- **Hierarchical optimization decomposition** (§**4**)**:** To address C1, we use a hierarchical decomposition of the resource optimization problem into two stages. First, the Bohatei global (i.e., ISP-wide) controller uses coarse-grained information (e.g., total spare capacity of each datacenter) to determine how many and what types of VMs to run in each datacenter. Then, each local (i.e., per-datacenter) controller uses more fine-grained information (e.g., location of available servers) to determine the specific server on which each defense VM will run.
- **Proactive tag-based forwarding** (§**5**)**:** To address C2, we design a scalable orchestration mechanism using two key ideas. First, switch forwarding rules are based on per-VM tags rather than per-flow to dramatically reduce the size of the forwarding tables. Second, we proactively configure the switches to eliminate frequent interactions between the switches and the control plane [40].

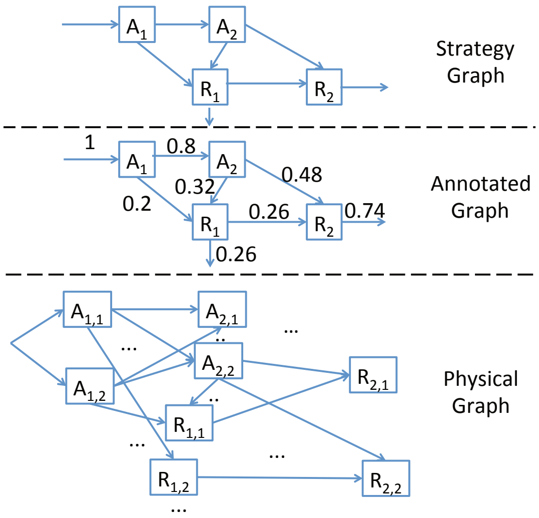

Figure 4: An illustration of strategy vs. annotated vs. physical graphs. Given annotated graphs and suspicious traffic volumes, the resource manager computes physical graphs.

- **Online adaptation** (§**6**)**:** To handle a dynamic adversary that changes the attack mix (C3), we design a defense strategy adaptation approach inspired by classical online algorithms for regret minimization [36].

4 Resource Manager

The goal of the resource management module is to efficiently determine network and compute resources to analyze and take action on suspicious traffic. The key here is responsiveness—a slow algorithm enables adversaries to nullify the defense by rapidly changing their attack characteristics. In this section, we describe the optimization problem that Bohatei needs to solve and then present a scalable heuristic that achieves near optimal results.

4.1 Problem inputs

Before we describe the resource management problem, we establish the main input parameters: the ISP's compute and network parameters and the defense processing requirements of traffic of different attack types. We consider an ISP composed of a set of edge PoPs[5] $E = \{E_e\}_e$ and a set of datacenters $D = \{D_d\}_d$.

ISP constraints: Each datacenter's traffic processing capacity is determined by a pre-provisioned uplink capacity C_d^{link} and compute capacity $C_d^{compute}$. The compute capacity is specified in terms of the number of VM slots, where each VM slot has a given capacity specification (e.g., instance sizes in EC2 [2]).

Processing requirements: As discussed earlier in §3.1, different attacks require different *strategy graphs*. However, the notion of a strategy graph by itself will not suf-

[5] We use the terms "edge PoP" and "ingress" interchangeably.

fice for resource management, as it is does not specify the traffic volume that at each module should process.

The input to the resource manager is in form of *annotated graphs* as shown in Figure 4. An annotated graph $DAG_a^{annotated}$ is a strategy graph annotated with edge weights, where each weight represents the fraction of the total input traffic to the graph that is expected to traverse the corresponding edge. These weights are precomputed based on prior network monitoring data (e.g., using NetFlow) and from our adaptation module (§6). $T_{e,a}$ denotes the volume of suspicious traffic of type a arriving at edge PoP e. For example, in Figure 4, weight 0.48 from node A_2 to node R_2 means 48% of the total input traffic to the graph (i.e., to A_1) is expected to traverse edge $A_2 \rightarrow R_2$.

Since modules may vary in terms of compute complexity and the traffic rate that can be handled per VM-slot, we need to account for the parameter $P_{a,i}$ that is the traffic processing capacity of a VM (e.g., in terms of compute requirements) for the logical module $v_{a,i}$, where $v_{a,i}$ is node i of graph $DAG_a^{annotated}$.

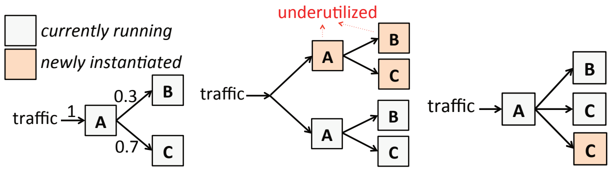
Network footprint: We denote the network-level cost of transferring the unit of traffic from ingress e to datacenter d by $L_{e,d}$; e.g., this can represent the path latency per byte of traffic. Similarly, within a datacenter, the units of intra-rack and inter-rack traffic costs are denoted by *IntraUnitCost* and *InterUnitCost*, respectively (e.g., they may represent latency such that *IntraUnitCost* < *InterUnitCost*).

4.2 Problem statement

Our resource management problem is to translate the annotated graph into a *physical graph* (see Figure 4); i.e., each node i of the annotated graph $DAG_a^{annotated}$ will be realized by one or more VMs each of which implement the logical module $v_{a,i}$.

Fine-grained scaling: To generate physical graphs given annotated graphs in a resource-efficient manner, we adopt a *fine-grained scaling* approach, where each logical module is scaled independently. We illustrate this idea in Figure 5. Figure 5a shows an annotated graph with three logical modules A, B, and C, receiving different amounts of traffic and consuming different amounts of compute resources. Once implemented as a physical graph, suppose module C becomes the bottleneck due to its processing capacity and input traffic volume. Using a monolithic approach (e.g., running A, B, and C within a single VM), we will need to scale the entire graph as shown in Figure 5b. Instead, we decouple the modules to enable scaling out individual VMs; this yields higher resource efficiency as shown in Figure 5c.

Goals: Our objective here is to (a) instantiate the VMs across the compute servers throughout the ISP, and (b) distribute the processing load across these servers to minimize the expected latency for legitimate traffic. Further, we want to achieve (a) and (b) while minimizing the footprint of suspicious traffic.[6]



(a) Annotated graph. (b) Monolithic. (c) Fine-grained.

Figure 5: An illustration of fine-grained elastic scaling when module C becomes the bottleneck.

To this end, we need to assign values to two key sets of decision variables: (1) the fraction of traffic $T_{e,a}$ to send to each datacenter D_d (denoted by $f_{e,a,d}$), and (2) the number of VMs of type $v_{a,i}$ to run on server s of datacenter D_d. Naturally, these decisions must respect the datacenters' bandwidth and compute constraints.

Theoretically, we can formulate this resource management problem as a constrained optimization via an Integer Linear Program (ILP). For completeness, we describe the full ILP in Appendix A. Solving the ILP formulation gives an optimal solution to the resource management problem. However, if the ILP-based solution is incorporated into Bohatei, an adversary can easily overwhelm the system. This is because the ILP approach takes several hours (see Table 2). By the time it computes a solution, the adversary may have radically changed the attack mix.

4.3 Hierarchical decomposition

To solve the resource management problem, we decompose the optimization problem into two subproblems: (1) the Bohatei global controller solves a *Datacenter Selection Problem (DSP)* to choose datacenters responsible for processing suspicious traffic, and (2) given the solution to the DSP, each local controller solves a *Server Selection Problem (SSP)* to assign servers inside each selected datacenter to run the required VMs. This decomposition is naturally scalable as the individual SSP problems can be solved independently by datacenter controllers. Next, we describe practical greedy heuristics for the DSP and SSP problems that yield close-to-optimal solutions (see Table 2).

Datacenter selection problem (DSP): We design a greedy algorithm to solve DSP with the goal of reducing ISP-wide suspicious traffic footprint. To this end, the algorithm first sorts suspicious traffic volumes (i.e.,

[6] While it is possible to explicitly minimize network congestion [33], minimizing suspicious traffic footprint naturally helps reduce network congestion as well.

$T_{e,a}$ values) in a decreasing order. Then, for each suspicious traffic volume $T_{e,a}$ from the sorted list, the algorithm tries to assign the traffic volume to the datacenter with the least cost based on $L_{e,d}$ values. The algorithm has two outputs: (1) $f_{e,a,d}$ values denoting what fraction of suspicious traffic from each ingress should be steered to each datacenter (as we will see in §5, these values will be used by network orchestration to steer traffic correspondingly), (2) the physical graph corresponding to attack type a to be deployed by datacenter d. For completeness, we show the pseudocode for the DSP algorithm in Figure 16 in Appendix B.

Server selection problem (SSP): Intuitively, the SSP algorithm attempts to preserve traffic locality by instantiating nodes adjacent in the physical graph as close as possible within the datacenter. Specifically, given the physical graph, the SSP algorithm greedily tries to assign nodes with higher capacities (based on $P_{a,i}$ values) along with its predecessors to the same server, or the same rack. For completeness we show the pseudocode for the SSP algorithm in Figure 17 in Appendix B.

5 Network Orchestration

Given the outputs of the resource manager module (i.e., assignment of datacenters to incoming suspicious traffic and assignment of servers to defense VMs), the role of the network orchestration module is to configure the network to implement these decisions. This includes setting up forwarding rules in the ISP backbone and inside the datacenters. The main requirement is scalability in the presence of attack traffic. In this section, we present our *tag-based* and *proactive* forwarding approach to address the limitations of the per-flow and reactive SDN approach.

5.1 High-level idea

As discussed earlier in §3.2, the canonical SDN view of setting up switch forwarding rules in a per-flow and reactive manner is not suitable in the presence of DDoS attacks. Furthermore, there are practical scalability and deployability concerns with using SDN in ISP backbones [21, 29]. There are two main ideas in our approach to address these limitations:

- Following the hierarchical decomposition in resource management, we also decompose the network orchestration problem into two-sub-problems: (1) Wide-area routing to get traffic to datacenters, and (2) Intra-datacenter routing to get traffic to the right VM instances. This decomposition allows us to use different network-layer techniques; e.g., SDN is more suitable inside the datacenter while traditional MPLS-style routing is better suited for wide-area routing.
- Instead of the controller reacting to each flow arrival, we *proactively* install forwarding rules before traffic arrives. Since we do not know the specific IP-level suspicious flows that will arrive in the future, we use logical *tag-based* forwarding rules with per-VM tags instead of per-flow rules.

5.2 Wide-area orchestration

The Bohatei global controller sets up forwarding rules on backbone routers so that traffic detected as suspicious is steered from edge PoPs to datacenters according to the resource management decisions specified by the $f_{e,a,d}$ values (see §4.3).[7]

To avoid a forklift upgrade of the ISP backbone and enable an immediate adoption of Bohatei, we use traditional tunneling mechanisms in the backbone (e.g., MPLS or IP tunneling). We proactively set up static tunnels from each edge PoP to each datacenter. Once the global controller has solved the DSP problem, the controller configures backbone routers to split the traffic according to the $f_{e,a,d}$ values. While our design is not tied to any specific tunneling scheme, the widespread use of MPLS and IP tunneling make them natural candidates [34].

5.3 Intra-datacenter orchestration

Inside each datacenter, the traffic needs to be steered through the intended sequence of VMs. There are two main considerations here:

1. The next VM a packet needs to be sent to depends on the *context* of the current VM. For example, the node *check UDP count of src* in the graph shown in Figure 3 may send traffic to either *forward to customer* or *log* depending on its analysis outcome.
2. With elastic scaling, we may instantiate several physical VMs for each logical node depending on the demand. Conceptually, we need a “load balancer” at every level of our annotated graph to distribute traffic across different VM instances of a given logical node.

