackers.

7 Discussion

In this paper, we proposed a new metric, *linkability*, to quantify the ability of different apps to link and aggregate their usage behaviors. This metric, albeit useful, is only a coarse upper-bound of the actual privacy threat, especially in the case of IPCs. Communication between two apps does not necessarily mean that they have conducted, or are capable of conducting, information aggregation. However, deciding on the actual intention of each IPC is by itself a difficult task. It requires an automatic and extensible way of conducting semantic introspection on IPCs, and is a challenging research problem on its own.

LinkDroid aims to reduce the linkability introduced covertly without the user's consent or knowledge — it couldn't and doesn't try to eliminate the linkability explicitly introduced by users. For example, a user may post photos of himself or exhibit very identifiable purchasing behavior in two different apps, thus establishing linkability. This type of linkability is app-specific, domain-dependent and beyond the control of LinkDroid. Identifiability or linkability of these domain-specific usage behaviors are of particular interest to other areas, such as anonymous payment [25], anonymous query processing [18] and data anonymization techniques.

The list of identifying information we considered in this paper is well-formatted and widely-used. These ubiquitous identifiers contribute the most to information aggregation, since they are persistent and consistent across different apps. We didn't consider some uncommon identifiers, such as walking patterns and microphone signatures, because we haven't yet observed any real-world adoption of these techniques by commercial apps. However, LinkDroid can easily include other types of identifying information, as long as a clear definition is given.

DLG introduces another dimension — linkability — to privacy protection on mobile OS and has some other potential usages. For example, when the user wants to perform a certain task in Android and has multiple optional apps, the OS can recommend him to choose the app which is the least linkable with others. We also noticed some interesting side-effect of LinkDroid's unlinkable mode. Since unlinkable mode allows users to enjoy finer-grained (session-level) unlinkability, it can be used to stop a certain app from continuously identifying a user. This can be exploited to infringe the benefits of app developers in the case of copyright protection, etc. For example, NYTimes only allows an unregistered user to read up to 10 articles every month. However, by restarting the app in unlinkable mode in each session, a user can stop NYTimes from linking himself across different sessions and bypass this quota restriction.

8 Conclusion

In this paper, we addressed the privacy threat of unregulated aggregation from a new perspective by monitoring, characterizing and reducing the underlying linkability across apps. This allows us to measure the potential threat of unregulated aggregation during runtime and promptly warn users of the associated risks. We observed how real-world apps abuse OS-level information and IPCs to establish linkability, and proposed a practical countermeasure, LinkDroid. It provides runtime monitoring and mediation of linkability across apps, introducing a new dimension to privacy protection on mobile device. Our evaluation on real users has shown that LinkDroid is effective in reducing the linkability across apps and only incurs marginal overheads.

Abstract

Modern mobile platforms like Android enable applications to read aggregate power usage on the phone. This information is considered harmless and reading it requires no user permission or notification. We show that by simply reading the phone's aggregate power consumption over a period of a few minutes an application can learn information about the user's location. Aggregate phone power consumption data is extremely noisy due to the multitude of components and applications that simultaneously consume power. Nevertheless, by using machine learning algorithms we are able to successfully infer the phone's location. We discuss several ways in which this privacy leak can be remedied.

1 Introduction

Our phones are always within reach and their location is mostly the same as our location. In effect, tracking the location of a phone is practically the same as tracking the location of its owner. Since users generally prefer that their location not be tracked by arbitrary 3rd parties, all mobile platforms consider the device's location as sensitive information and go to considerable lengths to protect it: applications need explicit user permission to access the phone's GPS and even reading coarse location data based on cellular and WiFi connectivity requires explicit user permission.

In this work we show that despite these restrictions applications can covertly learn the phone's location. They can do so using a seemingly benign sensor: the phone's power meter that measures the phone's power consumption over a period of time. Our work is based on the observation that the phone's location significantly affects the power consumed by the phone's cellular radio. The power consumption is affected both by the distance to the cellular base station to which the phone is currently attached (free-space path loss) and by obstacles, such as buildings and trees, between them (shadowing). The closer the phone is to the base station and the fewer obstacles between them the less power the phone consumes. The strength of the cellular signal is a major factor affecting the power used by the cellular radio [29]. Moreover, the cellular radio is one of the most dominant power consumers on the phone [14].

Suppose an attacker measures in advance the power profile consumed by a phone as it moves along a set of known routes or in a predetermined area such as a city. We show that this enables the attacker to infer the target phone's location over those routes or areas by simply analyzing the target phone's power consumption over a period of time. This can be done with no knowledge of the base stations to which the phone is attached.

A major technical challenge is that power is consumed simultaneously by many components and applications on the phone in addition to the cellular radio. A user may launch applications, listen to music, turn the screen on and off, receive a phone call, and so on. All these activities affect the phone's power consumption and result in a very noisy approximation of the cellular radio's power usage. Moreover, the cellular radio's power consumption itself depends on the phone's activity, as well as the distance to the base-station: during a voice call or data transmission the cellular radio consumes more power than when it is idle. All of these factors contribute to the phone's power consumption variability and add noise to the attacker's view: the power meter only provides aggregate power usage and cannot be used to measure the power used by an individual component such as the cellular radio.

Nevertheless, using machine learning, we show that the phone's aggregate power consumption over time completely reveals the phone's location and movement. Intuitively, the reason why all this noise does not mislead our algorithms is that the noise is not correlated with the phone's location. Therefore, a sufficiently long power measurement (several minutes) enables the learning algorithm to "see" through the noise. We refer to power consumption measurements as time-series and use methods for comparing time-series to obtain classification and pattern matching algorithms for power consumption profiles.

In this work we use machine learning to identify the routes taken by the victim based on previously collected power consumption data. We study three types of user tracking goals:

1. **Route distinguishability:** First, we ask whether an attacker can tell what route the user is taking among a fixed set of possible routes.
2. **Real-time motion tracking:** Assuming the user is taking a certain known route, we ask whether an attacker can identify her location along the route and track the device's position on the route in real-time.
3. **New route inference:** Finally, suppose a user is moving along an arbitrary (long) route. We ask if an attacker can learn the user's route using the previously measured power profile of many (short) road segments in that area. The attacker composes the power profile of the short road segments to identify the user's route and location at the end of the route.

We emphasize that our approach is based on measuring the phone's aggregate power consumption and nothing else. In particular, we do not use the phone's signal strength as this data is protected on Android and iOS devices and reading it requires user permission. In contrast, reading the phone's power meter requires no special permissions.

On Android reading the phone's aggregate power meter is done by repeatedly reading the following two files:

```
/sys/class/power_supply/battery/voltage_now
/sys/class/power_supply/battery/current_now
```

Over a hundred applications in the Play Store access these files. While most of these simply monitor battery usage, our work shows that all of them can also easily track the user's location.

Our contributions. Our work makes the following contributions:

- We show that the power meter available on modern phones can reveal potentially private information.
- We develop the machine learning techniques needed to use data collected from the power meter to infer location information. The technical details of our algorithms are presented in sections 4, 5 and 6, followed by experimental results.
- In sections 8 and 9 we discuss potential continuation to this work, as well as defenses to prevent this type of information leakage.

2 Threat Models

We assume a malicious application is installed on the victim's device and runs in the background. The application has no permission to access the GPS or any other location data such as the cellular or WiFi components. In particular, the application has no permission to query the identity of visible cellular base stations or the SSID of visible WiFi networks.

We only assume access to power data (which requires no special permissions on Android) and permission to communicate with a remote server. Network connectivity is needed to generate dummy low rate traffic to prevent the cellular radio from going into low power state. In our setup we also use network connectivity to send data to a central server for processing. However, it may be possible to do all processing on the phone.[1]

As noted earlier, the application can only read the *aggregate* power consumed by the phone. It cannot measure the power consumed by the cellular radio alone. This presents a significant challenge since many components on the phone consume variable amounts of power at any given time. Consequently, all the measurements are extremely noisy and we need a way to "see" though the noise.

To locate the phone, we assume the attacker has prior knowledge of the area or routes through which the victim is traveling. This knowledge allows the attacker to measure the power consumption profile of different routes in that area in advance. Our system correlates this data with the phone's measured power usage and we show that, despite the noisy measurements, we are able to correctly locate the phone. Alternatively, as for many other machine learning cases, the training data can also be collected after obtaining the unlabeled query data. For instance, an attacker obtained a power consumption profile of a user, the past location of whom it is extremely important to determine. She can still collect, after the fact, reference profiles for a limited area in which the user has likely been driving and carry out the attack.

For this to work we need the tracked phone to be moving by a car or a bus while being tracked. Our system cannot locate a phone that is standing still since that only provides the power profile for a single location. We need multiple adjacent locations for the attack to work.

Given the resources at our disposal, the focus of this work is on locating a phone among a set of local routes in a pre-determined area. A larger effort is needed to scale the system to cover the entire world by pre-measuring the power profile of all road segments worldwide. Nevertheless, our localized experiments already show that tracking users who follow a daily routine is quite possible. For example, a mobile device owner might choose one of a small number of routes to get from home to work. The

[1] It is important to mention here that while a network access permission will appear in the permission list for an installed application, it does not currently appear in the list of required permissions prior to application installation.

system correctly identifies what route was chosen and in real-time identifies where the phone is along that route. This already serves as a cautionary note about the type of information that can be leaked by a seemingly innocuous sensor like the power meter.

We note that scaling the system to cover worldwide road segments can be done by crowd-sourcing: a popular app, or perhaps even the core OS, can record the power profile of streets traveled by different users and report the results to a central server. Over time the resulting dataset will cover a significant fraction of the world. On the positive side, our work shows that service providers can legitimately use this dataset to improve the accuracy of location services. On the negative side, tracking apps can use it to covertly locate users. Given that all that is required is one widespread application, many actors in the mobile space are in a position to build the required dataset of power profiles and use it as they will.

3 Background

In this section we provide technical background on the relation between a phone's location and its cellular power consumption. We start with a description of how location is related to signal strength, then we describe how signal strength is related to power consumption. Finally, we present examples of this phenomenon, and we demonstrate how obtaining access to power measurements could leak information about a phone's location.

3.1 Location affects signal strength and power consumption

Distance to the base station is the primary factor that determines a phone's signal strength. The reason for this is, for signals propagating in free space, the signal's power loss is proportional to the square of the distance it travels over [11]. Signal strength is not only determined by path loss, it is also affected by objects in the signal path, such as trees and buildings, that attenuate the signal. Finally, signal strength also depends on multi-path interference caused by objects that reflect the radio signal back to the phone through various paths having different lengths.

In wireless communication theory signal strength is often modeled as random variation (e.g., log-normal shadowing [11]) to simulate many different environments[2]. However, in one location signal strength can be fairly consistent as base stations, attenuators, and reflectors are mostly stationary.

A phone's received signal strength to its base station affects its cellular modem power consumption. Namely, phone cellular modems consume less instantaneous power when transmitting and receiving at high signal strength compared to low signal strength. Schulman et. al. [29] observed this phenomenon on several different cellular devices operating on different cellular protocols. They showed that communication at a poor signal location can result in a device power draw that is 50% higher than at a good signal location.

The primary reason for this phenomenon is the phone's power amplifier used for transmission which increases its gain as signal strength drops [11]. This effect also occurs when a phone is only receiving packets. The reason for this is cellular protocols which require constant transmission of channel quality and acknowledgments to base stations.

3.2 Power usage can reveal location

The following results from driving experiments demonstrate the potential of leaking location from power measurements.

We first demonstrate that signal strength in each location on a drive can be static over the course of several days. We collected signal strength measurements from a smartphone once, and again several days later. In Figure 1 we plot the signal strength observed on these two drives. In this figure it is apparent that (1) the segments of the drive where signal strength is high (green) and low (red) are in the same locations across both days, and (2) that the progression of signal strength along the drive appears to be a unique irregular pattern.

Next, we demonstrate that just like signal strength, power measurements of a smartphone, while it communicates, can reveal a stable, unique pattern for a particular drive. Unlike signal strength, power measurements are less likely to be stable across drives because power depends on how the cellular modem reacts to changing signal strength: a small difference in signal strength between two drives may put the cellular modem in a mode that has a large difference in power consumption. For example, a small difference in signal strength may cause a phone to hand-off to a different cellular base station and stay attached to it for some time (Section 3.3).

Figure 2 shows power measurements for two Nexus 4 phones in the same vehicle, transmitting packets over their cellular link, while driving on the same path. The power consumption variations of the Nexus 4 phones are similar, indicating that power measurements can be mostly stable across devices.

Finally, we demonstrate that power measurements could be stable across different models of smartphones. This stability would allow an attacker to obtain a reference power measurement for a drive without using the same phone as the victim's. We recorded power

[2] Parameters of the model can be calibrated to better match a specific environment of interest.

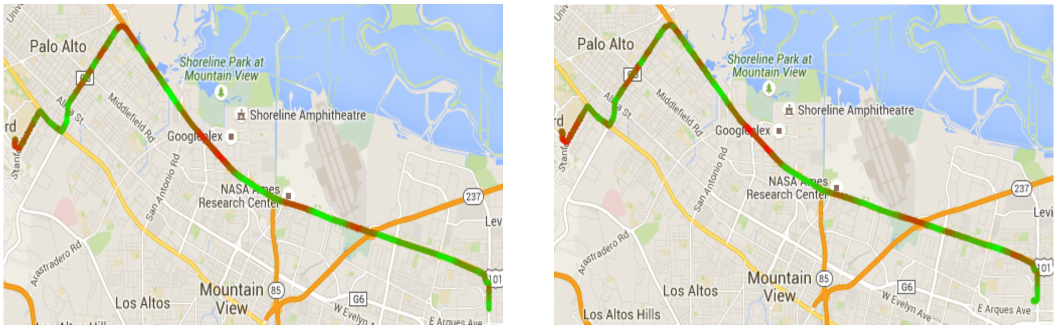

Figure 1: Signal strength profiles measured on two different days are stable.

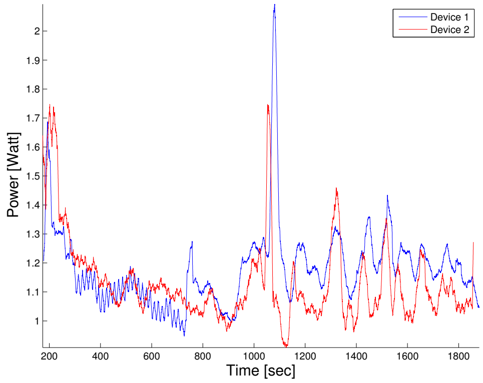

Figure 2: For two phones of the same model, power variations on the same drive are similar.

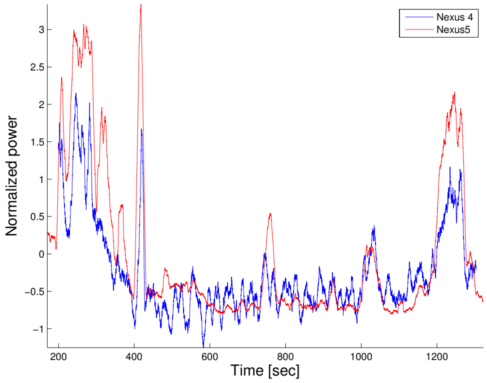

Figure 3: For two different phone models, power variations on the same drive are similar.

measurements, while transmitting packets over cellular, using two different smartphone models (Nexus 4 and Nexus 5) during the same ride, and we aligned the power samples, according to absolute time.

The results presented in Figure 3 indicate that there is similarity between different models that could allow one model to be used as a reference for another. This experiment serves as a proof of concept: we leave further evaluation of such an attack scenario, where the attacker and victim use different phone models, to future work. In this paper, we assume that the attacker can obtain reference power measurements using the same phone model as the victim.

3.3 Hysteresis

A phone attaches to the base station having the strongest signal. Therefore, one might expect that the base station to which a phone is attached and the signal strength will be the same in one location. Nonetheless, it is shown in [29] that signal strength can be significantly different at a location based on how the device arrived there, for example, the direction of arrival. This is due to the hysteresis algorithm used to decide when to hand-off to a new base station. A phone hands-off from its base station only when its received signal strength dips below the signal strength from the next base station by more than a given threshold [26]. Thus, two phones that reside in the same location can be attached to two different base stations.

Hysteresis has two implications for determining a victim's location from power measurements: (1) an attacker can only use the same direction of travel as a reference power measurement, and (2) it will complicate inferring new routes from power measurements collected from individual road segments (Section 6).

3.4 Background summary and challenges

The initial measurements in this section suggest that the power consumed by the cellular radio is a side channel that leaks information about the location of a smartphone. However, there are four significant challenges that must be overcome to infer location from the power meter. First, during the pre-measurement phase the attacker may have traveled at a different speed and encountered different stops than the target phone. Second, the attacker will have to identify the target's power profile from among many pre-collected power profiles along different routes. Third, once the attacker determines the target's path, the exact location of the target on the path may be ambiguous because of similarities in the path's power profile. Finally, the target may travel along a path that the attacker only partially covered during the pre-measurement phase: the attacker may have only pre-collected measurements for a subset of segments in the target's route. In the following sections we describe techniques that address each of these challenges and experiment with their accuracy.

4 Route distinguishability

As a warm-up we show how the phone's power profile can be used to identify what route the user is taking from among a small set of possible routes (say, 30 routes). Although we view it as a warm-up, building towards our main results, route distinguishability is still quite useful. For example, if the attacker is familiar with the user's routine then the attacker can pre-measure all the user's normal routes and then repeatedly locate the user among those routes.

Route distinguishability is a classification problem: we collected power profiles associated with known routes and want to classify new samples based on this training set. We treat each power profile as a time series which needs to be compared to other time series. A score is assigned after each comparison, and based on these scores we select the most likely matching route. Because different rides along the same route can vary in speed at different locations along the ride, and because routes having the same label can vary slightly at certain points (especially before getting to a highway and after exiting it), we need to compare profile features that can vary in time and length and allow for a certain amount of difference. We also have to compensate for different baselines in power consumption due to constant components that depend on the running applications and on differences in device models.

We use a classification method based on Dynamic Time Warping (DTW) [23], an algorithm for measuring similarity between temporal sequences that are misaligned and vary in time or speed. We compute the DTW distance[3] between the new power profile and all reference profiles associated with known routes, selecting the known route that yields the minimal distance. More formally, if the reference profiles are given by sequences $\{X\}_{i=1}^{n}$, and the unclassified profile is given by sequence Y, we choose the route i such that

$$i = \underset{i}{\operatorname{argmin}} \operatorname{DTW}(Y, X_i)$$

which is equivalent to 1-NN classification given DTW metric.

Because the profiles might have different baselines and variability, we perform the following normalization for each profile prior to computing the DTW distance: we calculate the mean and subtract it, and divide the result by the standard deviation. We also apply some preprocessing in the form of smoothing the profiles using a moving average (MA) filter in order to reduce noise and obtain the general power consumption trend, and we downsample by a factor of 10 to reduce computational complexity.

5 Real-time mobile device tracking

In this section we consider the following task: the attacker knows that a mobile user is traveling along a particular route and our objective is to track the mobile device as it is moving along the route. We do not assume a particular starting point along the route, meaning, in probabilistic terms, that our prior on the initial location is uniform. The attacker has reference power profiles collected in advance for the target route, and constantly receives new power measurements from an application installed on the target phone. Its goal is to locate the device along the route, and continue tracking it in real-time as it travels along the route.

5.1 Tracking via Dynamic Time Warping

This approach is similar to that of route distinguishability, but we use only the measurements collected up to this point, which comprise a sub-sequence of the entire route profile. We use the *Subsequence* DTW algorithm [23], rather than the classic DTW, to search a sub-sequence in a larger sequence, and return a distance measure as well as the corresponding start and end offsets.

We search for the sequence of measurements we have accumulated since the beginning of the drive in all our reference profiles and select the profile that yields the minimal DTW distance. The location estimate corresponds to the location associated with the end offset returned by the algorithm.

[3] In fact we compute a normalized DTW distance, as we have to compensate for difference in lengths of different routes - a longer route might yield larger DTW distance despite being more similar to the tested sequence.

5.2 Improved tracking via a motion model

While the previous approach can make mistakes in location estimation due to a match with an incorrect location, we can further improve the estimation by imposing rules based on a sensible motion model. We first need to know when we are "locked" on the target. For this purpose we define a similarity threshold so that if the minimal DTW distance is above this threshold, we are in a *locked* state. Once we are locked on the target, we perform a simple sanity check at each iteration: "Has the target displaced by more than X?"

If the sanity check does not pass we consider the estimate unlikely to be accurate, and simply output the previous estimate as the new estimated location. If the similarity is below the threshold, we switch to an *unlocked* state, and stop performing this sanity check until we are "locked" again. Algorithm 1 presents this logic as pseudocode.

Algorithm 1 Improved tracking using a simple motion model

```
$locked \leftarrow false$          ▷ Are we locked on the target?
while target moving do
    $loc[i], score \leftarrow estimateLocation()$
    $d \leftarrow getDistance(loc[i], loc[i-1])$
    if $locked$ and $d > MAX\_DISP$ then
        $loc[i] \leftarrow loc[i-1]$    ▷ Reuse previous estimate
    end if
    if $score > THRESHOLD$ then
        $locked \leftarrow true$
    end if
end while
```

5.3 Tracking using Optimal Subsequence Bijection

Optimal Subsequence Bijection (OSB) [17] is a technique, similar to DTW, that enables aligning two sequences. In DTW, we align the query sequence with the target sequence without skipping elements in the query sequence, thereby assuming that the query sequence contains no noise. OSB, on the other hand, copes with noise in both sequences by allowing to skip elements. A fixed jump-cost is incurred with every skip in either the query or the target sequence. This extra degree of freedom has potential for aligning noisy subsequences more efficiently in our case. In the evaluation section we present results obtained by using OSB and compare them to those obtained using DTW.

6 Inference of new routes

In Section 4 we addressed the problem of identifying the route traversed by the phone, assuming the potential routes are known in advance. This assumption allowed us to train our algorithm specifically for the potential routes. As previously mentioned, there are indeed many real-world scenarios where it is applicable. Nevertheless, in this section we set out to tackle a broader tracking problem, where the future potential routes are not explicitly known. Here we specifically aim to identify the final location of the phone after it traversed an unknown route. We assume that the area in which the mobile device owner moves is known, however the number of all possible routes in that area may be too large to practically pre-record each one. Such an area can be, for instance, a university campus, a neighborhood, a small town or a highway network.

We address this problem by pre-recording the power profiles of all the road segments within the given area. Each possible route a mobile device may take is a concatenation of some subset of these road segments. Given a power profile of the tracked device, we will reconstruct the unknown route using the reference power profiles corresponding to the road segments. The reconstructed route will enable us to estimate the phone's final location. Note that, due to the hysteresis of hand-offs between cellular base stations, a power consumption is not only dependent on the traveled road segment, but also on the previous road segment the device came from.

In Appendix A we formalize this problem as a hidden Markov model (HMM) [27]. In the following we describe a method to solve the problem using a particle filter. The performance of the algorithm will be examined in the next section.

6.1 Particle Filter

A particle filter [1] is a method that estimates the state of a HMM at each step based on observations up to that step. The estimation is done using a Monte Carlo approximation where a set of samples (particles) is generated at each step that approximate the probability distribution of the states at the corresponding steps. A comprehensive introduction to particle filters and their relation to general state-space models is provided in [28].

We implement the particle filter as follows. We denote $O^r = \{o^r_{xyz}\}$, where o^r_{xyz} is a power profile prerecorded over segment (y,z) while the segment (x,y) had been traversed just before it. We use a discrete time resolution $\tau = 3$ seconds. We denote $\Delta^{yz}_{\min}$ and $\Delta^{yz}_{\max}$ to be the minimum and maximum time duration to traverse road segment (y,z), respectively. We assume these bounds can be derived from prerecordings of the segments. At each iteration i we have a sample set of N routes $P_i = \{(Q,T)\}$. The initial set of routes P_0 are chosen according to Π. At each step, we execute the following algorithm:

Algorithm 2 Particle filter for new routes estimation

```
for all route $p$ in $P$ do
    $t_{\text{end}} \leftarrow$ end time of $p$
    $(x,y) \leftarrow$ last segment of $p$
    $z \leftarrow$ next intersection to traverse (distributed by $A$)
    $W_p \leftarrow \min_{\substack{t\in[\Delta^{yz}_{\text{min}},\Delta^{yz}_{\text{max}}] \\ o^r_{xyz}\in O^r_{xyz}}} \left\{\text{DTW}(O_{[t_{\text{end}},t_{\text{end}}+t]}, o^r_{xyz})\right\}$
    $p \leftarrow p||(y,z)$
    Update the end time of $p$
end for
Resample $P$ according to the weights $W_p$
```

At each iteration, we append a new segment, chosen according to the prior A, to each possible route (represented by a particle). Then, the traversal time of the new segment is chosen so that it will have a minimal DTW distance to the respective time interval of the tracked power profile. We take this minimal distance as the weight of the new route. After normalizing the weights of all routes, a resampling phase takes place. N routes are chosen from the existing set of routes according to the particle weights distribution[4]. The new resampled set of routes is the input to the next iteration of the particle filter. The total number of iterations should not exceed an upper bound on the number of segments that the tracked device can traverse. Note however that a route may exhaust the examined power profile before the last iteration (namely, the end time of that route reached t_{max}). In such a case we do not update the route in all subsequent iterations (this case is not described in Algorithm 2 to facilitate fluency of exposition).

Before calculating the DTW distance of a pair of power profiles the profiles are preprocessed to remove as much noise as possible. We first normalize the power profile by subtracting its mean and dividing by the standard deviation of all values included in that profile. Then, we zero out all power values below a threshold percentile. This last step allows us to focus only on the peaks in power consumption where the radio's power consumption is dominant while ignoring the lower power values for which the radio's power has a lesser effect. The percentile threshold we use in this paper is 90%.

Upon its completion, the particle filter outputs a set of N routes of various lengths. To select the best estimate route the simple approach is to choose the route that appears the most number of times in the output set as it has the highest probability to occur. Nonetheless, since a route is composed of multiple segments chosen at separate steps, at each step the weight of a route is determined solely based on the last segment added to the route. Therefore, the output route set is biased in favor of routes ending with segments that were given higher weights, while the weights of the initial segments have a diminishing effect on the route distribution with every new iteration. To counter this bias, we choose another estimate route using a procedure we call *iterative majority vote*, described is Appendix B.

7 Experiments

7.1 Data collection

Our experiments required collecting real power consumption data from smartphone devices along different routes. We developed the PowerSpy android application[5] that collects various measurements including signal strength, voltage, current, GPS coordinates, temperature, state of discharge (battery level) and cell identifier. The recordings were performed using Nexus 4, Nexus 5 and HTC mobile devices.

7.2 Assumptions and limitations

Exploring the limits of our attack, i.e. establishing the minimal necessary conditions for it to work, is beyond our resources. For this reason, we state the assumptions on which we rely in our methods.

We assume there is enough variability in power consumption along a route to exhibit unique features. Lack of variability may be due to high density of cellular antennas that flatten the signal strength profile. We also assume that enough communication is occurring for the signal strength to have an effect on power consumption. This is a reasonable assumption, since background synchronization of data happens frequently in smartphone devices. Moreover, the driver might be using navigation software or streaming music. However, at this stage, it is difficult to determine how inconsistent phone usage across different rides will affect our attacks.

Identifying which route the user took involves understanding which power measurements collected from her mobile device occurred during driving activity. Here we simply assume that we can identify driving activity. Other works (e.g., [22]) address this question by using data from other sensors that require no permissions, such as gyroscopes and accelerometers.

Some events that occur while driving, such as an incoming phone call, can have a significant effect on power

[4] Note that the resampling of the new routes can have repetitions. Namely, the same route can be chosen more than one time

[5] Source code can be obtained from https://bitbucket.org/ymcrcat/powerspy.

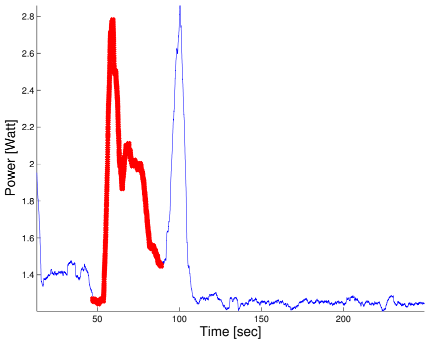

Figure 4: Power profile with a phone call occurring between 50-90 seconds. Profile region during phone call is marked in red.

consumption. Figure 4 shows the power profile of a device at rest when a phone call takes place (the part marked in red). The peak immediately after the phone call is caused by using the phone to terminate the phone call and turn off the display. We can see that this event appears prominently in the power profile and can cope with such transient effects by identifying and truncating peaks that stand out in the profile. In addition, smoothing the profile by a moving average should mitigate these transient effects.

7.3 Route distinguishability

To evaluate the algorithm for distinguishing routes (section 4) we recorded reference profiles for multiple different routes. The profiles include measurements from both Nexus 4 and Nexus 5 models. In total we had a dataset of 294 profiles, representing 36 unique routes. Driving in different directions along the same roads (from point A to B vs. from point B to A) is considered two different routes. We perform cross validation using multiple iterations (100 iterations), each time using a random portion of the profiles as a training set, and requiring equal number of samples for each possible class. The sizes of the training and test sets depend on how many reference routes per profile we require each time. Naturally, the more reference profiles we have, the higher the identification rate.

One evaluation round included 29 unique routes, with only 1 reference profile per route in the training set, and 211 test routes. It resulted in correct identification rate of 40%. That is compared to the random guess probability of only 3%. Another round included 25 unique routes, with 2 reference profiles per route in the training set and 182 routes in the test set, and resulted in correct identification rate of 53% (compared to the random guess probability of only 4%). Having 5 reference profiles per route (for 17 unique routes) raises the identification rate to 71%, compared to the random guess probability of 5.8%. And finally, for 8 reference profiles per route we get 85% correct identification. The results are summarized in table 1.

We can see that an attacker can have a significant advantage in guessing the route taken by a user.

7.4 Real-time mobile device tracking

We evaluate the algorithm for real-time mobile device tracking (section 5) using a set of 10 training profiles and an additional test profile. The evaluation simulates the conditions of real-time tracking by serially feeding samples to the algorithm as if they are received from an application installed on the device. We calculate the estimation error, i.e. the distance between the estimated coordinates and the true location of the mobile device at each step of the simulation. We are interested in the *convergence time*, i.e. the number of samples it takes until the location estimate is close enough to the true location, as well as in the distribution of the estimation errors given by a histogram of the absolute values of the distances.