Note that we can trivially address both requirements using a per-flow and reactive solution. Specifically, a local controller can track a packet as it traverses the physical graph, obtain the relevant context information from each VM, and determine the next VM to route the traffic to. However, this approach is clearly not scalable and can introduce avenues for new attacks. The challenge here is to meet these requirements without incurring the overhead of this per-flow and reactive approach.

Encoding processing context: Instead of having the controller track the context, our high-level idea is to en-

[7] We assume the ISP uses legacy mechanisms for forwarding non-attack traffic and traffic to non-Bohatei customers, so these are not the focus of our work.

code the necessary context as *tags* inside packet headers [31]. Consider the example shown in Figure 6 composed of VMs $A_{1,1}$, $A_{2,1}$, and $R_{1,1}$. $A_{1,1}$ encodes the processing context of outgoing traffic as tag values embedded in its outgoing packets (i.e., tag values 1 and 2 denote benign and attack traffic, respectively). The switch then uses this tag value to forward each packet to the correct next VM.

Tag-based forwarding addresses the control channel bottleneck and switch rule explosion. First, the tag generation and tag-based forwarding behavior of each VM and switch is configured proactively once the local controller has solved the SSP. We proactively assign a tag for each VM and populate forwarding rules before flows arrive; e.g., in Figure 6, the tag table of $A_{1,1}$ and the forwarding table of the router have been already populated as shown. Second, this reduces router forwarding rules as illustrated in Figure 6. Without tagging, there will be one rule for each of the 1000 flows. Using tag-based forwarding, we achieve the same forwarding behavior using only two forwarding rules.

Scale-out load balancing: One could interconnect VMs of the same physical graph as shown in Figure 7a using a dedicated load balancer (load balancer). However, such a load balancer may itself become a bottleneck, as it is on the path of every packet from any VM in the set $\{A_{1,1}, A_{1,2}\}$ to any VM in the set $\{R_{1,1}, R_{1,2}, , R_{1,3}\}$. To circumvent this problem, we implement the distribution strategy *inside each VM* so that the load balancer capability scales proportional to the current number of VMs. Consider the example shown in Figure 7b where due to an increase in attack traffic volume we have added one more VM of type A_1 (denoted by $A_{1,2}$) and one more VM of type R_1 (denoted by $R_{1,2}$). To load balance traffic between the two VMs of type R_1, the load balancer of A_1 VMs (shown as $LB_{1,1}$ and $LB_{1,2}$ in the figure) pick a tag value from a *tag pool* (shown by $\{2,3\}$ in the figure) based on the processing context of the outgoing packet and the intended load balancing scheme (e.g., uniformly at random to distribute load equally). Note that this tag pool is pre-populated by the local controller (given the defense library and the output of the resource manager module). This scheme, thus, satisfies the load balancing requirement in a scalable manner.

(a) A naive load balancer design.

(b) A distributed load balancer design.

Figure 7: Different load balancer design points.

Other issues: There are two remaining practical issues:

- *Number of tag bits:* We give a simple upper bound on the required number of bits to encode tags. First, to support context-dependent forwarding out of a VM with k relevant contexts, we need k distinct tag values. Second. to support load balancing among l VMs of the same logical type, each VM needs to be populated with a tag pool including l tags. Thus, at each VM we need at most $k \times l$ distinct tag values. Therefore, an upper bound on the total number of unique tag values is $k_{max} \times l_{max} \times \sum_{a} | V_a^{annotated} |$, where k_{max} and l_{max} are the maximum number of contexts and VMs of the same type in a graph, and $V_a^{annotated}$ is the set of vertices of annotated graph for attack type a. To make this concrete, across the evaluation experiments §8, the maximum value required tags was 800, that can be encoded in $\lceil log_2(800) \rceil = 10$ bits. In practice, this tag space requirement of Bohatei can be easily satisfied given that datacenter grade networking platforms already have extensible header fields [56].
- *Bidirectional processing:* Some logical modules may have bidirectional semantics. For example, in case of a DNS amplification attack, request and response traffic must be processed by the same VM. (In other cases, such as the UDP flood attack, bidirectionality is not required.). To enforce bidirectionality, ISP edge switches use tag values of outgoing traffic so that when the corresponding incoming traffic comes back, edge switches sends it to the datacenter within which the VM that processed the outgoing traffic is located. Within the datacenter, using this tag value, the traffic is steered to the VM.

6 Strategy Layer

As we saw in §4, a key input to the resource manager module is the set of $T_{e,a}$ values, which represents the volume of suspicious traffic of each attack type a arriving at each edge PoP e. This means we need to estimate the future attack mix based on observed measurements of the network and then instantiate the required defenses. We begin by describing an adversary that intends to thwart a Bohatei-like system. Then, we discuss limitations of strawman solutions before describing our *online adaptation* mechanism.

Interaction model: We model the interaction between the ISP running Bohatei and the adversary as a repeated interaction over several *epochs*. The ISP's "move" is one epoch behind the adversary; i.e., it takes Bohatei an epoch to react to a new attack scenario due to implementation delays in Bohatei operations. The epoch duration is simply the sum of the time to detect the attack, run the resource manager, and execute the network orchestration logic. While we can engineer the system to minimize this lag, there will still be non-zero delays in practice and thus we need an adaptation strategy.

Objectives: Given this interaction model, the ISP has to pre-allocate VMs and hardware resources for a specific attack mix. An intelligent and dynamic adversary can change its attack mix to meet two goals:

G1 *Increase hardware resource consumption:* The adversary can cause ISP to overprovision defense VMs. This may impact the ISP's ability to accommodate other attack types or reduce profits from other services that could have used the infrastructure.

G2 *Succeed in delivering attack traffic:* If the ISP's detection and estimation logic is sub-optimal and does not have the required defenses installed, then the adversary can maximize the volume of attack traffic delivered to the target.

The adversary's goal is to maximize these objectives, while the ISPs goal is to minimize these to the extent possible. One could also consider a third objective of collateral damage on legitimate traffic; e.g., introduce needless delays. We do not discuss this dimension because our optimization algorithm from §4 will naturally push the defense as close to the ISP edge (i.e., traffic ingress points) as possible to minimize the impact on legitimate traffic.

Threat model: We consider an adversary with a fixed budget in terms of the total volume of attack traffic it can launch at any given time. Note that the adversary can apportion this budget across the *types* of attacks and the *ingress* locations from which the attacks are launched. Formally, we have $\sum\limits_{e}\sum\limits_{a} T_{e,a} \leq B$, but there are no constraints on the specific $T_{e,a}$ values.

Limitations of strawman solutions: For simplicity, let us consider a single ingress point. Let us consider a strawman solution called *PrevEpoch* where we measure the attack observed in the previous epoch and use it as the estimate for the next epoch. Unfortunately, this can have serious issues w.r.t. goals **G1** and **G2**. To see why, consider a simple scenario where we have two attack types with a budget of 30 units and three epochs with the attack volumes as follows: T1: A1= 10, A2=0; T2: A1=20, A2=0; T3: A1=0; A2=30. Now consider the *PrevEpoch* strategy starting at the 0,0 configuration. It has a total wastage of 0,0,20 units and a total evasion of 10,10,30 units because it has overfit to the previous measurement. We can also consider other strategies; e.g., a *Uniform* strategy that provisions 15 units each for A1 and A2 or extensions of these to *overprovision* where we multiply the number of VMs given by the resource manager in the last epoch by a fixed value $\gamma > 1$. However, these suffer from the same problems and are not competitive.

Online adaptation: Our metric of success here is to have *low regret* measured with respect to the best static solution computed in hindsight [36]. Note that in general, it is not possible to be competitive w.r.t. the best dynamic solution since that presumes oracle knowledge of the adversary, which is not practical.

Intuitively, if we have a non-adaptive adversary, using the observed empirical average is the best possible static hindsight estimation strategy; i.e., $T^*_{e,a} = \frac{\sum_t T_{e,a,t}}{|t|}$ would be the optimal solution ($|t|$ denotes the total number of epochs). However, an attacker who knows that we are using this strategy can game the system by changing the attack mix. To address this, we use a follow the perturbed leader (FPL) strategy [36] where our estimation uses a combination of the past observed behavior of the adversary and a randomized component. Intuitively, the random component makes it impossible for the attacker to predict the ISP's estimates. This is a well-known approach in online algorithms to minimize the regret [36]. Specifically, the traffic estimates for the *next* epoch $t+1$, denoted by $\widehat{T_{e,a,t+1}}$ values, are calculated based on the average of the past values plus a random component: $\widehat{T_{e,a,t+1}} = \frac{\sum_{t'=1}^{t} T_{e,a,t'}}{|t|} + randperturb$.

Here, $T_{e,a,t'}$ is the empirically observed value of the attack traffic and *randperturb* is a random value drawn uniformly from $[0, \frac{2\times B}{nextEpoch \times |E| \times |A|}]$. (This is assuming a total defense of budget of $2 \times B$.) It can be shown that this is indeed a provably good regret minimization strategy [36]; we do not show the proof for brevity.

7 Implementation

In this section, we briefly describe how we implemented the key functions described in the previous sections. We have made the source code available [1].

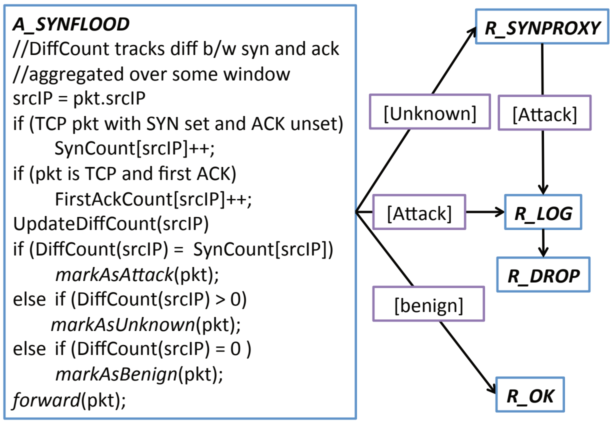
7.1 DDoS defense modules

The design of the Bohatei strategy layer is inspired by the prior modular efforts in Click [7] and Bro [46]. This modularity has two advantages. First, it allows us to adopt best of breed solutions and compose them for different attacks. Second, it enables more fine-grained scaling. At a high level, there are two types of logical building blocks in our defense library:

1. *Analysis (A)*: Each analysis module processes a suspicious flow and determines appropriate action (e.g., more analysis or specific response). It receives a packet and outputs a tagged packet, and the tags are used to steer traffic to subsequent analysis and response module instances as discussed earlier.
2. *Response (R)*: The input to an R module is a tagged packet from some A module. Typical responses include forward to customer (for benign traffic), log, drop, and rate limit. Response functions will depend on the type of attack; e.g., sending RST packets in case of a TCP SYN attack.

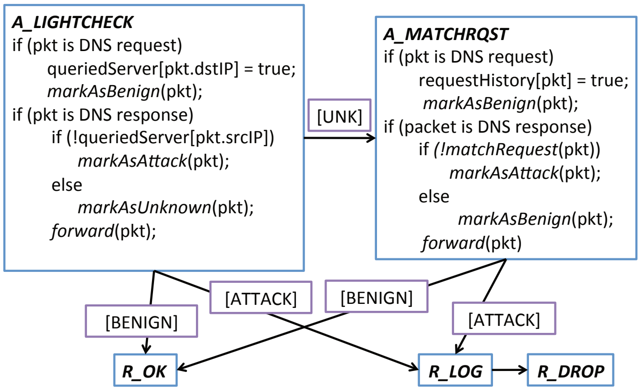
Next, we describe defenses we have implemented for different DDoS attacks. Our goal here is to illustrate the flexibility Bohatei provides in dealing with a diverse set of known attacks rather than develop new defenses.

1. **SYN flood** (Figure 8): We track the number of open TCP sessions for each source IP; if a source IP has no asymmetry between SYNs and ACKs, then mark its packets as benign. If a source IP never completes a connection, then we can mark its future packets as known attack packets. If we see a gray area where the source IP has completed some connections but not others, in which case we use a SYN-Proxy defense (e.g., [9, 28]).
2. **DNS amplification** (Figure 9): We check if the DNS server has been queried by some customer IP. This example highlights another advantage—we can decouple fast (e.g., the header-based *A_LIGHTCHECK* module) and slow path analyses (e.g., the second A module needs to look into payloads). The responses are quite simple and implement logging, dropping, or basic forwarding to the destination. We do not show the code for brevity.
3. **UDP flood:** The analysis node *A_UDP* identifies source IPs that send an anomalously higher number of UDP packets and uses this to categorize each packet as either attack or benign. The function *forward* will direct the packet to the next node in the defense strategy; i.e., *R_OK* if benign, or *R_LOG* if attack.
4. **Elephant flow:** Here, the attacker launches legitimate but very large flows. The A module detects abnormally large flows and flags them as attack flows. The response is to randomly drop packets from these large flows (not shown).



```
A_SYNFLOOD
//DiffCount tracks diff b/w syn and ack
//aggregated over some window
srcIP = pkt.srcIP
if (TCP pkt with SYN set and ACK unset)
    SynCount[srcIP]++;
if (pkt is TCP and first ACK)
    FirstAckCount[srcIP]++;
UpdateDiffCount(srcIP)
if (DiffCount(srcIP) =  SynCount[srcIP])
    markAsAttack(pkt);
else  if (DiffCount(srcIP) > 0)
    markAsUnknown(pkt);
else  if (DiffCount(srcIP) = 0 )
    markAsBenign(pkt);
forward(pkt);
```

Figure 8: SYN Flood defense strategy graph.



```
A_LIGHTCHECK
if (pkt is DNS request)
    queriedServer[pkt.dstIP] = true;
    markAsBenign(pkt);
if (pkt is DNS response)
    if (!queriedServer[pkt.srcIP])
        markAsAttack(pkt);
    else
        markAsUnknown(pkt);
    forward(pkt);
```

```
A_MATCHRQST
if (pkt is DNS request)
    requestHistory[pkt] = true;
    markAsBenign(pkt);
if (packet is DNS response)
    if (!matchRequest(pkt))
        markAsAttack(pkt);
    else
        markAsBenign(pkt);
    forward(pkt)
```

Figure 9: DNS amplification defense strategy graph.

Attack detection: We use simple time series anomaly detection using `nfdump`, a tool that provides NetFlow-like capabilities, and custom code [27]. The output of the detection module is sent to the Bohatei global controller as a 3-tuple $\langle Type, FlowSpec, Volume \rangle$, where *Type* indicates the type of DDoS attack (e.g., SYN flood, DNS amplification), *FlowSpec* provides a generic description of the *flow space* of suspicious traffic (involving wildcards), and *Volume* indicates the suspicious traffic volume based on the flow records. Note that this *FlowSpec* does not pinpoint specific attack flows; rather, it is a coarse-grained hint on characteristics of suspicious traffic that need further processing through the defense graphs.

7.2 SDN/NFV platform

Control plane: We use the `OpenDayLight` network control platform, as it has gained significant traction from key industry players [17]. We implemented the Bohatei global and local control plane modules (i.e., strategy, resource management, and network orchestration) as separate `OpenDayLight` plugins. Bohatei uses OpenFlow [40] for configuring switches; this is purely for ease of prototyping, and it is easy to integrate other network control APIs (e.g., YANG/NetCONF).

Data plane: Each physical node is realized using a VM running on KVM. We use open source tools (e.g., Snort, Bro) to implement the different Analysis (A) and

Attack type	Analysis	Response
UDP flood	A_UDP using Snort (inline mode)	R_LOG using iptables and R_RATELIMIT using tc library
DNS amp.	both LIGHTCHECK and MATCHRQST using netfilter library, iptables, custom code	R_LOG and R_DROP using iptables

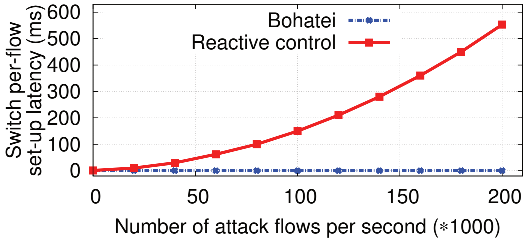

Figure 10: Bohatei control plane scalability.

Response (R) modules. Table 1 summarizes the specific platforms we have used. These tools are instrumented using FlowTags [31] to add tags to outgoing packets to provide contextual information. We used OpenvSwitch [16] to emulate switches in both datacenters and ISP backbone. The choice of OpenvSwitch is for ease of prototyping on our testbed.

Resource management algorithms: We implement the DSP and SSP algorithms using custom `Go` code.

8 Evaluation

In this section, we show that:

1. Bohatei is scalable and handles attacks of hundreds of Gbps in large ISPs and that our design decisions are crucial for its scale and responsiveness (§8.1)
2. Bohatei enables a rapid ($\leq$ 1 minute) response for several canonical DDoS attack scenarios (§8.2)
3. Bohatei can successfully cope with several dynamic attack strategies (§8.3)

Setup and methodology: We use a combination of real testbed and trace-driven evaluations to demonstrate the above benefits. Here we briefly describe our testbed, topologies, and attack configurations:

- *SDN Testbed:* Our testbed has 13 Dell R720 machines (20-core 2.8 GHz Xeon CPUs, 128GB RAM). Each machine runs KVM on CentOS 6.5 (Linux kernel v2.6.32). On each machine, we assigned equal amount of resources to each VM: 1 vCPU (virtual CPU) and 512MB of memory.
- *Network topologies:* We emulate several router-level ISP topologies (6–196 nodes) from the Internet Topology Zoo [22]. We set the bandwidth of each core link to be 100Gbps and link latency to be 10ms. The number of datacenters, which are located randomly, is 5% of the number of backbone switches with a capacity of 4,000 VMs per datacenter.
- *Benign traffic demands:* We assume a gravity model of traffic demands between ingress-egress switch pairs [50]. The total volume is scaled linearly with the size of the network such that the average link load on the topology backbone is 24Gbps with a maximum bottleneck link load of 55Gbps. We use `iperf` and custom code to generate benign traffic.
- *Attack traffic:* We implemented custom modules to generate attack traffic: (1) **SYN flood** attack by sending only SYN packets with spoofed IP addresses at a high rate; (2) **DNS amplification** using `OpenDNS` server with `BIND` (version 9.8) and emulating an attacker sending DNS requests with spoofed source IPs; (3) We use `iperf` to create some fixed bandwidth traffic to generate **elephant flows**, and (4) **UDP flood** attacks. We randomly pick one edge PoP as the target and vary the target across runs. We ramp up the attack volume until it induces maximum reduction in throughput of benign flows to the target. On our testbed, we can ramp up the volume up to 10 Gbps. For larger attacks, we use simulations.

8.1 Bohatei scalability

Resource management: Table 2 compares the run time and optimality of the ILP-based algorithm and Bohatei (i.e., DSP and SSP) for 3 ISP topologies of various sizes. (We have results for several other topologies but do not show it for brevity.) The ILP approach takes from several tens of minutes to hours, whereas Bohatei takes only a few milliseconds enabling rapid response to changing traffic patterns. The optimality gap is $\leq$ 0.04%.

Control plane responsiveness: Figure 10 shows the per-flow setup latency comparing Bohatei to the SDN per-flow and reactive paradigm as the number of attack flows in a DNS amplification attack increases. (The results are consistent for other types of attacks and are not shown for brevity.) In both cases, we have a dedicated machine for the controller with 8 2.8GHz cores and 64

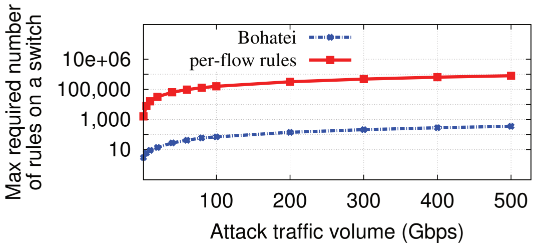

Figure 11: Number of switch forwarding rules in Bohatei vs. today's flow-based forwarding.

GB RAM. To put the number of flows in context, 200K flows roughly corresponds to a 1 Gbps attack. Note that a typical upper bound for switch flow set-up time is on the order of a few milliseconds [59]. We see that Bohatei incurs zero rule setup latency, while the reactive approach deteriorates rapidly as the attack volume increases.

Number of forwarding rules: Figure 11 shows the maximum number of rules required on a switch across different topologies for the SYN flood attack. Using today's flow-based forwarding, each new flow will require a rule. Using tag-based forwarding, the number of rules depends on the number of VM instances, which reduces the switch rule space by four orders of magnitude. For other attack types, we observed consistent results (not shown). To put this in context, the typical capacity of an SDN switch is 3K-4K rules (shared across various network management tasks). This means that per-flow rules will not suffice for attacks beyond 10Gbps. In contrast, Bohatei can handle hundreds of Gbps of attack traffic; e.g., a 1 Tbps attack will require $<$ 1K rules on a switch.

Benefit of scale-out load balancing: We measured the resources that would be consumed by a dedicated load balancing solution. Across different types of attacks with a fixed rate of 10Gbps, we observed that a dedicated load balancer design requires between 220–300 VMs for load balancing alone. By delegating the load balancing task to the VMs, our design obviates the need for these extra load balancers (not shown).

8.2 Bohatei end-to-end effectiveness

We evaluated the effectiveness of Bohatei under four different types of DDoS attacks. We launch the attack traffic of the corresponding type at 10th second; the attack is sustained for the duration of the experiment. In each scenario, we choose the attack volume such that it is capable of bringing the throughput of the benign traffic to zero. Figure 12 shows the impact of attack traffic on the throughput of benign traffic. The Y axis for each scenario shows the network-wide throughput for TCP traffic (a total of 10Gbps if there is no attack). The results shown in this figure are based on Cogent, the largest topology with 196 switches; the results for other topologies were consistent and are not shown. While we do see some small differences across attacks, the overall reaction time is short.

Attack type	# VMs needed	
	Monolithic	Fine-grained scaling
DNS Amplification	5,422	1,005
SYN Flood	3,167	856
Elephant flows	1,948	910
UDP flood	3,642	1,253

Table 3: Total hardware provisioning cost needed to handle a 100 Gbps attack for different attacks.

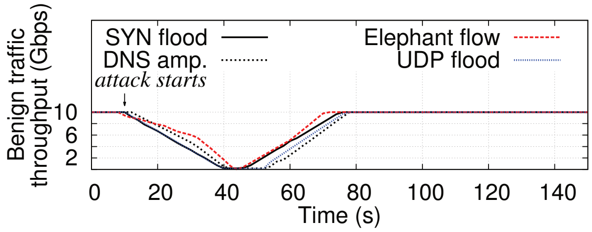

Figure 12: Bohatei enables rapid response and restores throughput of legitimate traffic.