Figure 5 illustrates the performance of our tracking algorithm for one of the routes, which was about 19 kilometers long. At the beginning, when there are very few power samples, the location estimation is extremely inaccurate, but after two minutes we lock on the true location. We obtained a precise estimate from 2 minutes up until 20 minutes on the route, where our estimate slightly diverges, due to increased velocity on a freeway segment. Around 26 minutes (in figure 5a) we have a large estimation error, but as we mentioned earlier, these kind of errors are easy to prevent by imposing a simple motion model (section 5.2). Most of the errors are small compared to the length of the route: 80% of the estimation errors are less than 1 km.

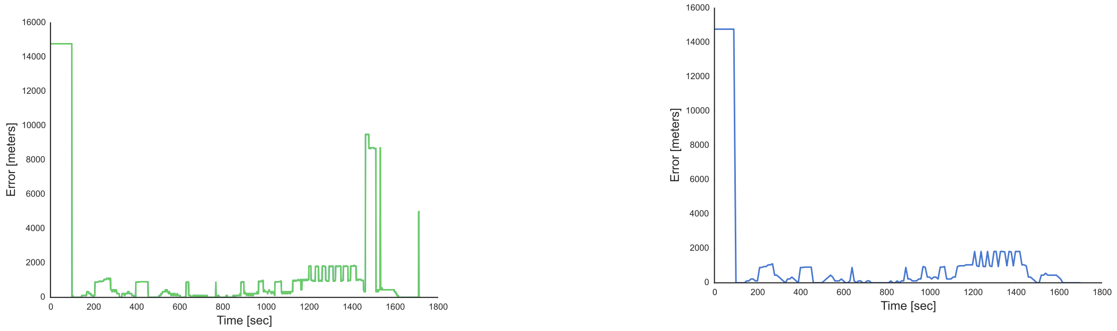
We also tested the improved tracking algorithm explained in section 5.2. Figure 5b presents the estimation error over time, and we can see that the big errors towards the end of the route that appeared in 5a are not present in fig. 5b. Moreover, now almost 90% of the estimation errors are below 1 km (fig. 6).

We provide animations visualizing our results for real-time tracking at the following links. The animations, generated using our estimations of the target's location, depict a moving target along the route and our estimation of its location. The first one corresponds to the method described in 5.1, and the second to the one described in 5.2 that uses the motion model based correction:

crypto.stanford.edu/powerspy/tracking1.mov
crypto.stanford.edu/powerspy/tracking2.mov

# Unique Routes	# Ref. Profiles/Route	# Test Routes	Correct Identification %	Random Guess %
8	10	55	85	13
17	5	119	71	6
17	4	136	68	6
21	3	157	61	5
25	2	182	53	4
29	1	211	40	3

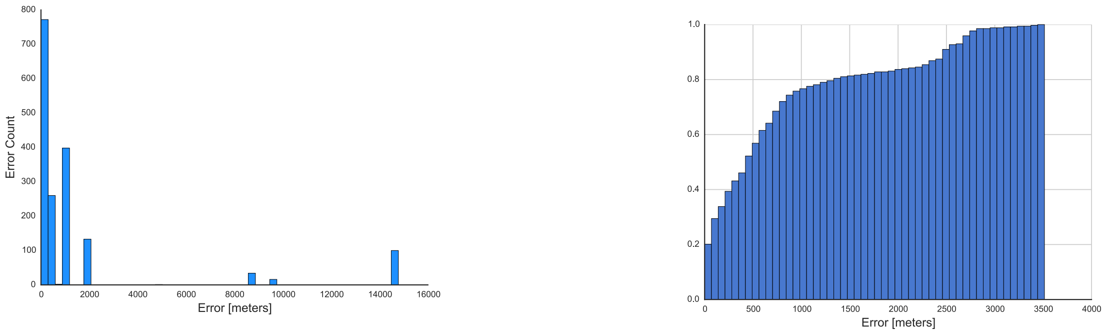
Table 1: Route distinguishability evaluation results. First column indicates the number of unique routes in the training set. Second column indicates the number of training samples per route at the attacker's disposal. Number of test routes indicates the number of power profiles the attacker is trying to classify. Correct identification percentage indicates the percentage of correctly identified routes as a fraction of the third column (test set size), which could be then compared to the expected success of random guessing in the last column.



(a) Convergence to true location.

(b) Location estimation error for improved tracking algorithm.

Figure 5: Location estimation error for online tracking.



(a) Errors histogram. Almost 90% of the errors are less than 1 km.

(b) Error cumulative distribution.

Figure 6: Estimation errors distribution for motion-model tracking.

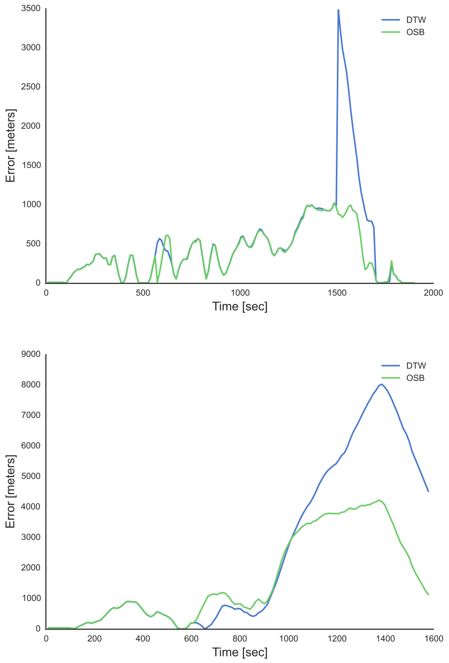


Figure 7: Comparison of DTW and OSB for real-time tracking.

7.4.1 OSB vs. DTW

We compare the performance of Dynamic Time Warping to that of Optimal Subsequence Bijection (section 5.3). Figure 7 present such a comparison for the same route, using two different recordings. The tracking was performed without compensating for errors using a motion model, to evaluate the performance of the subsequence matching algorithms as they are. We can see that, in both cases, Optimal Subsequence Bijection outperforms the standard Subsequence-DTW most of the time. Therefore, we suggest that further experimentation with OSB could potentially be beneficial for this task.

7.5 Inference of new routes

7.5.1 Setup

For the evaluation of the particle filter presented in Section 6 we considered an area depicted in Figure 8. The area has 13 intersections having 35 road segments[6]. The average length of a road segment is about 400 meters. The average travel time over the segments is around 70 seconds. The area is located in the center of Haifa, a city located in northern Israel, having a population density comparable to Philadelphia or Miami. Traffic congestion in this area varies across segments and time of day. For each power recording, the track traversed at least one congested segment. Most of the 13 intersections have traffic lights, and about a quarter of the road segments pass through them.

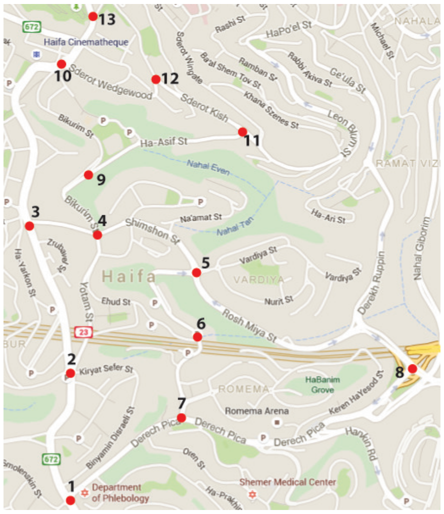

Figure 8: Map of area and intersections for route inference.

We had three pre-recording sessions which in total covered all segments. Each road segment was entered from every possible direction to account for the hysteresis effects. The pre-recording sessions were done using the same Nexus 4 phone.

We set the following parameters of the HMM (as they are defined in Appendix A):

1. A – This set defines the transition probabilities between the road segments. We set these probabilities to be uniformly distributed over all possible transitions. Namely, $a_{xyz} = \{1/|I_y| \; |I_y = \{w|(y,w) \in R, w \neq x\}\}$.

2. B – This set defines the distribution of power profile observations over each state. These probabilities depend on the road segments and their location relative to the nearby based stations. We do not need an explicit formulation of these probabilities to employ the particle filter. The likelihood of a a power profile to be associated with a road segment is estimated by the DTW distance of the power profile to prerecorded power profiles of that segment.

3. Π – This set defines the initial state distribution. We assume that the starting intersection of the tracked device is known. This applies to scenarios where the tracking begins from well-known locations, such as the user's home, office, or another location the attacker knows in advance.

For testing, we used 4 phones: two Nexus 4 (different from the one used for the pre-recordings), a Nexus 5

[6] Three of the segments are one way streets.

Phone	Track
Nexus 4 #1	8-5-6-7-1-2-3-4-5-6-4-3-2-1-7-8
Nexus 4 #2	7-1-2-3-4-5-8-7-6-5-4-2-1-7-8
Nexus 5	3-2-4-9-10-12-11-9-4-5-6-4-3-2-1-7-6-5-8-7
HTC Desire	10-12-11-9-4-2-1-7-6-5-8

Table 2: Test Routes

	random	frequent	Alg. 3	combined
Nexus 4 #1	33%	65%	48%	80%
Nexus 4 #2	31%	48%	56%	72%
Nexus 5	20%	33%	32%	55%
HTC Desire	22%	40%	41%	65%

Table 3: Destination localization

and an HTC Desire. Each phone was used to record the power profile of a different route. The four routes combined cover almost all of the road segments in the area. Table 2 details the routes by their corresponding sequences of intersection identifiers. These route recordings were done on different days, different time of day and varying weather conditions.

As noted, we can only measure the aggregate power consumption which can be significantly affected by applications that run continuously. To have a better sense of the effects of these applications the phones were run with different number of background applications. Nexus 4 #1, Nexus 5 and HTC Desire have a relatively modest number of applications which included (beyond the default Android apps): Email (corporate account), Gmail, and Google Calender. Nexus 4 #2 has a much higher number of application which included on top of the applications of phone #1: Facebook, Twitter, Skype, Waze, and WhatsApp. All those applications periodically send and receive traffic.

For each of the four tracks we derived all possible subtracks having 3 to 7 road segments. We estimated each such sub-track. In total we estimated around 200 subtracks. For each sub-track we employed Algorithms 2 and 3 to get two best estimates for the sub-track.

Tables 3 to 5 summarize the results of route estimation for each of the four phones. For each route we have two alternatives for picking an estimate (1) the most frequent route in the particle set as output by Algorithm 2; (2) the route output by Algorithm 3. For each alternative we note the road segment in which the phone is estimated to be after the completion of its track and compare it with the final road segment of the true route. This allows us to measure the accuracy of the algorithm for estimating the location of the user's destination (the end of the track). This is the most important metric for many attack scenarios where the attacker wishes to learn the destination of the victim.

In some cases it may also be beneficial for the attacker to know the actual route through which the victim traversed on his way to the destination. For this purpose, we also calculate for each alternative estimate the Levenshtein distance between it and the true route. The Levenshtein distance is a standard metric for measuring the difference between two sequences [18]. It equals the minimum number of updates required in order to change one sequence to the next. In this context, we treat a route as a sequence of intersections. The distance is normalized by the length of the longer route of the two. This allows us to measure the accuracy of the algorithm for estimating the full track the user traversed. For each estimate we also note whether it is an exact fit with the true route (i.e., zero distance). The percentage of successful localization of destination, average Levenshtein distance and percentage of exact full route fits are calculated for each type of estimated route. We also calculate these metrics for both estimates combined while taking into account for each track the best of the two estimates. To benchmark the results we note in each table the performance of a random estimation algorithm which simply outputs a random, albeit feasible, route.

The results in Table 3 show the accuracy of destination identification. It is evident that the performance of the most frequent route output by the particle filter is comparable to the performance of the best estimate output by Algorithm 3. However, their combined performance is significantly better than either estimates alone and predict more accurately the final destination of the phone. This result suggests that Algorithm 3 extracts significant amount of information from the routes output by the particle filter beyond the information gleaned from the most frequent route.

Table 3 indicates that for Nexus 4 #1 the combined route estimates were able to identify the final road segment for 80% of all scenarios. For Nexus 4 #2 which was running many applications the final destination estimates are somewhat less accurate (72%). This is attributed to the more noisy measurements of the aggregate power consumption. The accuracy for the two models – Nexus 5 and HTC Desire – is lower than the accuracy achieved for Nexus 4. Remember that all our pre-recordings were done using a Nexus 4. These results may indicate that the power consumption profile of the cellular radio is dependent on the phone's model. Nonetheless, for both phones we achieve significantly higher accuracy of destination localization (55% and 65%) as compared to the random case (about 20%).

Tables 4 and 5 present measures – Levenshtein distance and exact full route fit – of the accuracy of estimates for the full route the phone took to its destination. Here, again, the algorithm presented for Nexus 4 #1 superior performance. It was able to exactly estimate 45%

	random	frequent	Alg. 3	combined
Nexus 4 #1	0.61	0.38	0.27	0.24
Nexus 4 #2	0.63	0.61	0.59	0.52
Nexus 5	0.68	0.6	0.55	0.45
HTC Desire	0.65	0.59	0.5	0.45

Table 4: Levenshtein distance

	random	frequent	Alg. 3	combined
Nexus 4 #1	4%	38%	22%	45%
Nexus 4 #2	5%	8.5%	5%	15%
Nexus 5	3%	15%	9%	20%
HTC Desire	5%	10%	12%	17%

Table 5: Exact full route fit

of the full route to the destination. On the other hand, for the more busy Nexus 4 #2 and the other model phones the performance was worse. It is evident from the results that for these three phones the algorithm had difficulties producing an accurate estimate of the full route. Nonetheless, in all cases the accuracy is always markedly higher than that of the random case.

To have a better sense of the distance metric used to evaluate the quality of the estimated routes Figure 9 depicts three cases of estimation errors and their corresponding distance values in increasing order. It can be seen that even estimation error having relatively high distances can have a significant amount of information regarding the true route.

8 Future directions

In this section we discuss ideas for further research, improvements, and additions to our method.

8.1 Power consumption inference

While new (yet very common) smartphone models contain an internal ampere-meter and provide access to current data, other models (for instance Galaxy S III) supply voltage but not current measurements. Therefore on these models we cannot directly calculate the power consumption. V-edge [31] proposes using voltage dynamics to model a mobile device's power consumption. That and any other similar technique would extend our method and make it applicable to additional smartphone models.

Ref. [33] presents PowerTutor, an application that estimates power consumption by different components of the smartphone device based on voltage and state of discharge measurements. Isolating the power consumed by the cellular connectivity will improve our method by eliminating the noise introduced by other components such as audio/Bluetooth/WiFi etc. that do not directly depend on the route.

8.2 State of Discharge (SOD)

The time derivative of the State-of-Discharge (the battery level) is basically a very coarse indicator of power consumption. While it seemed to be too inaccurate for our purpose, there is a chance that extracting better features from it or having few possible routes may render distinguishing routes based on SOD profiles feasible. Putting it to the test is even more interesting given the HTML 5 Battery API that enables obtaining certain battery statistics from a web-page via JavaScript. Our findings demonstrate how future increases in the sampling resolution of the battery stats may turn this API even more dangerous, allowing web-based attacks.

8.3 Choice of reference routes

Successful classification depends among other factors on good matching between the power profile we want to classify and the reference power profiles. Optimal matching might be a matter of month, time of day, traffic on the road, and more. We can possibly improve our classification if we tag the reference profiles with those associated conditions and select reference profiles matching the current conditions when trying to distinguish a route. That of course requires collecting many more reference profiles.

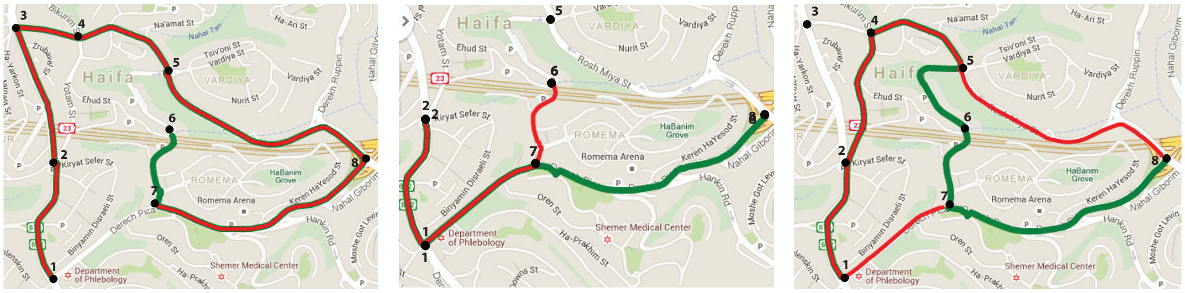
8.4 Collecting a massive dataset

Collecting a massive dataset of power profiles associated with GPS coordinates is a feasible task given vendors' capability to legally collect analytics about users' use of their smartphones. Obtaining such big dataset will enable us to better understand how well our approach can scale and whether it can be used with much less prior knowledge about the users.

9 Defenses

9.1 Non-defenses

One might think that by adding noise or limiting the sampling rate or the resolution of the voltage and current measurements one could protect location privacy. However, our method does not rely on high sampling frequency or resolution. In fact, our method works well with profiles much coarser than what we can directly get from the raw power data, and for the route distinguishing task we actually performed smoothing and downsampling of the data yet obtained good results. Our method also works well with signal strength, which is provided



(a) Distance = 0.125

(b) Distance = 0.25

(c) Distance = 0.43

Figure 9: Examples of estimation errors and their corresponding distances (partial map is depicted). The true route is green and the estimated route is red.

with much lower resolution and sampling frequency[7].

9.2 Risky combination of power data and network access

One way of reporting voltage and current measurements to the attacker is via a network connection to the attacker's server. Warning the user of this risky combination may somewhat raise the bar for this attack. There are of course other ways to leak this information. For instance, a malicious application disguised as a diagnostic software can access power data and log it to a file, without attempting to make a network connection, while another, seemingly unrelated, application reads the data from that file and sends it over the network.

9.3 Secure hardware design

The problem with access to total power consumption is that it leaks the power consumed by the transceiver circuitry and communication related tasks that indicate signal strength. While power measurements can be useful for profiling applications, in many cases, examining the power consumed by the processors executing the software logic might be enough. We therefore suggest that supplying only measurements of the power consumed by the processors (excluding the power consumed by the TX/RX chain) could be a reasonable trade-off between functionality and privacy.

9.4 Requiring superuser privileges

A simple yet effective prevention may be requiring superuser privileges (or being root) to access power supply data on the phone. Thus, developers and power-users can install diagnostic software or run a version of their application that collects power data on a rooted phone, whereas the release version of the software excludes this functionality. This would of course prevent the collection of anonymous performance statistics from the install-base, but as we have shown, such data can indicate much more than performance.

9.5 Power consumption as a coarse location indicator

Same as the cell identifier is defined as a coarse location indicator, and requires appropriate permissions to be accessed, power consumption data can also be defined as one. The user will then be aware, when installing applications that access voltage and current data, of the application's potential capabilities, and the risk potentially posed to her privacy. This defense may actually be the most consistent with the current security policies of smartphone operating systems like Android and iOS, and their current permission schemes.

10 Related work

Power analysis is known to be a powerful side-channel. The most well-known example is the use of high sample rate ($\sim$20 MHz) power traces from externally connected power monitors to recover private encryption keys from a cryptographic system [15]. Prior work has also established the relationship between signal strength and power consumption in smartphones [6, 29]. Further, Bartendr [29] demonstrated that paths of signal strength measurements are stable across several drives.

PowerSpy combines these insights on power analysis and improving smartphone energy efficiency to reveal a new privacy attack. Specifically, we demonstrate that an attacker can determine a user's location simply by monitoring the cellular modem's changes in power consumption with the smartphone's alarmingly unprotected $\sim$100 Hz internal power monitor.

[7] In fact, since it reflects more directly the environmental conditions, signal strength data can provide even better route identification and tracking. We did not focus on signal strength since accessing it requires access permissions and has already drawn research attention to it as useful for localization.

10.1 Many sensors can leak location

Prior work has demonstrated that data from cellular modems can be used to localize a mobile device (an extensive overview appears in Gentile et al. [10]). Similar to PowerSpy, these works fingerprint the area of interest with pre-recorded radio maps. Others use signal strength to calculate distances to base stations at known locations. All of these methods [16, 24, 25, 30] require signal strength measurements and base station ID or WiFi network name (SSID), which is now protected on Android and iOS. Our work does not rely on the signal strength, cell ID, or SSID. PowerSpy only requires access to power measurements, which are currently unprotected on Android.

PowerSpy builds on a large body of work that has shown how a variety of unprotected sensors can leak location information. Zhou et al. [34] reveal that audio on/off status is a side-channel for location tracking without permissions. In particular, they extract a sequence of intervals where audio is on and off while driving instructions are being played by Google's navigation application. By comparing these intervals with reference sequences, the authors were able to identify routes taken by the user. *SurroundSense* [3] demonstrates that ambient sound and light can be used for mobile phone localization. They focus on legitimate use-cases, but the same methods could be leveraged for breaching privacy. *AC-Complice* [12] demonstrates how continuous measurements from unprotected accelerometers in smartphones can reveal a user's location. Hua et al. [13] extend AC-Complice by showing that accelerometers can also reveal where a user is located in a metropolitan train system.

10.2 Other private information leaked from smartphone sensors

An emerging line of work shows that various phone sensors can leak private information other than location. In future work we will continue analyzing power measurements to determine if other private information is leaked.

Prior work has demonstrated how smartphone sensors can be used to fingerprint specific devices. *AccelPrint* [9] shows that smartphones can be fingerprinted by tracking imperfections in their accelerometer measurements. Fingerprinting of mobile devices by the characteristics of their loudspeakers is proposed in [7, 8]. Further, Bojinov et. al. [4] showed that various sensors in smartphones can be used to identify a mobile device by its unique hardware characteristics. Lukas et. al. [20] proposed a method for digital camera fingerprinting by noise patterns present in the images. [19] enhances the method enabling identification of not only the model but also particular cameras.

Sensors can also reveal a user's input such as speech and touch gestures. The *Gyrophone* study [21] showed that gyroscopes on smartphones can be used for eavesdropping on a conversation in the vicinity of the phone and identifying the speakers. Several works [2, 5, 32] have shown that the accelerometer and gyroscope can leak information about touch and swipe inputs to a foreground application.

11 Conclusion

PowerSpy shows that applications with access to a smartphone's power monitor can gain information about the location of a mobile device – without accessing the GPS or any other coarse location indicators. Our approach enables known route identification, real-time tracking, and identification of a new route by only analyzing the phone's power consumption. We evaluated PowerSpy on real-world data collected from popular smartphones that have a significant mobile market share, and demonstrated their effectiveness. We believe that with more data, our approach can be made more accurate and reveal more information about the phone's location.

Our work is an example of the unintended consequences that result from giving 3rd party applications access to sensors. It suggests that even seemingly benign sensors need to be protected by permissions, or at the very least, that more security modeling needs to be done before giving 3rd party applications access to sensors.

Acknowledgments

We would like to thank Gil Shotan and Yoav Shechtman for helping to collect the data used for evaluation, Prof. Mykel J. Kochenderfer from Stanford University for providing advice regarding location tracking techniques, Roy Frostig for providing advice regarding classification and inference on graphs, and finally Katharina Roesler for proofreading the paper. A Formal model of new route inference

In this section we formalize the problem of the new route inference (Section 6) as a hidden Markov model (HMM) [27]. Let I denote the set of intersections in an area in which we wish to track a mobile device. A road segment is given by an ordered pair of intersections (x,y), defined to be a continuous road between intersection x and intersection y. We denote the set of road segments as R.

We assume that once a device starts to traverse a road segment it does not change the direction of its movement until it reaches the end of the segment. We define a state for each road segment. We say that the tracked device is in state s_{xy} if the device is currently traversing a road segment (x, y), where $x, y \in I$. We denote the route of the tracked device as a (Q, T), where

$$Q = \left\{q_1 = s_{x_1 x_2}, q_2 = s_{x_2 x_3}, ...\right\} \quad T = \{t_1, t_2, ...\}$$

For such a route the device has traversed from x_i to x_{i+1} during time interval $[t_{i-1}, t_i]$ ($t_0 = 0, t_{i-1} < t_i\ \forall i > 0$).

Let $A = \left\{a_{xyz} | \forall x, y, z \in I\right\}$ be the state transition probability distribution, where

$$a_{xyz} = p\left\{q_{i+1} = s_{yz} | q_i = s_{xy}\right\} \tag{1}$$

Note that $a_{xyz} = 0$ if there is no road between intersections x and y or no road between intersections y and z. A traversal of the device over a road segment yields a power consumption profile of length equal to the duration of that movement. We denote a power consumption profile as an observation o. Let B be the probability distribution of yielding a given power profile while the device traversed a given segment. Due to the hysteresis of hand-offs between cellular base stations, this probability depends on the previous segment the device traversed. Finally, let $\Pi = \left\{\pi_{xy}\right\}$ be the initial state distribution, where π_{xy} is the probability that the device initially traversed segment (x, y). If there is no road segment between intersections x and y, then $\pi_{xy} = 0$. In our model we treat this initial state as the state of the device *before* the start of the observed power profile. We need to take this state into account due to the hysteresis effect. Note that an HMM is characterized by A, B, and Π.

The route inference problem is defined as follows. Given an observation of a power profile O over time interval $[0, t_{\max}]$, and given a model A, B and Π, we need to find a route (Q, T) such that $p\{(Q, T)|O\}$ is maximized. In the following we denote the part of O which begins at time t' and ends at time t'' by $O_{[t', t'']}$. Note that $O = O_{[0, t_{\max}]}$. We consider the time interval $[0, t_{\max}]$ as having a discrete resolution of τ.

B Choosing the best inferred route

Upon its completion, the particle filter described in section 6.1 outputs a set of N routes of various lengths. We denote this set by P_{final}. This set exhibits an estimate of the distribution of routes given the power profile of the tracked device. The simple approach to select the best estimate is to choose the route that appears most frequently in P_{final} as it has the highest probability to occur. Nonetheless, since a route is composed of multiple segments chosen at separate steps, at each step the weight of a route is determined solely based on the last segment added to the route. Therefore, in P_{final} there is a bias in favor of routes ending with segments that were given higher weights, while the weights of the initial segments have a diminishing effect on the route distribution with every new iteration.

To counter this bias, we choose another estimate using a procedure we call *iterative majority vote*. This procedure ranks the routes based on the prevalence of their prefixes. At each iteration i the procedure calculates – Prefix[i] – a list of prefixes of length i ranked by their prevalence out of the all routes that has a prefix in Prefix[i-1]. Prefix[i][n] denotes the prefix of rank n. The operation $p||j$ – where p is a route and j is an intersection – denotes the appending of j to p. At each iteration i algorithm 3 is executed. In the following we denote RoutePrefixed(R, p) to be the subset of routes out of the set R having p as their prefix.

Algorithm 3 Iterative majority vote

```
$I' \leftarrow I$
**while** not all prefixes found **do**
    Prf $\leftarrow$ next prefix from Prefix[i].
    Find $j \in I'$ that maximizes
      RoutePrefixed(RoutePrefixed($P_{\text{final}}$, Prf), Prf$||j$)
    **if** no such $j$ is found **then**
        $I' = I$
        continue loop
    **end if**
    Prefix$[i+1] \leftarrow$ Prefix$[i+1] \cup \{$Prf$||j\}$
    $I' = I' - \{j\}$
**end while**
```

At each iteration i we rank the prefixes based on the ranks of the previous iteration. Namely, prefixes which are extensions of a shorter prefix having a higher rank in a previous iteration will always get higher ranking over prefixes which are extensions of a lower rank prefix. At each iteration the we first find the most common prefixes of length $i+1$, which start with the most common prefix of length i found in the previous iteration, and rank them according to their prevalence. Then we look for common prefixes of length $i+1$, that start with the second most common prefix of length i found in the previous iteration, and so on until all prefixes of length $i+1$ are found. The intuition is as follows. The procedure prefers routes traversing segments that are commonly traversed by other routes. Those received a high score when were chosen. Since we cannot pick the most common segments separately from each step (a continuous route probably will not emerge), we iteratively pick the most common segment out of the routes that are prefixed with the segments that were already chosen.

In the Compression Hornet's Nest: A Security Study of Data Compression in Network Services

Abstract

In this paper, we investigate the current use of data compression in network services that are at the core of modern web-based applications. While compression reduces network traffic, if not properly implemented it may make an application vulnerable to DoS attacks. Despite the popularity of similar attacks in the past, such as *zip bombs* or *XML bombs*, current protocol specifications and design patterns indicate that developers are still mostly unaware of the proper way to handle compressed streams in protocols and web applications. In this paper, we show that denial of services due to improper handling of data compression is a persistent and widespread threat. In our experiments, we review three popular communication protocols and test 19 implementations against highly-compressed protocol messages. Based on the results of our analysis, we list 12 common pitfalls that we observed at the implementation, specification, and configuration levels. Additionally, we discuss a number of previously unknown resource exhaustion vulnerabilities that can be exploited to mount DoS attacks against popular network service implementations.

1 Introduction

Modern web-based software applications rely on a number of core network services that provide the basic communication between software components. For instance, the list includes Web servers, email servers, and instant messaging (IM) services, just to name some of the more widespread ones. As a consequence of their popularity, Denial of Service (DoS) may have very severe consequences on the availability of many web services. In fact, according to the 2014 Global Report on the Cost of Cyber Crime [35], the impact of application DoS is dramatic: 50% of the organizations have suffered from such an attack, and the average cost of a single attack is estimated to be over $166K US [35].

For performance reasons, many network services extensively use data compression to reduce the amount of data transferred between the communicating parties. The use of compression can be mandated by protocol specifications or it can be an implementation-dependent feature. While compression indeed reduces network traffic, at the same time, if not properly implemented, it may also make applications vulnerable to DoS attacks. The problem was first brought to users' attention in 1996 in the form of a recursively highly-compressed file archive prepared with the only goal of exhausting the resources of programs that attempt to inspect its content. In the past, these *zip bombs* were used, for example, to mount DoS attacks against bulletin board systems [1] and antivirus software [2, 57].

While this may now seem an old, unsophisticated, and easily avoidable threat, we discovered that developers did not fully learn from prior mistakes. As a result, the risks of supporting data compression are still often overlooked, and descriptions of the proper way to handle compressed messages are either lacking or misleading. In this paper, we investigate the current use of data compression in several popular protocol and network services. Through a number of experiments and by reviewing the source code of several applications, we have identified a number of improper ways to handle data compression at the implementation, specification, and configuration levels. These common mistakes are widespread in many popular applications, including Apache HTTPD and three of the top five most popular XMPP servers. Similar to the zip bombs of 20 years ago, our experiments show that these flaws can easily be exploited to exhaust the server resources and mount a denial of service attack.