The key takeaway is that Bohatei can help networks respond rapidly (within one minute) to diverse attacks and restore the performance of legitimate flows. We repeated the experiments with UDP as the benign traffic. In this case, the recovery time was even shorter, as the throughput does not suffer from the congestion control mechanism of TCP.

Hardware cost: We measure the total number of VMs needed to handle a given attack volume and compare two cases: (1) monolithic VMs embedding the entire defense logic for an attack, and (2) using Bohatei's fine-grained modular scaling. Table 3 shows the number of VMs required to handle different types of 100 Gbps attacks. Fine-grained scaling gives a 2.1–5.4× reduction in hardware cost vs. monolithic VMs. Assuming a commodity server costs $3,000 and can run 40VMs in Bohatei (as we did), we see that it takes a total hardware cost of less than about $32,000 to handle a 100 Gbps attack across Table 3. This is in contrast to the total server cost of about $160,000 for the same scenario if we use monolithic VMs. Moreover, since Bohatei is horizontally scalable by construction, dealing with larger attacks simply entails a linearly scale up of the number of VMs.

Routing efficiency: To quantify how Bohatei addresses the routing inefficiency of existing solutions (§2.2), we ran the following experiment. For each topology, we measured the end-to-end latency in two equivalently provisioned scenarios: (1) the location of the DDoS defense appliance is the node with the highest betweenness value[8], and (2) Bohatei. As a baseline, we consider

[8] Betweenness is a measure of a node's centrality, which is the fraction of the network's all-pairs shortest paths that pass through that node.

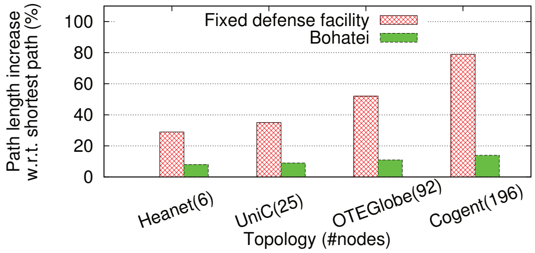

Figure 13: Routing efficiency in Bohatei.

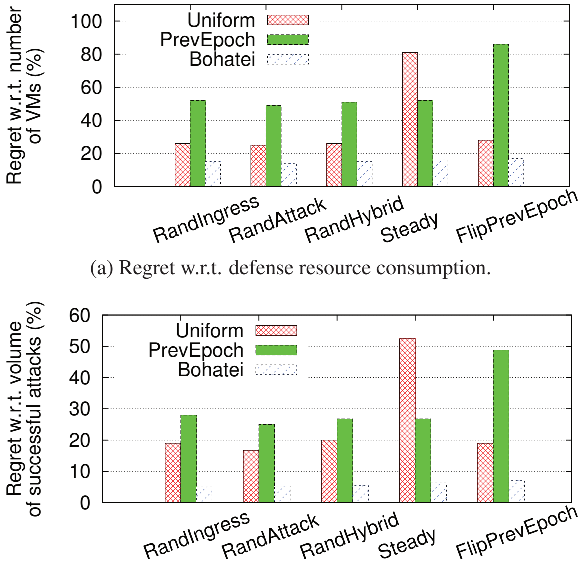

(a) Regret w.r.t. defense resource consumption.

(b) Regret w.r.t. successful attacks.

Figure 14: Effect of different adaptation strategies (bars) vs. different attacker strategies (X axis).

shortest path routing without attacks. The main conclusion in Figure 13 is that Bohatei reduces traffic latency by 20% to 65% across different scenarios.

8.3 Dynamic DDoS attacks

We consider the following dynamic DDoS attack strategies: (1) *RandIngress*: In each epoch, pick a random subset of attack ingresses and distribute the attack budget evenly across attack types; (2) *RandAttack*: In each epoch, pick a random subset of attack types and distribute the budget evenly across all ingresses; (3) *RandHybrid*: In each epoch, pick a random subset of ingresses and attack types independently and distribute the attack budget evenly across selected pairs; (4) *Steady*: The adversary picks a random attack type and a subset of ingresses and sustains it during all epochs; and (5) *FlipPrevEpoch*: This is conceptually equivalent to conducting two *Steady* attacks $A1$ and $A2$ with each being active during odd and even epochs, respectively.

Given the typical DDoS attack duration (≈ 6 hours [12]), we consider an attack lasting for 5000 5-second epochs (i.e., ≈7 hours). Bohatei is initialized with a zero starting point of attack estimates. The metric of interest we report is the *normalized regret* with respect to the best static decision in hindsight; i.e., if we had to pick a single static strategy for the entire duration. Figure 14a and Figure 14b show the regret w.r.t. the two goals G1 (the number of VMs) and G2 (volume of successful attack) for a 24-node topology. The results are similar using other topologies and are not shown here. Overall, Bohatei's online adaptation achieves low regret across the adversarial strategies compared to two strawman solutions: (1) uniform estimates, and (2) estimates given the previous measurements.

9 Related Work

DDoS has a long history; we refer readers to surveys for a taxonomy of DDoS attacks and defenses (e.g., [41]). We have already discussed relevant SDN/NFV work in the previous sections. Here, we briefly review other related topics.

Attack detection: There are several algorithms for detecting and filtering DDoS attacks. These include time series detection techniques (e.g., [27]), use of backscatter analysis (e.g., [42]), exploiting attack-specific features (e.g., [35]), and network-wide analysis (e.g., [38]). These are orthogonal to the focus of this paper.

DDoS-resilient Internet architectures: These include the use of capabilities [58], better inter-domain routing (e.g., [60]), inter-AS collaboration (e.g., [39]), packet marking and unforgeable identifiers (e.g., [26]), and traceback (e.g., [51]). However, they do not provide an immediate deployment path or resolution for current networks. In contrast, Bohatei focuses on a more practical, single-ISP context, and is aligned with economic incentives for ISPs and their customers.

Overlay-based solutions: There are overlay-based solutions (e.g., [25,52]) that act as a "buffer zone" between attack sources and targets. The design contributions in Bohatei can be applied to these as well.

SDN/NFV-based security: There are few efforts in this space such as FRESCO [53] and AvantGuard [54]. As we saw earlier, these SDN solutions will introduce new DDoS avenues because of the per-flow and reactive model [54]. Solving this control bottleneck requires hardware modifications to SDN switches to add "stateful" components, which is unlikely to be supported by switch vendors soon [54]. In contrast, Bohatei chooses a proactive approach of setting up tag-based forwarding rules that is immune to these pitfalls.

10 Conclusions

Bohatei brings the flexibility and elasticity benefits of recent networking trends, such as SDN and NFV, to DDoS defense. We addressed practical challenges in the design of Bohatei's resource management algorithms and control/data plane mechanisms to ensure that these do not become bottlenecks for DDoS defense. We implemented a full-featured Bohatei prototype built on industry-standard SDN control platforms and commodity network appliances. Our evaluations on a real testbed show that Bohatei (1) is scalable and responds rapidly to attacks, (2) outperforms naive SDN implementations that do not address the control/data plane bottlenecks, and (3) enables resilient defenses against dynamic adversaries. Looking forward, we believe that these design principles can also be applied to other aspects of network security.

A ILP Formulation

The ILP formulation for an optimal resource management (mentioned in §4.2) is shown in Figure 15.

Vairables: In addition to the parameters and variables that we have defined earlier in §4, we define the binary variable $q_{d,a,i,vm,s,i',vm',s',l}$ as follows: if it is 1, VM *vm* of

$$\text{Minimize } \alpha \times \sum_e \sum_a \sum_d f_{e,a,d} \times T_{e,a} \times L_{e,d} + \sum_d dsc_d \tag{1}$$

s.t.

$$\forall e,a : \sum_d f_{e,a,d} = 1 \triangleright \text{ all suspicious traffic should be served} \tag{2}$$

$$\forall a,d : t_{a,d} = \sum_e f_{e,a,d} \times T_{e,a} \triangleright \text{ traffic of each type to each datacenter} \tag{3}$$

$$\forall d : \sum_a t_{a,d} \leq C_d^{link} \triangleright \text{ datacenter link capacity} \tag{4}$$

$$\forall d,a,i : \sum_{s \in S_d} n_{a,i}^{d,s} \geq t_{a,d} \times \frac{\sum_{i':(i',i)=e_{a,i' \to i}^{annotated}} W_{a,i' \to i}}{P_{a,i}} \triangleright \text{ provisioning sufficient VMs (} S_d \text{ is the set of } d\text{'s servers.)} \tag{5}$$

$$\forall d,s \in S_d : \sum_a \sum_i n_{a,i}^{d,s} \leq C_{d,s}^{compute} \triangleright \text{ server compute capacity} \tag{6}$$

$$\forall d : dsc_d = intraR_d \times IntraUnitCost + interR_d \times InterUnitCost \triangleright \text{ total cost within each datacenter} \tag{7}$$

$$\forall d : intraR_d = \sum_a \sum_{(i,i')=e_{a,i \to i'}^{annotated}} \sum_{(s,s') \in sameRack} \sum_{vm=1}^{MaxVM} \sum_{vm'=1}^{MaxVM} \sum_{l=1}^{MaxVol} q_{d,a,i,vm,s,i',vm',s',l} \triangleright \text{ intra-rack cost} \tag{8}$$

$$\forall d : interR_d = \sum_a \sum_{(i,i')=e_{a,i \to i'}^{annotated}} \sum_{(s,s') \notin sameRack} \sum_{vm=1}^{MaxVM} \sum_{vm'=1}^{MaxVM} \sum_{l=1}^{MaxVol} q_{d,a,i,vm,s,i',vm',s',l} \triangleright \text{ inter-rack cost} \tag{9}$$

$$\forall d,a,i',vm' : \sum_s \sum_{s'} \sum_{i:(i,i')=e_{a,i \to i'}^{annotated}} \sum_{vm=1}^{MaxVM} \sum_{l=1}^{MaxVol} q_{d,a,i,vm,s,i',vm',s',l} \leq P_{a,i'} \triangleright \text{ enforcing VMs capacities} \tag{10}$$

$$\forall d,s \in S_d,a,i' : n_{a,i'}^{d,s} \times P_{a,i'} \geq \sum_{vm=1}^{MaxVM} \sum_{vm'=1}^{MaxVM} \sum_{i:(i,i')=e_{a,i \to i'}^{annotated}} \sum_{s'} \sum_{l=1}^{MaxVol} q_{d,a,i,vm,s,i',vm',s',l} \triangleright \text{ bound traffic volumes} \tag{11}$$

$$\forall d,s \in S_d,a,i' : n_{a,i'}^{d,s} \times P_{a,i'} \leq \sum_{vm=1}^{MaxVM} \sum_{vm'=1}^{MaxVM} \sum_{i:(i,i')=e_{a,i \to i'}^{annotated}} \sum_{s'} \sum_{l=1}^{MaxVol} q_{d,a,i,vm,s,i',vm',s',l} + 1 \triangleright \text{ bound traffic volumes} \tag{12}$$

$$\triangleright \text{ flow conservation for VM } vm \text{ of type logical node } k \text{ that has both predecessor(s) and successor(s)}$$
$$\forall d,a,k,vm : \sum_{vm'=1}^{MaxVM} \sum_{g:(g,k)=e_{a,g \to k}^{annotated}} \sum_s \sum_{s'} \sum_{l=1}^{MaxVol} q_{d,a,g,vm',s',k,vm,s,l} = \sum_{vm'=1}^{MaxVM} \sum_{h:(k,h)=e_{a,k \to h}^{annotated}} \sum_s \sum_{s'} \sum_{l=1}^{MaxVol} q_{d,a,k,vm,s,h,vm',s',l} \tag{13}$$

$$\forall link \in ISP\ backbone : \sum_{link \in Path_{e \to d}} \sum_a f_{e,a,d} \times T_{e,a} \leq \beta \times MaxLinkCapacity \triangleright \text{ per-link traffic load control} \tag{14}$$

$$f_{e,a,d} \in [0,1], q_{d,a,i,vm,s,i',vm',s',l} \in \{0,1\}, n_{a,i}^d, n_{a,i}^{d,s} \in \{0,1,\ldots\}, t_{a,d}, interR_d, intraR_d, dsc_d \in \mathbb{R} \triangleright \text{ variables} \tag{15}$$

Figure 15: ILP formulation for an optimal resource management.

type $v_{a,i}$ runs on server s and sends 1 unit of traffic (e.g., 1 Gbps) to VM vm' of type $v_{a,i'}$ that runs on server s', where $e_{a,i \to i'}^{annotated} \in E_a^{annotated}$, and servers s and s' are located in datacenter d; otherwise, $q_{d,a,i,vm,s,i',vm',s',l} = 0$. Here l is an auxiliary subscript indicating that the one unit of traffic associated with q is the lth one out of $MaxVol$ possible units of traffic. The maximum required number of VMs of any type is denoted by $MaxVM$.