The task of handling data compression is not as simple as it may sound. In general, compression amplifies the amount of data that a network service needs to process, and some components may not be designed to handle this volume of data. This may result in the exhaustion of resources for applications that were otherwise considered secure. However, in this paper we show that these mistakes are not only caused by unbounded buffers, and neither are they localized into single components. In fact, as message processing involves different modules, improper communication may result in a lack of synchronization, eventually causing an excessive consumption of resources. Additionally, we show similar mistakes when third-party modules and libraries are used. Here, misleading documentation may create a false sense of security in which the web application developers believe that the data amplification risks are already addressed at the network service level.

To summarize, this paper makes the following contributions:

- We show that resource exhaustion vulnerabilities due to highly-compressed messages are (still) a real threat that can be exploited by remote attackers to mount denial of service attacks;
- We present a list of 12 common pitfalls and susceptibilities that affect the implementation, specification, and configuration levels;
- We tested 11 network services and 10 third-party extensions and web application frameworks for a total of 19 implementations against compression-based DoS attacks;
- We discovered and reported nine previously unknown vulnerabilities, which would allow a remote attacker to mount a denial of service attack.

This paper is organized as follows. In Section 2, we introduce the case studies. Then, in Section 3, we discuss the security risks associated with data compression, revisit popular attacks, and outline the current situation. In Section 4, we detail the current situation and present a list of 12 pitfalls at the implementation, specification, and configuration levels. Then, in Section 5, we describe the experiments and present previously-unknown resource exhaustion vulnerabilities. In Section 6, we review related works, and finally, in Sections 7 and 8, we outline future work and draw some conclusions.

2 Data Compression

Data compression is a coding technique that aims at reducing the number of bits required to represent a string by removing redundant data. Compression is *lossless* when it is possible to reconstruct an exact copy of the original string, or *lossy* otherwise. For a detailed survey on compression algorithms please refer to Salomon et al. [45]. Since the focus of our paper is on the incorrect *use* of compression and it is independent of the algorithm itself, we will discuss our finding and examples using the popular *Deflate* algorithm.

Table 1: Case studies and Implementations

Deflate is a lossless data compression technique that combines together a Huffman encoding with a variant of the `LZ78` algorithm. It is specified in the Request For Comments (RFC) number 1951 [13], released in May 1996, and it is now implemented by the widely used `zlib` library [19], the `gzip` compression tool [18], and the `zip` file archiver tool [22], just to name few popular examples.

Deflate is widely used in many Internet protocols such as the HyperText Transfer Protocol (HTTP) [17], the eXtensible Messaging and Presence Protocol (XMPP) [42], the Internet Message Access Protocol (IMAP) [11], the Transport Layer Security (TLS) protocol [26], the Point-to-Point Protocol (PPP) [60], and the Internet Protocol (IP) [33]. The list includes both text-based and binary protocols. However, since the first category contains fields of arbitrary length where the decompression overhead is more evident, we decided to focus our study on three popular text-based protocols: HTTP, XMPP and IMAP. For each protocol we selected a number of implementations, summarized in Table 1. The columns *Native* and *External* show if the compression is natively supported by the application or if it is provided by an external component.

HTTP - Starting from version 1.1, HTTP supports compression of the HTTP *response* body using different compression algorithms (including Deflate) [17]. While the specification only covers the compression of the response body, we manually verified that several HTTP server im-

Table 2: Service detection for HTTP, XMPP, and IMAP servers

plementations additionally support the compression of the *request* body. Table 2a shows the result of the HTTP *service detection*[1] in order to identify the most popular HTTP server implementations among the top 1000 domains of the Alexa Top Sites database[2]. From Table 2a, we selected Apache HTTPD 2.2.22 [53] and Apache Tomcat 7 [52] as they are available for GNU/Linux. The former supports message decompression via the module `mod-deflate`, while the latter can be extended with third-party filters. In this paper, we used the 2Way HTTP Compression Servlet Filter 1.2 [37] (2Way for short) and Webutilities 0.0.6 [32].

In our experiments, we considered three use cases that may benefit from request compression: distributed computing, web applications, and sharing static resources. For Apache HTTPD, we selected gSOAP 2.8.7 [59] to develop SOAP-based RPC servers, CSJRPC 0.1 [9] to develop PHP-based JSON RPC servers, the PHP Apache module [55] (mod-php, for short) to develop PHP-based web applications, and WebDAV [21] (as implemented by the built-in Apache module mod-dav) to share static files. For Tomcat, we selected Apache CXF 2.2.7 [51], Apache Axis 2 [50], jsonrpc4j 1.0 [15], json-rpc 1.1 [41], and lib-json-rpc 1.1.2 [7].

We test web servers with the following HTTP request:

```
POST $resource HTTP/1.1\r\n
Host: $domain\r\n
Content-Encoding: gzip\r\n
\r\n
$payload
\r\n
```

where `$resource` is the path to the resource, `$domain` the web server domain, and `$payload` is the compressed payload, or the *compression bomb*. The type of payload varies according to the implementation under test, i.e., JSON or SOAP message requests, and HTML form parameters. For example, the SOAP compression bomb is the following:

```
<soapenv:Envelope [...]>
   $spaces
   <soapenv:Body>[...]</soapenv:
      Body>
</soapenv:Envelope>
```

where `$spaces` can be, for example, a 4GB-long string of blank spaces. Once compressed, this payload is reduced to about 4MB with a compression ratio of about 1:1000, a value close to the maximum compression factor that can be achieved with Zlib, i.e., 1:1024 [19]. It might be possible to generate payloads with higher ratios, for instance, by modifying the compressor to return shorter, but still legal, strings. However, in this paper, we did not investigate this direction and leave this as future work.

XMPP - XMPP is an XML-based protocol offering messaging and presence, and request-response services [43, 44]. XMPP is at the core of several public and IM services, such as Google Talk, in which users exchange text-based messages in real-time. We performed service detection on the list of XMPP services available at `xmpp.net`[3]. Table 2b shows the result of the service detection. We selected the five most popular XMPP servers for our tests: ejabberd 2.1.10 [38], Openfire 3.9.1 [27], Prosody 0.9.3 [56], jabberd2 2.2.8 [54], and Tigase 5.2.0 [58].

To test XMPP servers, we used a similar trick as used in SOAP compression bombs. The highly-compressed XMPP message (i.e., *xmppbomb*) is the following:

```
<?xml version='1.0' ?>
  <stream:stream
```

[1] *Service detection* is a technique to identify the name of a network service by analyzing the server response against a database of fingerprints. In this paper, we used the Nmap Security Scanner tool [30]).

[2] See `http://www.alexa.com/`

[3] `xmpp.net` maintains a publicly accessible list of XMPP services: `http://xmpp.net/services.xml`. We retrieved it on 2013-09-03 and it contained 106 domains.

```
$spaces
to='server' xmlns='jabber:
    client'
[...]>
```

where $spaces can be a 4GB-long string of blank spaces. Also in this case, the compression ratio is about 1:1000.

IMAP - IMAP is a command-response protocol that allows a client to manage emails and mailboxes on a remote server [11]. The protocol supports compression algorithms to reduce the size of both commands and responses [23]. We obtained a list of popular IMAP servers from the first 1000 domains of the Alexa database. We first resolved the Mail eXchange (MX) domain and then we performed service detection. Table 2c shows the results of the service detection. As opposed to HTTP, we report percentages of the total number of the discovered servers because the majority of MX domains do not offer IMAP access to the email boxes. Two of the five IMAP servers were available for GNU/Linux and supported data compression: Dovecot 2.0.19 [16] and Cyrus 2.4.12 [8].

To test for IMAP, we crafted an email which can be compressed with a ratio of about 1:1000. The structure of the email is the following:

```
From: sender@foo\r\n
To:   receiver@foo\r\n
Subject: I am a bomb!\r\n
$spaces
```

where $spaces can be a 4GB-long string of blank spaces[4].

3 Decompression Security Risks

Applications can use the Deflate decompression algorithm in three main ways. First, they can invoke the functions provided by widely available libraries, such as `zlib` for `C` and `java.util.zip` for Java. Second, they can adopt a high-level wrapper built around one of the previously mentioned libraries (e.g., the `zlib` module in Python or the `Zlib` module in PHP). Finally, applications can implement their own version of the Deflate algorithm. Either way, in this paper we show that it is not trivial to properly decompress user-generated data streams. The risk arises from three aspects of the compression/decompression process:

1. Decompression is a computationally intensive task entailing an extensive use of CPU, memory, and disk space. If not properly limited, this process can be abused to stall an application and cause a denial of service;

2. Decompression amplifies the amount of data that software needs to process. Other components may not be designed to handle this volume of data. Therefore, the use of other functionalities on compressed data may result in the exhaustion of resources for components that were otherwise considered secure;

3. Compressed data can often be pre-computed by an attacker, thus creating a largely unbalanced scenario in which the input can be sent very fast, but the server needs to invest a lot of resources to process it. Moreover, the compressed input can often be meaningless or even malformed, because applications are often designed to discard bad inputs only *after* they are entirely decompressed.

3.1 The Past: Zip Bombs and Billion Laughs

Abusing data amplification to cause application or system denial of services is an old trick. The first documented DoS attack via a highly-compressed file archive dates back to 1996 when an attacker uploaded a malicious compressed file archive (a zip bomb) to the Bulletin Board System (BBS) of Fidonet, waiting for the system administrator to decompress it [1]. The classic zip bomb was a 42-kilobyte zip file archive that contained five nested layer of compressed files whose total size amounted to 4.5 petabytes. In 2001, zip bombs were used by attackers as email attachments [57] to disable anti-virus software designed to scan incoming messages [2].

A second popular exploitation of data amplification flaws was the so-called Billion Laughs attack [49] in 2003 (CVE-2003-1564). The Billion Laughs attack, also called the Exponential Entity Expansion attack, is an attack that exploits resource exhaustion vulnerabilities of XML document parsers when processing recursive entity definitions. An attacker may exploit this behavior by crafting a valid XML document (an XML bomb) which will cause the parser to generate an exponential amount of data. This results in CPU monopolization and memory exhaustion that can be exploited to mount a denial of service attack. This vulnerability was first reported in 2003 as a weakness of `libxml2` (CVE-2003-1564), an XML parser library. The same vulnerability was later discovered in some network servers, e.g., in 2009 in WebDAV as implemented by Apache HTTPD (CVE-2009-1955), and in a number of XMPP servers in 2011 (see, for example, CVE-2011-1755 and CVE-2011-3288).

[4] Due to limitations of the IMAP servers, in our experiments we used a 2GB-long string.

3.2 The present

Despite the popularity of previous attacks, a quick look at current protocol specifications, coding rules, and design patterns suggests that developers remain mostly unaware of the risks of using data compression. The risks of using compression are often overlooked, and guidelines on the proper way to handle compressed messages are either misleading or completely missing. In the rest of this section we briefly describe what protocol specifications, design patterns, and secure coding practices mention about the security issues related to data compression. Then, in Section 4, we show how this lack of common knowledge and understanding about the possible decompression attack vectors leads to a multitude of mistakes in many popular applications and protocols. Finally, in Section 5, we show experiments and the software vulnerabilities that we discovered on our case studies.

3.2.1 Protocol Specifications

A closer look at the specifications of the case studies revealed that none of them discuss potential security issues related to the use of data compression at the protocol level.

The Deflate specifications are mainly concerned with data integrity issues, suggesting developers implement means of validating the integrity of compressed data [13]. The HTTP protocol is concerned with loss of data confidentiality and unauthorized access, e.g., via path traversal attacks [17]. HTTP also addresses other DoS-related issues, such as broken clients when handling the status code 100 and with HTTP proxies [17]. The XMPP stream compression [25] does not describe any XMPP-specific security concern due to the use of data compression. Instead, it refers to SSL/TLS [26], which is concerned with data leakage, buffer overrun in the compression library, and enforcing packet size limits for uncompressed data. However, the specifications do not elaborate on how these concerns apply to XMPP, and therefore the developer may be left to personal interpretation that, ultimately, translates into vulnerable implementations. Finally, the IMAP compression specification [23] refers again to the SSL/TLS specifications for everything related to the decompression process.

3.2.2 Security Design Patterns

Security design patterns [3] are used to prevent vulnerabilities during the software design phase as well as to mitigate security risks. They address security concerns at a high level of abstraction (i.e., *DoS Safety*, *Compartmentalization*, and *Small Process* [24]) but unfortunately lack the details to address the specific concerns at the implementation level.

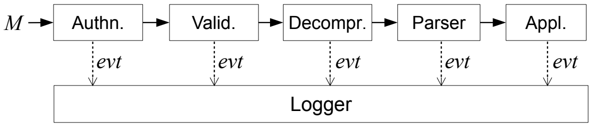

Figure 1: Message Pipeline

3.2.3 Secure Development Rules

Secure development rules suggest ways to write secure source code via secure code patterns (See, for example, coding rules for Java [29] and C++ [46]) or by means of software testing (see, for example, the OWASP Testing Guide [31]). The only existing rule on processing securely compressed data suggests a technique to validate a zip archive file before decompressing it. Sadly, the rule proposes an insecure technique, making the applications that implement it vulnerable to DoS via disk space exhaustion. We give more details of this rule in Section 4.2.

4 Common Pitfalls

In our study, we analyzed the implementation and documentation of our case studies, the protocol specifications (i.e., [11, 13, 17, 23, 25, 42]), and the software development best practices (i.e., [3, 24, 29, 31, 46]) looking for proper and incorrect ways to handle data compression. In this section, we distill our findings into 12 common pitfalls we observed at the implementation, specification, and configuration levels. Table 3 shows the list of pitfalls and maps them to the implementations of Table 1 that are affected by them.

4.1 Implementation Level

We start our survey of common compression-related mistakes by looking at the software implementation. As mentioned in Section 3, the decompression of a user-provided input is a delicate task that is prone to many errors. Software developers may be unaware of or underestimate the risks involved in this process, leading to implementation mistakes that can introduce denial of service vulnerabilities in the final product.

In this section, we list common pitfalls using a pipeline that processes incoming compressed requests. A pipeline is a linear chain of processing units in which the output of a unit is the input of the following one. Data pipelines are used to process incoming messages in blocks, in which each unit processes a single piece of information at the time, and provides an input to the next unit. Data compression can be used at different stages of message processing. For instance, it can be the first processing unit,

Table 3: Distribution of the pitfalls within the implementations under test

as it is for XMPP messages, or it can be placed after the message parsing, as implemented by the HTTP message processing.

Figure 1 shows a generic data pipeline to process an incoming message M. This pipeline is extracted from our case studies and is used to guide the description of the pitfalls. The pipeline has four processing units: user *authentication*, message *validation*, message *decompressor*, and message *parser*. The user authentication verifies that the request is sent by an authenticated user. This step may not be present in certain protocols, e.g., HTTP. The message validation unit implements a decision procedure to establish whether the incoming message can be accepted. The decompressor implements the data decompression algorithm to reconstruct the original message. Finally, the message parser performs a syntactic analysis of the message according to the rules of the communication protocol. As we already mentioned, the actual order of the blocks can be different, to reflect the protocol specification. The four units can send messages to the logger in order to store errors or unusual events in a log file. Finally, the output of the pipeline is consumed by the *application logic*. Here, by application we refer to an abstract representation of a message consumer. The consumer can be the rest of the software, e.g., a web application, as well as an additional component used to support application software, e.g., a web-based RPC framework.