The ILP involves two key decision variables: *(1)* $f_{e,a,d}$ is the fraction of traffic $T_{e,a}$ to send to datacenter D_d, and *(2)* $n_{a,i}^{d,s}$ is the number of VMs of type $v_{a,i}$ on server s of datacenter d, hence physical graphs $DAG_a^{physical}$.

Objective function: The objective function (1) is composed of inter-datacenter and intra-datacenter costs, where constant $\alpha > 0$ reflects the relative importance of inter-datacenter cost to intra datacenter cost.

Constraints: Equation (2) ensures all suspicious traffic will be sent to data centers for processing. Equation (3) computes the amount of traffic of each attack type going to each datacenter, which is ensured to be within datacenters bandwidth capacity using (4). Equation (5) is intended to ensure sufficient numbers of VMs of the required types in each datacenter. Servers compute capacities are enforced using (6). Equation (7) sums up the cost associated with each datacenter, which is composed of two components: intra-rack cost, given by (8), and inter-rack component, given by (9). Equation (10) ensures the traffic processing capacity of each VM is not exceeded. Equations (11) and (12) tie the variables for number of VMs (i.e., $n_{a,i}^{d,s}$) and traffic (i.e., $q_{d,a,i,vm,s,i',vm',s',l}$) to each other. Flow conservation of nodes is guaranteed by (13). Inequality (14) ensures no ISP backbone link gets congested (i.e., by getting a traffic volume of more than a fixed fraction β of its maximum capacity), while $Path_{e \to d}$ is a path from a precomputed set of paths from e to d. The ILP decision variables are shown in (15).

B DSP and SSP Algorithms

As described in §4.3, due to the impractically long time needed to solve the ILP formulation, we design the DSP and SSP heuristics for resource management. The ISP global controller solves the DSP problem to assign suspicious incoming traffic to data centers. Then each local controller solves an SSP problem to assign servers to

VMs. Figure 16 and 17 show the detailed pseudocode for the DSP and SSP heuristics, respectively.

```
▷ Inputs: $L$, $T$, $DAG_a^{annotated}$, $C_d^{link}$, and $C_d^{compute}$
▷ Outputs: $DAG_{a,d}^{physical}$ and $f_{e,a,d}$ values

Build max-heap $T^{maxHeap}$ of attack volumes $T$
while $!Empty(T^{maxHeap})$
      do $t \leftarrow ExtractMax(T^{maxHeap})$
          $d \leftarrow$ datacenter with min. $L_{t.e,t.d}$ and cap.$> 0$
          ▷ enforcing datacenter link capacity
          $t_1 \leftarrow min(t, C_d^{link})$
          ▷ compute capacity of $d$ for traffic type $a$
          $t_2 \leftarrow \frac{C_d^{Compute}}{\sum_i \frac{\sum_{i'} W_{a,i' \rightarrow i}}{P_{a,i}}}$
          ▷ enforcing datacenter compute capacity
          $t_{assigned} \leftarrow min(t_1, t_2)$
          $f_{e,a,d} \leftarrow \frac{t_{assigned}}{T_{t.e,t.a}}$
          for each module type $i$
               do ▷ update $n_{a,i}^d$ given new assignment
                    $n_{a,i}^d = n_{a,i}^d + t_{assigned}^d \frac{\sum_{i'} W_{a,i' \rightarrow i}}{P_{a,i}}$
          $C_d^{link} \leftarrow C_d^{link} - t_{assigned}$
          $C_d^{compute} \leftarrow C_d^{compute} - t_{assigned} \sum_i \frac{\sum_{i'} W_{a,i' \rightarrow i}}{P_{a,i}}$
          ▷ leftover traffic
          $t_{unassigned} = t - t_{assigned}$
          if ($t_{unassigned} > 0$)
             then $Insert(T^{maxHeap}, t_{unassigned})$
for each datacenter $d$ and attack type $a$
      do Given $n_{a,i}^d$ and $DAG_a^{annotated}$, compute $DAG_{a,d}^{physical}$
```

Figure 16: Heuristic for datacenter selection problem (DSP).

```
▷ Inputs: $DAG_{a,d}^{physical}$, $IntraUnitCost$, $InterUnitCost$,
and $C_{d,s}^{compute}$ values
▷ Outputs: $n_{a,i}^{d,s}$ values

while entire $DAG_{a,d}^{physical}$ is not assigned to $d$'s servers
      do $N \leftarrow v_{a,i}^{annotated}$ whose all predecessors are assigned
          if ($N == NIL$)
             then $N \leftarrow v_a^{annotated}$ with max $P_{a,i}$
          $localize$(nodes of $DAG_{a,d}^{physical}$ corresponding to $N$)

▷ function $localize$ tries to assign all of its
input physical nodes to the same server or rack
$localize$(inNodes){
assign all inNodes to emptiest server
if failed
   then assign all inNodes to emptiest rack
          if failed
             then split inNodes $V_a^{physical}$ across racks
update $n_{a,i}^{d,s}$ values
}
```

Abstract

The high price of incoming international calls is a common method of subsidizing telephony infrastructure in the developing world. Accordingly, international telephone system interconnects are regulated to ensure call quality and accurate billing. High call tariffs create a strong incentive to evade such interconnects and deliver costly international calls illicitly. Specifically, adversaries use VoIP-GSM gateways informally known as "simboxes" to receive incoming calls over wired data connections and deliver them into a cellular voice network through a local call that appears to originate from a customer's phone. This practice is not only extremely profitable for simboxers, but also dramatically degrades network experience for legitimate customers, violates telecommunications laws in many countries, and results in significant revenue loss. In this paper, we present a passive detection technique for combating simboxes at a cellular base station. Our system relies on the raw voice data received by the tower during a call to distinguish errors in GSM transmission from the distinct audio artifacts caused by delivering the call over a VoIP link. Our experiments demonstrate that this approach is highly effective, and can detect 87% of real simbox calls in only 30 seconds of audio with no false positives. Moreover, we demonstrate that evading our detection across multiple calls is only possible with a small probability. In so doing, we demonstrate that fraud that degrades network quality and costs telecommunications billions of dollars annually can easily be detected and counteracted in real time.

1 Introduction

Cellular networks provide digital communications for more than five billion people around the globe. As such, they represent one of the largest, most integral pieces of critical infrastructure in the modern world. Deploying these networks requires billions of dollars in capital by providers, and often necessitates government subsidies in poorer nations where such investments may not produce returns for many decades. As a means of maintaining these systems, international calls destined for such networks are often charged a significant tariff, which distributes the costs of critical but expensive cellular infrastructure to callers from around the world.

Many individuals seek to avoid such tariffs by any means necessary through a class of attacks known as *interconnect bypass fraud.* Specifically, by avoiding the regulated network interconnects and instead finding unintended entrances to the provider network, a caller can be connected while dramatically lowering his or her costs. Such fraud constitutes a "free rider" problem, a term from economics in which some participants enjoy the benefits of expensive infrastructure without paying to support it. The most common implementation of interconnect bypass fraud is known as simboxing. Enabled by VoIP GSM gateways (i.e., "simboxes"), simboxing connects incoming VoIP calls to local cellular voice network via a collection of SIM cards and cellular radios. Such calls appear to originate from a customer phone to the network provider and are delivered at the subsidized domestic rate, free of international call tariffs. Interconnection bypass fraud negatively impacts availability, reliability and quality for legitimate consumers by creating network hotspots through the injection of huge volumes of tunneled calls into underprovisioned cells, and costs operators over $2 Billion annually [28].

In this paper, we present Ammit[1], a system for detecting simboxing designed to be deployed in a cellular network. Our solution relies on the fact that audio transmitted over the Internet before being delivered to the GSM network will be degraded in measurable, distinctive ways. We develop novel techniques and build

[1] Ammit was an Egyptian funerary deity who was believed to separate pure and impure souls, preventing the latter from achieving immortality in the afterlife.

on mechanisms from the Pindr0p call fingerprinting system [25] to measure these degradations by applying a number of light-weight signal processing methods to the received call audio and examining the results for distinguishing characteristics. These techniques rapidly and automatically identify simboxed calls and the SIMs used to make such connections, thereby allowing us to quickly shut down these rogue accounts. In so doing, our approach makes these attacks far less likely to be successful and stable, thereby largely closing these illegal entrances to provider networks.

We make the following contributions:

- **Identify audio characteristics useful for detecting simboxes:** We identify features in simboxed call audio that make it easily differentiable from traditional GSM cellular calls and argue why such features are difficult for adversaries to avoid.

- **Develop rapid detection architecture for the network edge:** We design and implement Ammit, a detection tool that uses signal processing techniques for identifying illicitly tunneled VoIP audio in a GSM network, and demonstrate that our techniques can easily execute in real time. Such performance means that our solution can be practically deployed at the cellular network edge.

- **Demonstrate high detection rate for SIM cards used in simboxes:** Through experimental analysis on a real simbox, we show that Ammit can quickly profile and terminate *87% of simboxed calls with no false positives*. Such a high detection rate arguably makes interconnect bypass fraud uneconomical.

We note that our techniques differ significantly from related work, which requires either large-scale post hoc analysis [42] or serendipitous test calls to network probes [10, 13, 15, 16, 18]. Our approach is intended to be used in real time, allowing for rapid detection and elimination of simboxes. We specifically characterize these techniques in Section 8.

It should be noted that the authors are not attempting to combat the spread of inexpensive VoIP calls in this paper. Traditional VoIP calls, which connect users through IP or a licensed VoIP-PSTN (Public Switched Telephone Network) gateway, are not considered a problem in countries that combat simboxes. Instead, we seek to prevent the creation of unauthorized entry points into private cellular networks that degrade performance for legitimate users and cost providers and governments two billion dollars annually. This is analogous to the problem of rogue Wi-Fi access points; simboxing prevents network administrators from controlling access to the network and can degrade service for other users. Moreover, similar to other economic free rider problems, failure to combat such behavior can lead to both underprovisioning and the overuse of such networks, making quality and stability difficult to achieve [49]. *Failure to combat simbox fraud may ultimately lead to raising prices and lower reliability for subsidized domestic calls in developing nations, where the majority of citizens can rarely afford such cost increases.*

The remainder of this paper is organized as follows: Section 2 provides background information on cellular networks; Section 3 describes simbox operation and their consequences; Section 4 presents our detection methodology; Section 6 describes our experimental methodology; Section 7 discusses our results; Section 8 offers an overview of important related work; and Section 9 presents our final remarks.