4.1.1 Improper Input Validation during Decompression

One of the first mistakes we observed in our study is related to the erroneous way in which the size of incoming compressed messages is validated. We observed three ways to validate the message size: validation of the compressed message size, validation of the decompressed message size, and validation of the compression ratio of the message.

The first approach is the most straightforward to implement. Unfortunately, it is hard to estimate the size of a message by looking at its compressed form. For instance, while accepting an input no longer than 1MB could be insufficient for many types of data (e.g., when uploading a compressed picture), the same value is already sufficient for an attacker to generate extremely large decompressed output (e.g., by compressing a very repetitive string of bytes) that may cause an application denial of service.

The second approach consists in checking the size of the message by setting a limit to the amount of decompressed data. While this is a better solution, the validation of the decompressed size of an object is not straightforward to implement. To the best of our knowledge, we are not aware of any technique that allows one to compute the uncompressed size without first decompressing the input. Unfortunately, if the application needs to fully decompress the data before checking its size, it cannot protect itself against DoS attacks. However, many libraries (such as zlib and other language-specific wrappers) allow the application to decompress the incoming message in chunks. The size of each chunk is controlled by the application, which creates two buffers to store the compressed and the decompressed data streams. These two buffers are passed to the decompressor function of the library, which reads from one and writes to the other. The decompressor function returns when there are no more input bytes to process or when the output buffer is full. At this point, the application can provide more data or empty the output buffer. This interface allows an application to decompress a large message a piece at a time, constantly monitoring the amount of decompressed data. If a threshold is reached, the application can reject the input without the need to fully decompress the entire message.

The third approach consists of calculating the compression ratio. The compression ratio is the ratio between the sizes of the compressed and the decompressed messages. If the value exceeds a certain threshold, the decompression is halted and the message discarded. However, the compression ratio may vary according to the redundancies contained in the original message and it may cause the rejection of valid inputs. Moreover, the problem of deciding the appropriate threshold for the ratio must be solved. This may not be a simple task, as its value may depend on the protocol itself and on the way it is used by the application. Developers may leave the choice to educated guesses, experience, or experiments. This can result in under- or overestimation of this parameter. The former may increase the risk of rejecting valid messages, while the latter may introduce an uncontrolled use of resources.

To summarize, the first approach is a security mistake, the second is correct (if properly implemented), and the third one is potentially risky.

Apache HTTPD and gSOAP standalone provide examples of all three of these approaches. The first, vulnerable, approach is used by mod-deflate when it decompresses data for mod-php or mod-gsoap. This approach is insecure and we will discuss the details of this vulnerability in Section 5.4. When a message enters Apache HTTPD, it is processed by a chain of filters which transform the message and perform additional checks. The core module of Apache HTTPD offers a basic filter that allows setting a limit on the size of any incoming request body[5]. If the body exceeds the limit, then the message is rejected. However, the limit refers only to the compressed body size and it may render applications vulnerable to resource exhaustion.

The second approach is also implemented by mod-deflate, this time when it decompresses XML messages for mod-dav. The core module of Apache HTTPD offers a second parameter to limit the size of XML body objects[6]. As opposed to the previous one, the limit correctly applies to the decompressed form of the body. The third approach is now implemented by the patched versions of mod-deflate and gSOAP standalone. mod-deflate allows the user to configure a threshold for the compression ratio and the number of violations of the ratio that are allowed. gSOAP instead has the ratio built into the source code. In this case, the decompression is halted upon one violation.

4.1.2 Use of Compression before Authentication

We observed a great variety of practices for enforcing user authentication before the message decompression. For example, authentication is mandatory in SSL/TLS [14], recommended in XMPP [25], and undefined in IMAP [23]. In some cases, the implementation may even diverge from the specifications to postpone the use of compression (e.g., as done by OpenSSH), or to use compression where not prescribed (e.g., decompression of HTTP requests). This great variety of cases clearly indicates the lack of a consistent best practice. This may lead developers to underestimate the risk and overlook the recommendation. For example, we discovered that Prosody accepts compressed messages before user authentication, thus violating the recommendation of the XMPP protocol [25].

4.1.3 Improper Inter-Units Communication

When a processing unit in the pipeline detects a fault, i.e., the buffer limit is reached, then the unit should halt and notify the other units and the logger of this event. The communication between units can be direct or indirect via a third-party component, i.e., the pipeline manager. If a unit does not halt the execution, then the application may continue to consume resources until the resources are exhausted.

We observed this problem in Apache HTTPD in the interaction between mod-deflate and mod-php. mod-php can limit the size of the incoming request body via the parameter post_max_size. This parameter applies to the amount of data received in input by mod-php. However, if the incoming message is compressed, then it is first decompressed and then passed to mod-php. In this case, once the limit is reached, mod-php has no means to signal mod-deflate to stop processing the incoming data. As result, mod-deflate will keep on decompressing data, thus wasting system resources. The same problem was also observed between mod-deflate and mod-gsoap. The

[5] Via the configuration parameter LimitRequestBody

[6] Via the configuration parameter LimitXMLRequestBody

developers of mod-php and mod-gsoap confirmed this behavior.

4.1.4 Logging Decompressed Messages

Log files are used to store events generated by a running program (or an entire operating system), and they are particularly important to monitor the execution of background processes that have little interaction with the user, as is the case for web services. The information stored in log files can cover a wide range of events, including warning messages, malfunction errors, and verbose reports of the current activity of a given process.

While the use of log files is a good practice, both developers and users should carefully select the frequency and the verbosity of the generated events. An excessive level of verbosity may be useful to debug unusual behaviors, but it may have side effects from a security perspective. In particular, when the unusual behavior is caused by compressed data, developers and users may underestimate the resources needed to generate and store the event and, as a result, the application can exhaust all the available resources.

For instance, we observed this type of issue in Apache CXF. Upon receiving an invalid request, Apache CXF stores the request in a temporary file, and then adds an entry in the log file containing the first 100 KB of the request. However, if the invalid message is compressed, Apache CXF decompresses the entire request on disk just to extract the 100KB header to log. As a result, in our experiments we observed that a single request of 4MB (containing 4GB of data after decompression) can cause Apache CXF to store on the disk 8 GB of temporary data.

4.1.5 Unbounded Resource Usage

In general, the best way to avoid DoS attacks against an application is to properly limit the size of decompressed inputs. However, whenever such thresholds need to be set very high because the application has to accept large amounts of user-provided data, the developers should carefully design the code to bound the CPU and memory usage of the decompression routine. We found unbounded CPU and memory usage in different applications. Below, we discuss these pitfalls separately.

Unbounded Memory - The data amplification introduced by a decompressor may be underestimated by the developers who may leave buffers uncontrolled on the size both in peripheral (e.g., input validation components) and internal components (e.g., message parsers). For example, we observed this type of mistake in Prosody and json-rpc. Prosody decompresses incoming messages in chunks. Each chunk is passed to the XMPP message parser, which internally accumulates the chunks without bounds before the processing. A single highly-compressed message results in consuming all the available memory and, finally, being terminated by the operating system. A similar behavior was observed in json-rpc. Upon receiving a JSON request, json-rpc accumulates the uncompressed request into a memory buffer until no more memory is available.

Unbounded CPU - Decompressors are *CPU-bound* software procedures, as they tend to monopolize the CPU usage for the entire duration of the operation. If an attacker can influence their execution, then she may degrade system performance and mount a CPU DoS attack.

Unfortunately, best practices in secure software coding [29, 46] do not provide techniques for controlling CPU-bound tasks. As a result, developers may not be aware of the risks and leave the CPU usage unbounded. One way to control CPU-bound operations is to introduce idle time intervals in which a task is suspended for a period of time. The size of the interval and the moment in which it is introduced can be decided at run-time by taking into account the current status of the process. For example, a task may introduce idle times in order to keep constant the bandwidth of the decompressor throughput.

We observed an unbounded CPU usage in many implementations of our case studies, including Apache mod-deflate, Apache CXF, Webutilities, 2Way, Prosody, and Tigase. On the other hand, we found that CPU controls via idle time intervals were already implemented by ejabberd and jabberd2.

4.2 Specification Level

In this section, we review common data compression pitfalls stemming from imprecise protocol specifications, misleading documentation, and erroneous best practices.

4.2.1 Misleading Documentation

Modern software is a collection of reusable components. The developers of each component should carefully document the security risks related to the usage of their own components in order to allow a more secure integration. For this purpose, we reviewed the documentation of Apache mod-deflate, Webutilities, 2Way Filter, Axis 2, and gSOAP. None of the above components discuss the security risks related to the use of data compression. Even worse, the user documentation of Webutilities and 2Way even reassure their users that (i) a developer can plug in the decompression "*without changing the source code*" [37], and (ii) that "*nothing [else is] needed*" [32] from the user. In general, misleading documentation may create a false sense of security in which a developer may believe that she does not need to address the problem in her application because the possible security concerns are already addressed at the underlying level.

4.2.2 Erroneous Best Practices

Unawareness and underestimation of the risks in using data compression may also affect best practices. In our review of secure coding rules, we found out that the security risks specific to the decompression of compressed messages are not properly addressed. Design patterns are too generic to address the specificity of data compression, and secure code patterns address only the risks of storage exhaustion due to zip archive bombs [29]. Finally, testing guides only propose tests against information leakage vulnerabilities caused by the simultaneous usage of data compression and data encryption [31].

Interestingly enough, we discovered that the only available pattern on the topic is also insecure[7]. In fact, it suggests developers verify the decompressed size reported in the file headers before accepting a Zip archive. Unfortunately, this information can be easily forged by an attacker to contain any arbitrary value, thus successfully bypassing the security checks. We disclosed the flaw in the pattern to the authors, who marked it as vulnerable and provided a newer, secure version.

4.2.3 API Specifications Inconsistency

Data compression is an optional feature and it is transparent from the point of view of the application. However, in our review we found out that the use of compression may also violate the contract of other APIs. For example, the method `ServletRequest.getContentLength()` of J2EE 7 is supposed to return the length of the request body as it is made available through the input stream. The *input stream* refers to the object used by the servlet developer to access the content of the body of the message. This parameter may be used in the logic of the servlet to allocate a buffer, or to accept or reject the resource. Unfortunately, when the HTTP decompression is enabled, `getContentLength` returns a wrong value. In our experiments, we verified that `getContentLength` returns the value stored in the `Content-Length` HTTP header, while the input stream contains the much larger uncompressed body.

4.3 Configuration Level

In this section, we list common pitfalls in the way compression can be configured in different services.

4.3.1 Insufficient Configuration Options

In Section 4.1, we described a number of secure approaches to handle data compression at the implementation level. These solutions allow one to control the resource consumption by setting limits to the amount of resources to be used. The actual threshold may vary depending from a number of factors. For example, a web application that manages an online storage service may require the web server to accept large input messages to upload big files. In order to allow use of network services in different scenarios, the resource limits need to be parametric and the proper thresholds should be selected by the user during the deployment phase.

However, we observed that the number of configuration parameters provided by common servers is often insufficient. This is mainly due to the lack of implementations of the resource consumption controls. For example, Prosody only allows the use of data compression to be enabled or disabled; it does not offer any parameters to specify the maximum size of decompressed data to be accepted, nor the output bandwidth of the decompressor.

4.3.2 Insecure Default Values

Recently, it has been demonstrated that compression may be problematic when used together with data encryption, as it can lead to information leakage (e.g., CRIME [39] and BREACH [36]). The exploitation of these flaws may depend on the deployment scenario and the capability of the attacker to choose the plaintext. For these reasons, the use of data compression should be at the discretion of the user, who should assess the characteristics of the deployment scenario and the usage of the service.

While data compression should be an optional feature, in our survey we observed network service configurations in which data compression was enabled by default, such as in Openfire and Tigase.

4.3.3 Decentralized Configuration Parameters

The time to identify and resolve an attack is critical to contain the costs of a cyber-incident [34]. The response to an attack may require changing the configuration of a running system, and this task is simplified if the security-relevant configuration parameters are easily accessible to the security response team. In our survey, we verified that this is not always the case. For example, compression in CXF can be enabled in two ways. First, it can be enabled by adding the decompressor filter in the configuration of the servlet (i.e., the `web.xml` file). Second, it can be enabled within the Java code of the service using a Java annotation. In both cases, in order to disable the compression, the security response team needs to modify the configuration of all the servlets or, in the worst

[7] See https://www.securecoding.cert.org/confluence/display/java/IDS04-J.+Safely+extract+files+from+ZipInputStream

case, to modify even their source code. However, the response team may not have access to the source code. As a result, they may need to involve developers in this activity, which may increase the time required to react to an attack.

5 Analysis

In this section, we describe the experiments that we performed to detect resource exhaustion vulnerabilities. This section is organized as follows. In Section 5.1, we describe the experiment setup. Then, in Section 5.2 we present our results, and in Section 5.3 we discuss them. Finally, in Section 5.4, we present the complete list of vulnerabilities.

5.1 Experiment Setup

The services we tested in our experiments are developed using different programming languages, including C, C++, Java, PHP, Erlang, and Lua. While automatic code-based techniques could be used to detect software vulnerabilities, these techniques are language-dependent and therefore cannot be used in our analysis. For this reason, we followed a black-box testing approach in which we probed the implementation with malicious inputs, and then measured the resource consumption and the service availability.

Tests - Each test consists of two parts: *baseline test* and *attack*. The baseline test measures the point of reference for resource consumption and service availability when compression is not used and there are no attacks. Baseline measurements are sampled over a period of 60 seconds by probing the target with 4MB-long, honest protocol messages. The attack measures instead the resource consumption and service availability when stressing the implementation with malicious messages sent by one, 12, and 24 simultaneous attackers—a very low number compared with the number of clients that participate in most of the distributed DoS attacks. Malicious messages are presented in Section 2. Both the baseline and the attack requests have a 4MB payload in order to rule out the overhead of transferring the data over the network.

Testbed - We performed the experiments on a testbed of three machines to host, respectively, the server, the attackers, and the honest client. The server machine runs the IUT and the internal monitor, the attackers execute the test cases to send highly-compressed messages to the server, and the client executes baseline tests to measure the availability of the service.

To test the HTTP services, we used (i) a 4MB static file resource; (ii) two PHP scripts for mod-php, each using a different PHP interface[8] to read the content of the request body; and (iii) PHP, Java, and C++ classes and functions to be deployed as a web services with CSJRPC, Axis 2, CXF, jsonrpc4j, json-rpc, lib-json-rpc, and gSOAP (both mod-gsoap and standalone). To test the XMPP and the IMAP servers, we created user accounts for both the attackers and the honest client. In our tests, we considered different IUT configurations. For example, we tested Apache HTTPD, mod-php, Apache Tomcat, ejabberd, and jabberd2 with different maximum message sizes.

Table 4: Resource Consumption Vulnerabilities

Monitoring - We monitored the IUT with a combination of internal and external monitors. The external monitor measures the service availability in terms of number of honest messages processed per second. We used the client to continuously provide the server with honest messages and measure the server's response time. The internal monitor is a modified version of `pidstat` from the sysstat tool suite [20], which repeatedly polls the `/proc` filesystem. It measures (1) CPU usage, (2) virtual size (VSZ) and the resident set size (RSS) memory and (3) disk I/O of the processes associated with the IUT.