2 Background

2.1 Cellular Networks

The Global System for Mobile Communications (GSM) is a suite of standards used to implement cellular communications. It is used by the majority of carriers in the US and throughout Europe, Africa, and Asia. GSM is a "second generation" (2G) cellular network and has evolved into UMTS (3G) and LTE (4G) standards. We focus on GSM because it is the most available for direct experimentation. Note that the methods we present in the paper can easily be ported to other cellular standards.

GSM manages user access to the network by issuing users a small smartcard called a Subscriber Identity Module (SIM card) that contains identity and cryptographic materials. A carrier SIM card can be placed in any device authorized to operate on a carrier's network. Because GSM networks cryptographically authenticate almost every network transaction, cellular network activity can always be attributed to a specific SIM card. In the past, the ability to clone a SIM card negated this guarantee; however, modern SIM cards now have hardware protections that prevent practical key recovery and card cloning.

In addition to describing network functionality, the GSM standards also specify a method for encoding audio known as the GSM Full Rate (GSM-FR) codec [23]. Although designed for mobile networks, it is also used as a general purpose audio codec and is frequently implemented in VoIP software. To avoid ambiguity, we use "GSM" or "air transmission" to mean GSM cellular networks and "GSM-FR" to indicate the audio codec.

2.2 VoIP

Voice over Internet Protocol (VoIP) is a technology that implements telephony over IP networks such as the Internet. Two clients can complete a VoIP call using exclusively the Internet, or calls may also be routed from a VoIP client to a PSTN line (or vice-versa) through a VoIP Gateway. Providers including Vonage, Skype, and Google Voice provide both IP-only and IP-PSTN calls. The majority of VoIP calls are set up using a text-based protocol called the Session Initiation Protocol (SIP). One of the jobs of SIP is to establish which audio codec will be used for the call. Once a call has been established, audio flows between callers using the Realtime Transport Protocol (RTP), which is typically carried over UDP.

VoIP call quality is affected by packet loss and jitter. Absent packets, whether they are the result of actual loss or jitter, cause gaps in audio. Such gaps are filled in with silence by default. Some VoIP clients attempt to improve over this standard behavior and implement Packet Loss Concealment (PLC) algorithms to fill in missing packets with repeated or generated audio. Specifically, PLC algorithms take advantage of the fact that speech waveforms are more or less stationary for short time periods, so clients can generate a plausible section of audio from previous packets. Many codecs have mandatory PLCs, although some are optional (as in the case of the G.711 audio codec) or are not implemented (as is frequently the case when GSM-FR is used outside of cellular networks). Some VoIP software (including Asterisk) implements their own PLC algorithms, but do not activate them unless configured by an administrator.

3 What is a Simbox?

A simbox is a device that connects VoIP calls to a GSM voice (*not data*) network. A simple mental model for a simbox is a VoIP client whose audio inputs and outputs are connected to a mobile phone. The term "simbox" derives from the fact that the device requires one or more SIM cards to wirelessly connect to a GSM network.

There is a strong legitimate market for these devices in private enterprise telephone networks. GSM-VoIP gateways are sold to enterprises to allow them to use a cellular calling plan to terminate[2] calls originating in an office VoIP network to mobile devices. This is typically a cost saving measure because the cost of maintaining a mobile calling plan is often lower that the cost of paying termination fees to deliver the VoIP call through a VoIP PSTN provider (as well as the cost to the receiving party). *Such a setup is done with the permission of a licensed telecommunications provider and is only done for domestic calls.* This is in direct opposition to simboxers, who purchase subsidized SIM cards to deliver traffic onto a local network without paying the legally mandated tariffs.

Because there is a high demand for GSM-VoIP gateways, they span a wide range of features and number of concurrent calls supported. Some gateways support limited functionality and only a single SIM card, while others hold hundreds of cards and support many audio codecs. Some simboxes used in simbox fraud rings are actually distributed, with one device holding hundreds of cards in a "SIM server" while one or more radio interfaces connect calls using the "virtual SIM cards" from the server. This allows for simple provisioning of SIM cards, as well as the ability to rotate the cards to prevent high-use or location-based fraud detection.

3.1 How Simbox Fraud Works

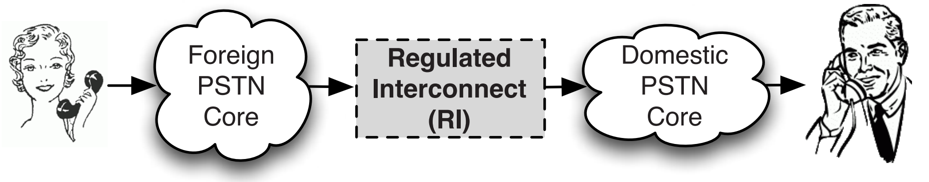
Simboxing is a lucrative attack. Because simboxers can terminate calls at local calling rates, they can significantly undercut the official rate for international calls while still making a handsome profit. In doing so, simboxers are effectively acting as an unlicensed and unregulated telecommunications carrier. Simboxers' principal costs include simbox equipment (which can represent an investment up to $200,000 US in some cases), SIM cards for local cellular networks, airtime, and an Internet connection. Successfully combating this type of fraud can be accomplished by making any of these costs prohibitively high.

Figure 1 demonstrates in greater detail how simboxing compares to typical legitimate international call termination. Figure 1 shows two international call paths: a typical path (Figure 1a) and one simbox path (Figure 1b).

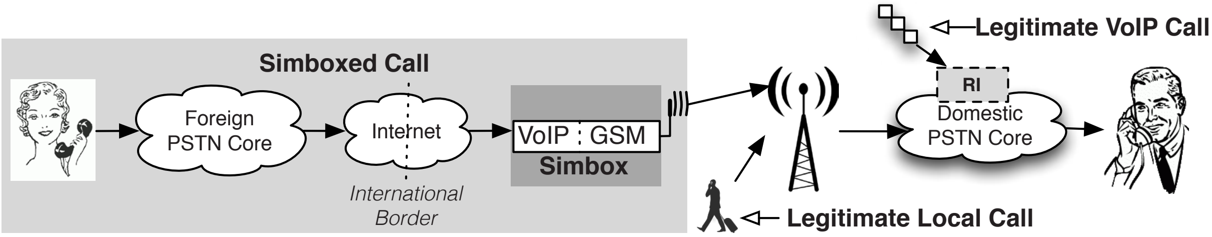
In the typical case, when Alice calls Bob, her call is routed through the telephone network in her country (labeled "Foreign PSTN Core") to an interconnect between her network and Bob's network. The call is passed through the interconnect, routed through Bob's domestic telephone network ("Domestic PSTN Core") to Bob's phone. If Alice and Bob are not in neighboring countries, there may be several interconnects and intermediate networks between Alice and Bob. The process essentially remains the same if Alice or Bob are using mobile phones. The interconnect in this scenario is crucial — interconnects are heavily regulated and monitored to ensure both call quality and billing accuracy (especially for tariffs).

In the simbox case, Alice's call is routed through her domestic telephone network, but rather than passing through a regulated interconnect, her call is routed over IP to a simbox in the destination country. The simbox then places a separate call on the cellular network in the

[2] In cellular and telephone networks, "terminating a call" has the counterintuitive meaning of "establishing a complete circuit from the caller to the callee."



(a) A typical international call is routed through a regulated interconnect. Note that VoIP calls from services such as Skype that terminate on a mobile phone also pass through this regulated interconnect and are not the target of this research.



(b) A simboxed international call (gray box) avoids the regulated interconnect by routing the call to a simbox that completes the call using the local cellular network.

Figure 1: Typical and Simboxed Calls

destination country, then routes the audio from the IP call into the cellular call, which is routed to Bob through the domestic telephone network.

In practice, simboxers execute this attack and profit in one of two ways. The most common method is for the simboxer to present themselves as a legitimate telecommunications company that offers call termination as a service to other telecom companies. As a call is routed through these intermediate networks, neither of the end users is aware that the call is being routed through a simbox. This agreement is analogous to a contract between two ISPs who have agreed to route traffic between their networks. While the end user has no knowledge of how his traffic is routed, the intermediate network owners profit from reduced prices for routed traffic.

The second method simboxers use to profit is to offer discounted call rates directly to end consumers, primarily through the sale of international calling cards. Such cards have a number that the user must dial before she can dial the recipient's number; this number will route to a number provided by a VoIP provider that points to the simbox in the recipient's country. When the user calls the number on her calling card, the simbox will answer, prompt her to dial the recipient's number, then the simbox will connect the call.

3.2 Consequences of Simbox Operation

The consequences of simboxing are significant to users who place simbox calls, users who share the cellular network with simboxers, and to cellular carriers and national governments.

As for the effects on users, Alice is likely unaware of the details of her call routing. However, Alice and Bob may both notice a degradation in quality, and Bob may notice that the Caller ID for Alice does not show her correct number. Bob may blame his local carrier for poor call quality, and so the carrier unfairly suffers in reputation.

Other users in the same cell as the simbox also suffer negative consequences. Cellular networks are provisioned to meet an expected demand of *mobile* users who only use the network a fraction of the time, and accordingly may only be able to support a few dozen simultaneous calls. When a simboxer sets up an unauthorized carrier and routes dozens of calls through a cell provisioned to support only a handful of simultaneous calls, the availability of that cell to service legitimate calls is significantly impaired. Connectivity within the cell may be further impaired by the dramatic increase in control traffic [50].

4 Methodology

Legitimate VoIP calls and other international calls enter a cellular network through a regulated interconnect or network border gateway. To halt simboxed calls, we only need to monitor incoming calls from devices containing a SIM card. Figure 1b shows the path of legitimate and simboxed audio, respectively, from the calling source to the final destination. In both cases, the tower believes it is servicing a voice call from a mobile phone. However, the audio received by the tower from a simboxed call will contain losses, indicating that the audio signal has traveled over an Internet connection, while the audio from a legitimate call will not contain these losses, having been recorded directly on the transmitting mobile phone. As discussed in Section 2, jitter and loss in Internet telephony manifest as unconcealed and concealed gaps of audio to the receiving client (the simbox, in this case). These features are *inherent* to VoIP transmission, and the only variant is the frequency of these events. All simboxed calls will have some amount of packet loss and jitter, so we design Ammit to detect these audio degradations. Because the audio transmitted *to* the mobile device could have originated from a variety of connection types, Ammit only analyzes audio received *from* mobile devices. If the mobile device is a simbox, the characteristics of this audio will exhibit the loss patters consistent with a VoIP connection, making the call distinguishable from audio recorded and sent by a mobile phone.

4.1 Inputs to Ammit

The most common codec supported by simboxes is G.711 [3] (see the Appendix for details). The G.711 codec is computationally simple, royalty-free, and serves as a least common denominator in VoIP systems. It was originally developed in 1972 for digital trunking of audio in the PSTN, and it is still the digital encoding used in PSTN core networks. The original standard indicated that G.711 should insert silence when packets are delayed or lost, so we examine G.711 using this setting.

Simboxers will have a clear incentive to configure their simboxes to evade detection, and an obvious evasion strategy is to ensure that audio is as close as possible to legitimate audio by using the GSM-FR codec for the VoIP link. Therefore, we show how Ammit accounts for this difficult case where GSM-FR is used with and without PLC. We discuss how Ammit addresses other evasion techniques in Section 5.