5.2 Results

Table 4 shows a summary of the results of our experiments on the 19 implementations. Out of them, only four implemented the compression in a secure way. Both ejabberd and jabberd2 keep a constant resource usage even during multiple simultaneous attacks. In fact, through a manual source code analysis, we were able to

[8] `php://input` interface and `$HTTP_RAW_POST_DATA`

verify that both servers implement two separate mechanisms to limit the use of memory and CPU usage during decompression. Table 4 shows a possible disk-based DoS attack against Dovecot and Cyrus; however, this is not to be considered a vulnerability, as IMAP servers are designed to store on disk the email used as the attack vector. All the other 15 services we tested showed an uncontrolled increase in at least one of the three system resources, making them potentially vulnerable to decompression-based DoS attacks. All results were reported to (and confirmed by) the developers of the corresponding applications and libraries.

Table 5 shows an excerpt of our experiments on three vulnerable implementations: Prosody, Apache HTTPD, and Apache CXF with the WebUtilities filter. For each implementation in Table 5, we performed four experiments (col. *Attackers*): the baseline and three attacks respectively with one, 12, and 24 parallel attackers. For each experiment, we report the requests response time (col. *Resp.*), the median value of the CPU usage (col. *Mdn*), the maximum virtual size memory allocated (col. *VSZ*), the maximum resident set size[9] allocated (col. *RSS*), and the total amount of data written to disk (col. *WR*). The columns *mult* report the ratio between the measured value during the attack and the baseline. In the rest of this section we detail the results of Table 5.

Prosody allocates up to 7.8GB of RSS memory and 22GB of VSZ memory when processing a single malicious request. The process is then killed by the operating system due to a system out of memory error. Even worse, Prosody also exhibits the same behavior when we sent the malicious message before the user authentication. Similarly as seen for Prosody, the measurements for Apache CXF show a significant resource utilization: starting from 0.03 GB of the baseline, Apache CXF can write about 1 TB, which is 3243 times the baseline. These value indicates that Apache CXF may be vulnerable to disk space exhaustion. Other services, while still potentially vulnerable, had a more controlled behavior. For instance, Apache HTTPD monopolizes the CPU at about 100% for 17 seconds with a single attacker, and up to 140 seconds by sending 24 malicious payloads in parallel.

5.3 Experiment Results Discussion

In this section, we discuss three factors that play an important role in our black-box experiments.

First, the baseline sets the amplitude of the proportions with the measurements done during the attack. The choice of the baseline is crucial because it can affect the conclusion of the analysis. As we already explained, the choice of the baseline was to offer a reference point that rules out network delay. This results in ratio values that cannot be directly transferred to real-size servers.

Second, the quantification of the severity of the observed degradation heavily depends on a number of variables that our testbed does not realistically reproduce, e.g., number of CPU cores, size of main memory, disk space, and average load of the server. Small-size servers can be DoSed with few requests, while large and powerful servers may be able to sustain a higher load before showing signs of resource exhaustion. As a result, to obtain an externally visible effect, it may be necessary to use a larger number of simultaneous attackers.

Finally, it is hard to develop an automated procedure to detect DoS vulnerabilities on the basis of the data we collected. The measures do not offer an accurate view of the internal behavior of the application, and the figures depend on so many factors that sometimes it is hard to make a final conclusion. For this reason, we manually verified each case, often complementing the experiments with a source code analysis of the affected components. Moreover, we discussed each problem with the developers, and obtained confirmation of each vulnerability reported in this paper.

5.4 Vulnerabilities

Our experiments led to the discovery of nine vulnerabilities. After we completed our experiments, our results were also reproduced on other three additional XMPP network services (M-Link, Metronome, and MongooseIM), discovering resource exhaustion vulnerabilities also in these products as well.

We followed the principle of responsible disclosure and informed the developers, the community, and the security response teams. In most of the cases, developers reacted to our first reports and worked on a patch. If developers were unresponsive for over a month, we tried a second time and then alerted the US CERT to support the disclosure. Eventually, all the developers acknowledge the reported vulnerabilities. The way in which each product was patched is described in the rest of this section.

5.4.1 HTTP

Apache HTTPD - The component that caused CPU and memory consumption is mod-deflate. This affected mod-php, CSJRPC, and mod-gsoap applications. Unfortunately, mod-php and mod-gsoap developers are unable to solve this issue on their components, as they are unaware of a suitable interface to control mod-deflate. As a result, we escalated the issue to the Apache Security Team. The security team acknowledged the presence of the vulnerability, fixed it in Apache HTTPD 2.4.10, and disclosed

[9] The total RAM size of the server machine is 8 GB.

		Attacks		CPU		Memory				Disk	
Prot.	Network Service	No.	Resp.	Mdn	mult.	RSS	mult.	VSZ	mult.	WR	mult.

Table 5: Excerpt of the experiment results

it publicly (CVE-2014-0118). Our contribution was also rewarded by the bounty program of Hackerone[10].

Apache HTTPD developers implemented two new mechanisms to control CPU and memory consumptions that can be configured via the following new parameters: `DeflateInflateLimitRequestBody`, `DeflateInflateRatioLimit`, and `DeflateInflateRatioBurst`. The first parameter limits the maximum amount of memory that can be allocated to decompress incoming HTTP requests. The second enforces a ratio between the compressed and decompressed message. This mechanism also allows specifying the number of tolerated violations of the ratio before halting the decompression. While this mechanism limits the use of resources in the presence of highly-compressed messages (not necessarily compression bombs), it does not limit the amount of CPU used by the decompressor.

gSOAP - gSOAP standalone suffers from uncontrolled CPU usage. The developers acknowledged the presence of the vulnerability and released a patch. The patch implements a ratio-based technique similar to the mechanism implemented now by mod-deflate. However, as opposed to mod-deflate, the ratio is not parametric but it is built into the source code.

Webutilities and 2Way - Webutilities and 2Way filters are the components that cause unbounded CPU usage in Axis 2, CXF, and jsonrpc4j. After our reports, the developers of Webutilities fixed the vulnerability using a CPU throttling mechanism that can be configured via a new parameter, `decompressMaxBytesPerSecond`. This mechanism monitors the throughput in bytes per second of the decompressor and, if the limit is reached, it introduces idle time intervals in which the decompressor is suspended from execution for a short period of time. The developers of 2Way acknowledged the presence of the issue and are working on a patch (still unavailable at the time of writing).

Apache CXF - Apache CXF suffers from a disk exhaustion vulnerability. We reported the issue to the Apache Security Team. The security team acknowledged the presence of the vulnerability in two branches of the software, fixed it in version 2.6.14 and 2.7.11, and disclosed it publicly (CVE-2014-0109 and CVE-2014-0110). This vulnerability is described in Section 4.1.4.

json-rpc and lib-json-rpc - json-rpc and lib-json-rpc suffer from an uncontrolled memory vulnerability. Upon receiving a JSON request, both frameworks try to store all of the uncompressed data in a single memory buffer, causing an out of memory error. The developers acknowledged the issue and are currently working on a patch.

5.4.2 XMPP

The disclosure of the XMPP vulnerabilities was conducted with the involvement of the XMPP community. We supported the community in coordinating the disclosure and preparing a common secure notice about the multiple vulnerabilities. In total, our experiments directly discovered four vulnerabilities in three XMPP servers, and three other servers were found vulnerable during the disclosure. All the vulnerabilities are fixed and new versions of the servers are already available[11]. Also in this case, our contribution and efforts were rewarded by the bounty program of Hackerone[12].

Openfire - Openfire does not properly restrict the resources used in processing incoming XMPP messages (see, CVE-2014-2741 and VU#495476).

Prosody - Prosody suffers from memory exhaustion due

[10] See https://hackerone.com/reports/20861

[11] See `http://xmpp.org/resources/security-notices/`

[12] See https://hackerone.com/reports/5928

to an uncontrolled buffer (CVE-2014-2745) and allows unauthenticated users to use data compression (CVE-2014-2744).

Tigase - Tigase does not properly limit the memory used to process incoming XMPP messages (CVE-2014-2746).

M-Link - M-Link does not properly restrict the resources used in processing incoming XMPP messages (CVE-2014-2742).

Metronome - Metronome suffers from unbounded memory consumption (CVE-2014-2743) and allows the use of compression before user authentication (CVE-2014-2744, shared with Prosody).

MongooseIM - MongooseIM does not properly restrict the resources used in processing incoming XMPP messages (CVE-2014-2829).

6 Related Work

In this section, we review works that are related to this paper from different perspectives. In particular, we discuss attacks that exploit data amplification, leakage due to the use of data compression, worst-case complexity, and bandwidth exhaustion.

Data Amplification Attacks - To the best of our knowledge, zip bombs [1] and XML bombs [49] are among the first documented abuses of data amplification. We already discussed the details of these attacks in Section 3. Data amplification can also be achieved by using external servers for which the response size is bigger than the request size [40]. An attacker can spoof the network address of a victim and sends small request packets to a large number of servers. These requests trigger voluminous response traffic that accumulates on the network link of the victim and leads to bandwidth exhaustion. Similar to an asymmetry in the request/response traffic volume, our work considers an asymmetry in creating and processing compressed data for attack amplification.

Compression and Encryption - Data compression can lead to information leakage when used together with encryption. CRIME [39] and BREACH [36] are two attacks that exploit the change of size of a ciphertext due to the compression of the plaintext. These attacks target the SSL/TLS layer when used to carry HTTP conversations and rely on an attacker that is capable of performing a chosen-plaintext attack. These attacks and our work show orthogonal security issues in using data compression. While CRIME and BEAST aim at breaking the SSL/TLS encryption layer, our paper addresses software vulnerabilities due to the data amplification of decompression algorithms.

Algorithmic Attacks - Resource exhaustion can also result from the worst-case performance of the data structure algorithms [12] and rule matching algorithms [47]. Similarly to these attacks, in this paper we exploit the worst-case scenario of decompression algorithms in which the attacker can cause resource exhaustion with a compression rate of 1:1000.

Bandwidth Exhaustion - A variety of DoS attacks target network bandwidth exhaustion [6, 28, 48]. The Coremelt attack [48] and the Crossfire attack [28] achieve DoS through network bandwidth exhaustion of a targeted Autonomous System backbone routers. The attacker does not connect to the victim, but instead she uses machines under her control to exchange data over the link used by the victim. As both Coremelt and Crossfire work by exposing network links to high traffic, their effects can arguably be mitigated by using compression. However, the results presented in this paper demonstrate that there is a catch to such strategies, as compression bears risks for the communication's end nodes. Büscher and Holz [6] show that the vast majority of attacks launched by the DirtJumper/Ruskill botnet target HTTP port 80 [6] and that an average number of 185 DoS threads is sufficient to saturate the link between the botnet and the victim. Our results indicate that service disruptions can be achieved with a much lesser number if compression is used, thereby circumventing the detection and analysis proposed in the paper [6].

7 Future Work

As future work, we plan to investigate two directions: secure data compression, and automated detection techniques for resource exhaustion vulnerabilities.

Solving the mistakes presented in Section 4 is only part of the problem. Data compression introduces an unbalanced scenario in which the sender can generate *offline* compressed messages while the receiver needs to perform *online* decompression. This gives a large advantage to the attacker. The first direction of our research is to tackle this problem by studying new techniques that introduce *fairness* in data compression. The idea is to allow the receiver to decompress an incoming message when it has evidence that the sender has performed the compression online. The evidence can be provided by the means of single-use or session-based compression keys.

The problem of detecting resource exhaustion vulnerabilities has been addressed in the past [4, 5, 10]. However, existing techniques are fragmented and suffer from a number of limitations which hinder their use: they cannot scale to real programs (See [5]), are not fully automated (See [4]), and can be applied only to a subset of the resource exhaustion vulnerabilities (See [10]). As a second research direction, we plan to develop an intelligent fuzzer which combines code analysis and blackbox testing: The code analysis can be responsible for extracting a set of program constraints that the fuzzer would then use to generate inputs using a constraint solver.

8 Conclusion

In this paper, we presented a study on the current use of data decompression in three popular network services that are at the core of modern web-based applications. We analyzed 19 network services and extensions, protocol specifications, and documentation looking for proper and incorrect ways to handle data compression. We grouped our findings into 12 common pitfalls that we observed at the implementation, specification, and configuration levels. Furthermore, in our tests we discovered and reported nine previously unknown vulnerabilities. While these problems have been now being patched, we believe that this paper shows how the risks of supporting data compression are still too often overlooked, even by very popular web and network services.

Acknowledgments

We thank the anonymous reviewers for the valuable comments. We also thank Gabriel Serme (SAP) for the valuable discussion that originated this line of research, and various members of the standardization and software development groups for fruitful discussions. In no specific order, we thank the Apache Security Team, Daniel Kulp (CXF), Stanislav Malyshev (PHP), Matthew Wild (Prosody), Andrzej Wójcik (Tigase), Guus der Kinderen (Openfire), Peter Saint-Andre (XMPP Standards Foundation), Philipp Hancke (XMPP Standards Foundation), Kevin Smith (XMPP Standards Foundation), Waqas Hussain (XMPP Standards Foundation), Robert van Engelen (gSOAP), and Rajendra Patil (Webutilities). This project was supported in part by the German Ministry for Education and Research (BMBF) through funding for the project 13N13250, H2020 ESCUDO-Cloud, and TU Darmstadt CASED/EC-SPRIDE.

Bohatei: Flexible and Elastic DDoS Defense

*Seyed K. Fayaz** *Yoshiaki Tobioka** *Vyas Sekar** *Michael Bailey*†
**CMU* †*UIUC*

Abstract

DDoS defense today relies on expensive and proprietary hardware appliances deployed at fixed locations. This introduces key limitations with respect to flexibility (e.g., complex routing to get traffic to these "chokepoints") and elasticity in handling changing attack patterns. We observe an opportunity to address these limitations using new networking paradigms such as software-defined networking (SDN) and network functions virtualization (NFV). Based on this observation, we design and implement Bohatei, a *flexible* and *elastic* DDoS defense system. In designing Bohatei, we address key challenges with respect to scalability, responsiveness, and adversary-resilience. We have implemented defenses for several DDoS attacks using Bohatei. Our evaluations show that Bohatei is scalable (handling 500 Gbps attacks), responsive (mitigating attacks within one minute), and resilient to dynamic adversaries.

1 Introduction

In spite of extensive industrial and academic efforts (e.g., [3, 41, 42]), distributed denial-of-service (DDoS) attacks continue to plague the Internet. Over the last few years, we have observed a dramatic escalation in the number, scale, and diversity of DDoS attacks. For instance, recent estimates suggest that over 20,000 DDoS attacks occur per day [44], with peak volumes of 0.5 Tbps [14, 30]. At the same time, new vectors [37, 55] and variations of known attacks [49] are constantly emerging. The damage that these DDoS attacks cause to organizations is well-known and include both monetary losses (e.g., $40,000 per hour [12]) and loss of customer trust.