In summary, Ammit must detect the two audio phenomena characteristic of VoIP transmission: concealed and unconcealed packet losses. The following subsections detail how Ammit detects these phenomena, but first we briefly describe the data that Ammit receives from the tower before detecting audio features.

In GSM, audio encoded with the GSM-FR codec is transmitted between a mobile station (MS, i.e., a phone) and a base transceiver station (BTS, i.e., a cell tower) using a dedicated traffic channel. The encoding used by GSM-FR causes certain bits in a frame to be of greater importance than others. When an audio frame is transmitted, frame bits are separated by their importance. "Class 1" bits containing the most important parameters are protected by a parity check and error correcting codes, while "Class 2" bits are transmitted with no protections because bit error in these bits has only a small effect on the quality of the audio. The approach of only protecting some bits is a compromise between audio quality and the cost of the error correcting code. When Class 1 bit errors cannot be corrected, the receiver erases (i.e., drops) the entire frame. When Class 2 bits are modified, the audio is modified, but the receiver has no mechanism to detect or correct these modifications. This is termed "bit error." It should be noted that bit error and frame erasure are distinct concerns in GSM.

The receiving device (MS or BTS) may use PLC to conceal this frame erasure. When a BTS erases a frame, it conceals the loss before forwarding the audio into the core network. Visibility into frame erasures motivates our choice to place Ammit at the tower. However, there are additional benefits to locating Ammit at a tower. Specifically, this allows for scalable detection of simboxes because a single Ammit instance is only responsible for the dozens of calls that pass through the tower instead of the thousands of concurrent calls in a region or nation. Finally, if Ammit has a high confidence that a call is simboxed (as defined by a network administrator policy), ending a call at the tower is simpler than in other parts of the network. This policy would further frustrate the efforts of simboxers. It is also possible to deploy Ammit closer to the network core, perhaps at BSC or MSC nodes, but GSM loss information would need to be forwarded.

Ammit takes two inputs: a stream of GSM-encoded audio frames and a vector indicating which audio frames were erased (both of which can be collected by the BTS connecting the call). Ammit uses the frame erasure vector to ignore the effects of the air interface on the call audio. Ignoring erased frames ensures that losses on the air interfaces are not misinterpreted as losses caused by VoIP.

4.2 Detecting Unconcealed Losses

Ammit must detect two degradation types: unconcealed packet loss and concealed packet loss. To detect unconcealed loss, Ammit looks for portions of audio where the energy of the audio drops to a minimum value then

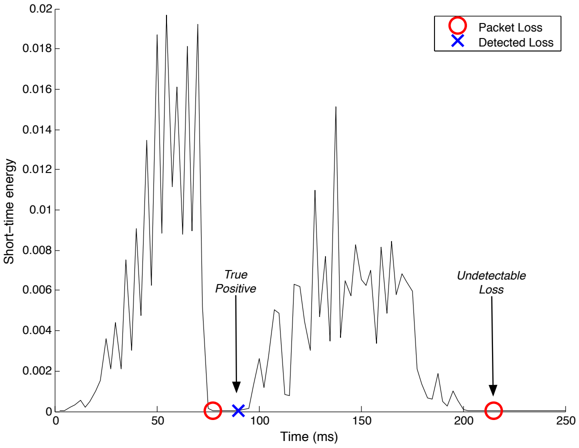


Figure 2: The short-term energy of speech during audio can reveal silence insertion. Packet loss that falls in naturally silent sections of audio is undetectable.

quickly rises again. This technique is also used in the Pindr0p system. The following discussion describes the Pindr0p approach to detecting unconcealed losses, with additional implementation insight and details.

Figure 2 demonstrates unconcealed packet loss in a clip of audio at 78 ms and 215 ms. At 78 ms, a packet is lost and silence begins. A short time later, at 90 ms, the energy rises again, indicating that a new packet has arrived containing speech. Because the time between the energy fall and rise is less than typical in speech, Ammit marks that section of audio as containing a lost packet.

While the intuition is simple, there are several challenges to using this technique to detect losses from simboxed audio. The first challenge is that many packet losses will occur during naturally silent audio — meaning that there will be no significant change in energy. This fact merely limits the amount of detectable loss events. The second challenge is that speech regularly has short pauses (causing false positives). A third challenge is that because there is no guarantee that VoIP frames are fully contained within a single GSM frame, a VoIP loss could begin in the middle of a GSM packet. Finally, uncorrected packet losses will have very low but non-zero energy because the pure silence is altered by bit errors in air transmission or by degradations within the simbox.

The first step of detecting unconcealed packet loss is to compute the energy of the audio signal. Ammit uses Short Time Energy (STE) as its measure of signal energy. Short time energy is a frequently used metric in speech analysis [38]. STE is computed by taking small windows of data and summing the squared values of the signal in the window. More formally, STE can be written as

$$E_n = \sum_{i=n-N+1}^{n} ((x(i))w(n-i))^2$$

where x is the audio signal, w is the window function, n is the frame number and N is the frame size.

Ammit computes STE using a 10ms audio frame, not the 20ms frames used in GSM-FR and many other codecs, because 10ms is the minimum frame size used by a VoIP codec, as standardized in RFC 3551 [47]. We use the standard practice of using a Hamming window half the length of the frame with a 50% overlap. Therefore, each STE measurement covers 5ms of audio and overlaps with 2.5ms of audio with the last window. This fine-grained measurement of energy ensures that Ammit can detect packet loss that begins in the middle of a GSM air frame.

With STE computed, Ammit then computes the lower envelope of the energy. In the presence of noise, the "silence" inserted in the VoIP audio will have non-zero energy. We define the lower envelope as the mean of the minimum energy found in the 10 ms frames. We also determine a tolerance around the minimum energy consisting of 50% of the lower envelope mean (this was determined experimentally).

Once Ammit has determined the lower envelope, it looks for energies that fall within the minimum envelope tolerance but then rise after a short number of energy samples. We experimentally chose 40ms as the maximum value for a sudden drop in packet energy, and our experimental results reflect the fact that this period is lower than the minimum for pauses in standard speech (which is around 50–60ms).

Because this method simply looks for silence, it is effective for both codecs we study, and it is fundamentally suited for all codecs that insert silence in the place of lost packets.

4.3 Detecting Concealed Losses in GSM-FR

Before we describe how Ammit detects GSM-FR packet loss concealment, we first describe GSM-FR PLC [24] at a high level. On the first frame erasure, the erased frame is replaced entirely by the last good frame. On each consecutive frame erasure, the previous frame is attenuated before replacing the erased frame. After 320ms (16 frames) of consecutive frame erasures, silence is inserted. Attenuation of repeated frames is motivated by the fact that while speech is stationary in the short term, longer-term prediction of audio has a high error that users perceive as unnatural.

Repeating frames wholesale has the frequency domain effect of introducing harmonics every $\frac{1}{20ms} = 50Hz$ [43]. Thus, there will be a spike in the cepstrum[3] at the 20ms

[3] A "Cepstrum" is a signal representation defined as the inverse Fourier transform of the logarithm of the Fourier transform. A rough mental model is to think of the "cepstrum" as the "Fourier transform

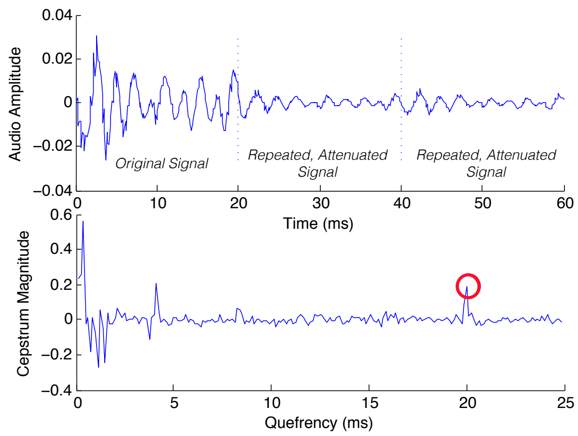

Figure 3: GSM-FR repeats and attenuates the last good frame to conceal packet loss. This results in a clear peak at 20ms in the cepstrum of the audio that can be used to detect a simboxed call.

quefrency. Because 50Hz is well below human pitch, this is a distinctive indicator of GSM packet loss. Figure 3 shows a clip of audio that has had GSM-FR packet loss concealment applied and the corresponding cepstrum. Note that the audio repeats (but is attenuated) every 20ms resulting in a peak at the cepstrum at 20ms. To detect GSM-FR PLC, Ammit computes the cepstrum of a window of three frames of audio and looks for a coefficient amplitude in the 20ms quefrency bin that is double the standard deviation of amplitudes of the other cepstral coefficients and not located in a silent frame.

4.4 Simbox Decision and SIM Detection

While concealed and unconcealed packet loss are measurable indicators of simboxing, there is a small false positive rate caused by the imperfection of our signal processing techniques. Accordingly, a single instance of a detected loss or concealed loss is not sufficient to consider a call to be originated from a simbox. Instead, we normalize the counts of loss events by the number of total frames in a call and consider a call as simboxed if the loss event percentage is much higher than the average loss event percentage for legitimate audio. We show in the following section that this approach is effective for all but the highest quality VoIP links, which provide few loss events to detect.

Even with this thresholding, some legitimate calls will occasionally be marked as a simbox. To ensure detection of simboxes with even improbably low loss rates, and to reduce the impact of false positives, we propose that the network should keep track of the number of times a call placed from a SIM is marked as a simboxed call. We term this technique “SIM detection” and show in the following sections that by using this technique we can further discriminate the legitimate subscribers from simboxers.

4.5 Efficiency of Ammit

Ammit is designed to analyze call audio in real time as it is received by the cellular tower. So, the system must be designed to function efficiently using minimal computation and network resources. To accomplish this, we avoid using costly analysis associated with machine learning or complex signal feature analysis, and instead apply simple threshold checks to processed audio signals. For each time window collected by Ammit, we apply two iterations of the Fast Fourier Transform (FFT) and a comparison operation to the distinguishing criteria noted above. The FFT is a well-known algorithm that can be run with $O(n \log n)$ complexity, and is used to analyze audio in real time for applications such as audio visualizers. We further verify empirically that these operations can be executed in real time in Section 7.

In addition, any added load on the network will cause a minimal impact on the overall throughput. While Traynor et al. [50] demonstrated that added signaling within the cellular network can cause a DDoS effect, Ammit sends only a single message to the HLR for any call flagged as a simboxed call. For this added messaging to cause an effect on the internal cellular network, a cell containing a simbox would have to simultaneously send significantly more messages than there are channels to handle cellular calls, which is not possible.

5 Threat Model and Evasion

To evade Ammit, simboxers must either compromise Ammit’s measurement abilities or successfully prevent or hide VoIP losses. While simboxers will take every economically rational action to preserve their profitability, attempting to evade Ammit will be difficult and likely expensive. This will hold true even if simboxers are aware of Ammit’s existence and detection techniques, and even if simboxers are able to place arbitrary numbers of calls to test evasion techniques. In this section, we outline basic assumptions about our adversary. We then provide details about how Ammit can be expanded to address stronger adversaries that could defeat the prototype described in this paper.

of the Fourier Transform of a signal. ”The domain of the function is termed “quefrency” and has the units of seconds

5.1 Security Assumptions

The effectiveness of Ammit relies on four reasonable assumptions to ensure that Ammit cannot be trivially evaded by simboxers. First, we assume that the Ammit system (hardware and software) is no more accessible to the attacker than any other core network system (including routing and billing mechanisms). Second, we assume that Ammit will be used to analyze all call audio so that simboxers cannot evade a known evaluation period. We show in Section 7.4 that Ammit can efficiently analyze calls. Third, we assume that Ammit will report measurements to a single location (like the HLR) so that simboxers cannot evade Ammit by frequently changing towers. Finally, we recommend that Ammit be widely deployed throughout a carrier's infrastructure because a wider deployment will provide fewer places for simboxes to operate.

5.2 Evasion

If the simboxer cannot avoid Ammit analysis, he must hide or prevent VoIP packet loss and jitter. Hiding packet loss and jitter was the very goal of over two decades of intense academic and industrial research that has so far only provided good *but algorithmically detectable* solutions, including jitter buffering and loss concealment.

Extreme jitter buffering VoIP clients (including simboxes) routinely use short audio buffers to prevent low levels of jitter from causing delays in playback. Simboxers could set the jitter buffer to a large value (say, several seconds of audio) to prevent jitter from causing noticeable audio artifacts. However, this would be intrusive to users, and Ammit could still detect true losses as well as the added false starts and double talk. While we leave the testing of this approach to future work, we briefly describe how high jitter buffers could be detected by measuring the incidence of double talk. Double talk is the phenomenon where, after a lull in conversation, two users begin to talk (apparently) simultaneously. Because double talk increases with audio latency, increased double talk will be indicative of increased latency. Because an increased jitter buffer (combined with the already high call latency from an international call) will lead to higher than "normal" latency, detecting anomalous double talk will help in detecting simboxing. Detecting double talk is an important task in equipment quality testing, and ITU-T standard P.502 provides an off-the-shelf method for measuring it. Feasibility and appropriate thresholds can be determined using call data through simboxes and from legitimate subscribers. While such data is unavailable to outside researchers (including the authors of this paper), it is available to the carriers who would be fielding such a system.

Alternative PLC approaches Ammit looks for brief silences as one signal of VoIP loss, so simboxers could replace silence with noise or other audio. This is a well known form of Packet Loss Concealment. In general, PLC algorithms (like the GSM-FR PLC) fall into three categories: insertion, interpolation, and regeneration [44]. Although there are a number of algorithms in each category, the majority are published (and those that are not are often similar to those that are). All will have some artifacts that can lead to detection, and because the Pindr0p project has developed techniques to identify other codecs[25], we leave detecting other PLCs as future engineering work not essential to confirming our hypothesis that audio features can identify simboxes.

Improved link quality In addition to jitter and loss concealment, simboxers could reduce losses and jitter with high-quality network links or a redundant transmission scheme, but there are several barriers to this. First, finding a reliable provider may not be possible given the low connectivity conditions in simboxing nations. If a provider is available, the costs will likely be prohibitive. For example, in Kenya one can expect to pay $200,000 US *per month* for a high-quality 1 Gbps link[40]. This connection also guarantees little beyond the first routing hop. Beyond the costs, having a better quality connection than many universities and businesses may raise undesirable scrutiny and attention to the simboxers. Even if a high-quality link is available, it would not remove degradations from the call that occur before the call arrives at the entry point to the simbox.

Garbled frame transmission Finally, Simboxers could evade Ammit detection by failing to transmit valid GSM air frames when an IP frame is lost. In effect, Ammit would believe that all VoIP losses were air losses and would not detect VoIP losses. Ammit could detect this evasion by noting anomalous air loss patterns.

Currently, conducting a simboxing operation requires the technical sophistication of systems administrator. This evasion technique will require significant engineering resources (with expertise in embedded system design, implementation, and production) because GSM modems are typically sold as packages that accept an audio stream and high-level control commands (e.g. "place a call" or "send an SMS"). These tightly integrated chips are not capable of sending damaged packets on command. While the Osmocom baseband project [20] could provide a start for a custom radio, Osmocom targets inexpensive (though relatively rare) feature phone variants and would not be a turnkey GSM baseband for a custom simbox[4]. Finally, even if the simboxers develop such a modem, they would have to conceal all detectable artifacts from both the final VoIP step as well as any intermediate networks (like a caller's mobile network). For these reasons, this strategy would only be effective for the most motivated and very well-funded simboxers.

However, in the event that simboxers do pursue this strategy, we propose the following methodology to detect such an attack. Given the considerable difficulty in developing the attack as well as constructing a suitable test environment, we leave testing this detection methodology to future work. We hypothesize that this a garbled packet evasion strategy can be detected from anomalous air interface loss patterns because simboxed calls will see the "typical" amount of loss *plus* the loss created by the simboxer. Loss patterns may be anomalous for improbable amounts of loss, or for improbably bursty sequences of lost frames. These anomalies could be determined on a tower-by-tower basis to take into account local transmission conditions (like a tunnel affecting signal quality). Because mobile stations (i.e. phones) do not know which frames are erased when they arrive at the tower, simboxers will not be able to tune their loss rate to be within the bounds used by this strategy.

6 Experimental Setup

In this section, we describe how we characterize Ammit through the use of simulation and test its effectiveness against a real simbox.

We simulate simboxed calls by taking a corpus of recorded audio and passing them first through a VoIP simulator then through a GSM air simulator (again, we use the term "air" to distinguish GSM cellular transmission). The GSM air simulator provides Ammit with both audio and a vector of GSM frame errors. To simulate legitimate calls, we pass the audio corpus through the air simulator only. We motivate the use of simulation in Section 6.6.

We test Ammit against three simbox codec choices: G.711 with no packet loss concealment and GSM-FR with and without packet loss concealment (we discussed this choice in Section 4. We evaluate single simbox call detection and SIM detection at 1%, 2%, and 5% loss rates (we justify this choice later in this section).

6.1 Speech corpus

The source of voice data for our experiments was the TIMIT Acoustic-Phonetic Continuous Speech corpus [33]. This is a *de facto* standard dataset for call audio testing. The TIMIT corpus consists of recordings of audio of 630 English speakers from 8 distinct regions each reading 10 "phonetically rich" standard sentences [5]. The recordings are 16kHz 16-bit signed Pulse Code Modulation (PCM), which are downsampled to 8kHz to conform to telephone quality. For the single call detection tests, we concatenate the 10 sentences for each of the 462 speakers into 1 call per speaker, creating a dataset of 462 calls [6]. Each call is approximately 30 seconds in length. The SIM detection test requires a larger call corpus, so for 98 randomly selected speakers we generate 20 calls for each speaker using permutations of the 10 sentences for each speaker (for a total of 1960 calls). Calls consist of only one speaker because Ammit analyzes each direction of the call separately.

6.2 VoIP Degradation and Loss

VoIP simulation takes TIMIT call audio as input and outputs audio that has been degraded by VoIP transmission. The simulator must convert the input audio from its original format (PCM) to the VoIP codec simulated (GSM or G.711), simulate loss, implement packet loss concealment in the case of GSM-FR, and output the final degraded audio. We examine these steps in greater detail in this subsection.

Audio conversions: The input audio files, encoded using PCM, must either be converted to G.711 or GSM-FR. We use the widely-used open source utility `sox` [8] for all codec transitions throughout the Ammit testing infrastructure. Note that these codec transitions are standard practice throughout PSTN and VoIP networks.

Packet Loss Modeling: We model Internet losses with the widely-used [39] Gilbert-Elliot packet loss model [34]. The Gilbert-Elliot model is a 2-state Markov model that models packet losses with bursty tendencies. A given channel can be in either a "good" state or a "bad" state. If the channel is in the "bad" state, packets are dropped. The Gilbert-Elliot model can be described with two parameters: p, the likelihood that the channel enters the "bad" state, and r, the likelihood that the channel leaves the bad state. p controls the frequency of loss events while r controls how long bursts last. We parameterize the model such that p is the target loss rate (for these experiments, 1%,2%, and 5%) and $r = 1 - p$. This means that the higher the loss rate, the greater the tendency of losses to be bursty.

Although jitter is a source of audio artifacts, we do not model jitter explicitly. Instead, because the audio symp-

[4] We pursued this line of research ourselves before finally purchasing a commercial simbox

[5] N.B. We use a subset of 462 male and female speakers from all 8 regions

[6] We set aside 12 of these calls as a training set to develop and verify our algorithms and set detection thresholds. These calls were not used for testing.

toms of jitter and packet loss are the same (i.e., audio is not present when needed), we simply consider jitter as a special case of packet loss, as is done by Jiang and Schulzrinne [39].

Loss Rate Justification: The reader may note that we are modeling loss rates that are considered high for Internet loss. Our model is justified for several reasons. The first consideration is that the typical Internet connection conditions in simboxing countries are of much lower quality than what most of Europe, East Asia, or even North America experiences [40, 51], with loss rates *often exceeding 10%*. Second, because conditions can vary from hour to hour or even moment to moment, examining performance at higher loss rates than typical is justified [39].

G.711 processing: To implement VoIP loss in G.711 audio, we use a packet loss simulation tool from the G.711 reference implementation available in the ITU Software Tools Library [7]. This tool implements concealed and unconcealed loss on 16-bit 8kHz PCM audio. We use `sox` to encode our input files to G.711 and back to 16-bit PCM before processing by the tool. This step is required because G.711 is a lossy codec, and the act of encoding and decoding irreversibly changes the audio. The tool takes a frame error vector as input, allowing us to use the Gilbert-Elliot Model described above.

GSM-FR processing: We developed our own GSM-FR VoIP loss simulator in Matlab. All audio processing in this tool is done on GSM-FR encoded audio. The tool implements the previously discussed packet loss model, the GSM-FR PLC as defined in 3GPP Standard 46.011 [24], and unconcealed packet loss by inserting GSM-FR silent frames.

6.3 GSM Air Loss

As we discussed in Section 6.6, we simulate simbox calls out of necessity. To simulate GSM cellular transmission (i.e., "air loss") we modify a GSM Traffic Channel simulation model for Simulink [41]. This model takes frames of GSM-encoded audio and encodes them as transmission frames for transmission over a GSM traffic channel as specified in 3GPP Standard 45.003 [21]. The transmission encoding includes interleaving as well as the error correcting codes and parity checks applied to Class 1 bits (as discussed in Section 4).

The model then simulates the modulation and transmission of the encoded frame using GMSK (Gaussian Minimum Shift Keying) in the presence of Gaussian white noise in the RF channel. This white noise is the source of random transmission errors in the model.

The model then demodulates the transmitted channel frame, evaluates the error correcting codes, and computes the parity check to determine if the frame is erased or not. Finally, the model outputs the received audio and a vector indicating which frames were erased.

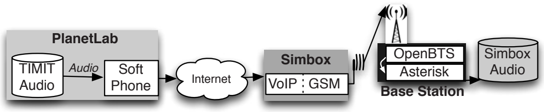

Figure 4: Our detection mechanisms are run against a real simbox deployment (Hybertone GoIP-1) communicating to a modified Range Networks OpenBTS base station.

The channel model signal-to-noise ratio is tuned to produce a frame erasure rate (FER) of 3% at the receiver, which is considered nominal according to 3GPP Standard 45.005 [22].

6.4 Simboxing SIM Detection Test

Our SIM detection mechanism is tailored to reduce the effect of a single false positive or false negative call judgment by examining multiple calls.

To measure the effectiveness of this mechanism, we use 20 audio files from 98 unique speakers (for a total of 1960 calls) to simulate legitimate and simboxed calls using our GSM and VoIP simulators. We examine legitimate calls as well as simboxes covering all three codecs (GSM-FR, GSM-FR with PLC, and G.711) at 1%, 2%, and 5% loss rates. We model individual SIM cards as groups of 20 calls. For legitimate SIM cards, all calls from a particular speaker are assigned to a single SIM card, while simbox SIM cards consist of groups of randomly selected calls. This models the fact that simbox SIMs will rarely be used to