DDoS defense today is implemented using expensive and proprietary hardware appliances (deployed in-house or in the cloud [8, 19]) that are *fixed* in terms of placement, functionality, and capacity. First, they are typically deployed at fixed network aggregation points (e.g., a peering edge link of an ISP). Second, they provide fixed functionality with respect to the types of DDoS attacks they can handle. Third, they have a fixed capacity with respect to the maximum volume of traffic they can process. This fixed nature of today's approach leaves network operators with two unpleasant options: (1) to overprovision by deploying defense appliances that can handle a high (but pre-defined) volume of every known attack type at each of the aggregation points, or (2) to deploy a smaller number of defense appliances at a central location (e.g., a scrubbing center) and reroute traffic to this location. While option (2) might be more cost-effective, it raises two other challenges. First, operators run the risk of underprovisioning. Second, traffic needs to be explicitly routed through a fixed central location, which introduces additional traffic latency and requires complex routing hacks (e.g., [57]). Either way, handling larger volumes or new types of attacks typically mandates purchasing and deploying new hardware appliances.

Ideally, a DDoS defense architecture should provide the *flexibility* to seamlessly place defense mechanisms where they are needed and the *elasticity* to launch defenses as needed depending on the type and scale of the attack. We observe that similar problems in other areas of network management have been tackled by taking advantage of two new paradigms: software-defined networking (SDN) [32, 40] and network functions virtualization (NFV) [43]. SDN simplifies routing by decoupling the control plane (i.e., routing policy) from the data plane (i.e., switches). In parallel, the use of virtualized network functions via NFV reduces cost and enables elastic scaling and reduced time-to-deploy akin to cloud computing [43]. These potential benefits have led major industry players (e.g., Verizon, AT&T) to embrace SDN and NFV [4, 6, 15, 23].[1]

In this paper, we present Bohatei[2], a flexible and

[1] To quote the SEVP of AT&T: "To say that we are both feet in [on SDN] would be an understatement. We are literally all in [4]."

[2] It means breakwater in Japanese, used to defend against tsunamis.

elastic DDoS defense system that demonstrates the benefits of these new network management paradigms in the context of DDoS defense. Bohatei leverages NFV capabilities to elastically vary the required scale (e.g., 10 Gbps vs. 100 Gbps attacks) and type (e.g., SYN proxy vs. DNS reflector defense) of DDoS defense realized by defense virtual machines (VMs). Using the flexibility of SDN, Bohatei steers suspicious traffic through the defense VMs while minimizing user-perceived latency and network congestion.

In designing Bohatei, we address three key algorithmic and system design challenges. First, the resource management problem to determine the number and location of defense VMs is NP-hard and takes hours to solve. Second, existing SDN solutions are fundamentally unsuitable for DDoS defense (and even introduce new attack avenues) because they rely on a per-flow orchestration paradigm, where switches need to contact a network controller each time they receive a new flow. Finally, an intelligent DDoS adversary can attempt to evade an elastic defense, or alternatively induce provisioning inefficiencies by dynamically changing attack patterns.

We have implemented a Bohatei controller using `OpenDaylight` [17], an industry-grade SDN platform. We have used a combination of open source tools (e.g., OpenvSwitch [16], Snort [48], Bro [46], iptables [13]) as defense modules. We have developed a scalable resource management algorithm. Our evaluation, performed on a real testbed as well as using simulations, shows that Bohatei effectively defends against several different DDoS attack types, scales to scenarios involving 500 Gbps attacks and ISPs with about 200 backbone routers, and can effectively cope with dynamic adversaries.

Contributions and roadmap: In summary, this paper makes the following contributions:

- Identifying new opportunities via SDN/NFV to improve the current DDoS defense practice (§2);
- Highlighting the challenges of applying existing SDN/NFV techniques in the context of DDoS defense(§3);
- Designing a responsive resource management algorithm that is 4-5 orders of magnitude faster than the state-of-the-art solvers (§4);
- Engineering a practical and scalable network orchestration mechanism using proactive tag-based forwarding that avoids the pitfalls of existing SDN solutions (§5);
- An adaptation strategy to handle dynamic adversaries that can change the DDoS attack mix over time (§6);
- A proof-of-concept implementation to handle several known DDoS attack types using industry-grade SDN/NFV platforms (§7); and
- A systematic demonstration of the scalability and effectiveness of Bohatei (§8).

We discuss related work (§9) before concluding (§10).

2 Background and Motivation

In this section, we give a brief overview of software-defined networking (SDN) and network functions virtualization (NFV) and discuss new opportunities these can enable in the context of DDoS defense.

2.1 New network management trends

Software-defined networking (SDN): Traditionally, network control tasks (e.g., routing, traffic engineering, and access control) have been tightly coupled with their data plane implementations (e.g., distributed routing protocols, ad hoc ACLs). This practice has made network management complex, brittle, and error-prone [32]. SDN simplifies network management by decoupling the network control plane (e.g., an intended routing policy) from the network data plane (e.g., packet forwarding by individual switches). Using SDN, a network operator can centrally program the network behavior through APIs such as OpenFlow [40]. This flexibility has motivated several real world deployments to transition to SDN-based architectures (e.g., [34]).

Network functions virtualization (NFV): Today, network functions (e.g., firewalls, IDSes) are implemented using specialized hardware. While this practice was necessary for performance reasons, it leads to high cost and inflexibility. These limitations have motivated the use of virtual network functions (e.g., a virtual firewall) on general-purpose servers [43]. Similar to traditional virtualization, NFV reduces costs and enables new opportunities (e.g., elastic scaling). Indeed, leading vendors already offer virtual appliance products (e.g., [24]). Given these benefits, major ISPs have deployed (or are planning to deploy) datacenters to run virtualized functions that replace existing specialized hardware [6, 15, 23]. One potential concern with NFV is low packet processing performance. Fortunately, several recent advances enable line-rate (e.g., 10-40Gbps) packet processing by software running on commodity hardware [47]. Thus, such performance concerns are increasingly a non-issue and will further diminish given constantly improving hardware support [18].

2.2 New opportunities in DDoS defense

Next, we briefly highlight new opportunities that SDN and NFV can enable for DDoS defense.

Lower capital costs: Current DDoS defense is based on specialized hardware appliances (e.g., [3, 20]). Network operators either deploy them on-premises, or outsource DDoS defense to a remote packet scrubbing site (e.g., [8]). In either case, DDoS defense is expensive.

For instance, based on public estimates from the General Services Administration (GSA) Schedule, a 10 Gbps DDoS defense appliance costs ≈$128,000 [11]. To put this in context, a commodity server with a 10 Gbps Network Interface Card (NIC) costs about $3,000 [10]. This suggests roughly 1-2 orders of magnitude potential reduction in capital expenses (ignoring software and development costs) by moving from specialized appliances to commodity hardware.[3]

Time to market: As new and larger attacks emerge, enterprises today need to frequently purchase more capable hardware appliances and integrate them into the network infrastructure. This is an expensive and tedious process [43]. In contrast, launching a VM customized for a new type of attack, or launching more VMs to handle larger-scale attacks, is trivial using SDN and NFV.

Elasticity with respect to attack volume: Today, DDoS defense appliances deployed at network chokepoints need to be provisioned to handle a predefined maximum attack volume. As an illustrative example, consider an enterprise network where a DDoS scrubber appliance is deployed at each ingress point. Suppose the projected resource footprint (i.e., defense resource usage over time) to defend against a SYN flood attack at times t_1, t_2, and t_3 is 40, 80, and 10 Gbps, respectively.[4] The total resource footprint over this entire time period is $3 \times max\{40,80,10\} = 240$ Gbps, as we need to provision for the worst case. However, if we could elastically scale the defense capacity, we would only introduce a resource footprint of $40+80+10 = 130$ Gbps—a 45% reduction in defense resource footprint. This reduced hardware footprint can yield energy savings and allow ISPs to repurpose the hardware for other services.

Flexibility with respect to attack types: Building on the above example, suppose in addition to the SYN flood attack, the projected resource footprint for a DNS amplification attack in time intervals t_1, t_2, and t_3 is 20, 40, and 80 Gbps, respectively. Launching only the required types of defense VMs as opposed to using monolithic appliances (which handle both attacks), drops the hardware footprint by 40%; i.e., from $3 \times (max\{40,80,10\} + max\{20,40,80\}) = 480$ to 270.

Flexibility with respect to vendors: Today, network operators are locked-in to the defense capabilities offered by specific vendors. In contrast, with SDN and NFV, they can launch appropriate best-of-breed defenses. For example, suppose vendor 1 is better for SYN flood defense, but vendor 2 is better for DNS flood defense. The physical constraints today may force an ISP to pick only one hardware appliance. With SDN/NFV we can avoid the undesirable situation of picking only one vendor and rather have a deployment with both types of VMs each for a certain type of attack. Looking even further, we also envision that network operators can mix and match capabilities from different vendors; e.g., if vendor 1 has better detection capabilities but vendor 2's blocking algorithm is more effective, then we can flexibly combine these two to create a more powerful defense platform.

Simplified and efficient routing: Network operators today need to employ complex routing hacks (e.g., [57]) to steer traffic through a fixed-location DDoS hardware appliance (deployed either on-premises or in a remote site). As Figure 1 illustrates, this causes additional latency. Consider two end-to-end flows $flow_1$ and $flow_2$. Way-pointing $flow_2$ through the appliance (the left hand side of the figure) makes the total path lengths 3 hops. But if we could launch VMs where they are needed (the right hand side of the figure), we could drop the total path lengths to 2 hops—a 33% decrease in traffic footprint. Using NFV we can launch defense VMs on the closest location to where they are currently needed, and using SDN we can flexibly route traffic through them.

In summary, we observe new opportunities to build a flexible and elastic DDoS defense mechanism via SDN/NFV. In the next section, we highlight the challenges in realizing these benefits.

3 System Overview

In this section, we envision the deployment model and workflow of Bohatei, highlight the challenges in realizing our vision, and outline our key ideas to address these challenges.

3.1 Problem scope

Deployment scenario: For concreteness, we focus on an ISP-centric deployment model, where an ISP offers DDoS-defense-as-a-service to its customers. Note that several ISPs already have such commercial offerings (e.g., [5]). We envision different monetization avenues. For example, an ISP can offer a value-added security service to its customers that can replace the customers' in-house DDoS defense hardware. Alternatively, the ISP can allow its customers to use Bohatei as a cloudbursting option when the attack exceeds the customers' on-

[3] Operational expenses are harder to compare due to the lack of publicly available data.

premise hardware. While we describe our work in an ISP setting, our ideas are general and can be applied to other deployment models; e.g., CDN-based DDoS defense or deployments inside cloud providers [19].

In addition to traditional backbone routers and interconnecting links, we envision the ISP has deployed multiple datacenters as shown in Figure 2. Note that this is not a new requirement; ISPs already have several in-network datacenters and are planning additional rollouts in the near future [15, 23]. Each datacenter has commodity hardware servers and can run standard virtualized network functions [45].

Threat model: We focus on a general DDoS threat against the victim, who is a customer of the ISP. The adversary's aim is to exhaust the network bandwidth of the victim. The adversary can flexibly choose from a *set of candidate attacks* $AttackSet = \{A_a\}_a$. As a concrete starting point, we consider the following types of DDoS attacks: TCP SYN flood, UDP flood, DNS amplification, and elephant flow. We assume the adversary controls a large number of bots, but the total *budget* in terms of the maximum volume of attack traffic it can launch at any given time is fixed. Given the budget, the adversary has a complete control over the choice of (1) type and mix of attacks from the *AttackSet* (e.g., 60% SYN and 40% DNS) and (2) the set of ISP ingress locations at which the attack traffic enters the ISP. For instance, a simple adversary may launch a single fixed attack A_a arriving at a single ingress, while an advanced adversary may choose a mix of various attack types and multiple ingresses. For clarity, we restrict our presentation to focus on a single customer noting that it is straightforward to extend our design to support multiple customers.

Defenses: We assume the ISP has a pre-defined *library of defenses* specifying a defense strategy for each attack type. For each attack type A_a, the defense strategy is specified as a directed acyclic graph DAG_a representing a typical multi-stage attack analysis and mitigation procedure. Each node of the graph represents a logical module and the edges are tagged with the result of the previous nodes processing (e.g., "benign" or "attack" or "analyze further"). Each logical node will be realized by one (or more) *virtual appliance(s)* depending on the attack volume. Figure 3 shows an example strategy graph with 4 modules used for defending against a UDP flood attack. Here, the first module tracks the number of UDP packets each source sends and performs a simple threshold-based check to decide whether the source needs to be let through or throttled.

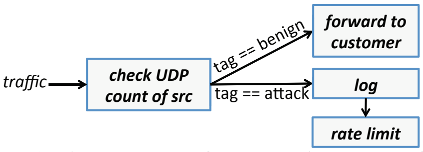

Figure 3: A sample defense against UDP flood.

Our goal here is not to develop new defense algorithms but to develop the system orchestration capabilities to enable flexible and elastic defense. As such, we assume the *DAG*s have been provided by domain experts, DDoS defense vendors, or by consulting best practices.

3.2 Bohatei workflow and challenges

The workflow of Bohatei has four steps (see Figure 2):

1. *Attack detection:* We assume the ISP uses some out-of-band anomaly detection technique to flag whether a customer is under a DDoS attack [27]. The design of this detection algorithm is outside the scope of this paper. The detection algorithm gives a coarse-grained specification of the suspicious traffic, indicating the customer under attack and some coarse identifications of the type and sources of the attack; e.g., "srcprefix=*,dstprefix=cust,type=SYN".
2. *Attack estimation:* Once suspicious traffic is detected, the strategy module estimates the volume of suspicious traffic of each attack type arriving at each ingress.
3. *Resource management:* The resource manager then uses these estimates as well as the library of defenses to determine the type, number, and the location of defense VMs that need to be instantiated. The goal of the resource manager is to efficiently assign available network resources to the defense while minimizing user-perceived latency and network congestion.
4. *Network orchestration:* Finally, the network orchestration module sets up the required network forwarding rules to steer suspicious traffic to the defense VMs as mandated by the resource manager.

Given this workflow, we highlight the three challenges we need to address to realize our vision:

C1. Responsive resource management: We need an efficient way of assigning the ISP's available compute and network resources to DDoS defense. Specifically, we need to decide how many VMs of each type to run on each server of each datacenter location so that attack traffic is handled properly while minimizing the latency experienced by legitimate traffic. Doing so in a *responsive* manner (e.g., within tens of seconds), however, is challenging. Specifically, this entails solving a large NP-hard optimization problem, which can take several hours to solve even with state-of-the-art solvers.

C2. Scalable network orchestration: The canonical view in SDN is to set up switch forwarding rules in a *per-flow* and *reactive* manner [40]. That is, every time a switch receives a flow for which it does not have a forwarding entry, the switch queries the SDN controller to get the forwarding rule. Unfortunately, this per-flow and reactive paradigm is fundamentally unsuitable for DDoS defense. First, an adversary can easily saturate the control plane bandwidth as well as the controller compute resources [54]. Second, installing per-flow rules on the switches will quickly exhaust the limited rule space (≈4K TCAM rules). Note that unlike traffic engineering applications of SDN [34], coarse-grained IP prefix-based forwarding policies would not suffice in the context of DDoS defense, as we cannot predict the IP prefixes of future attack traffic.

C3. Dynamic adversaries: Consider a dynamic adversary who can rapidly change the attack mix (i.e., attack type, volume, and ingress point). This behavior can make the ISP choose between two undesirable choices: (1) wasting compute resources by overprovisioning for attack scenarios that may not ever arrive, (2) not instantiating the required defenses (to save resources), which will let attack traffic reach the customer.

3.3 High-level approach

Next we highlight our key ideas to address C1–C3:
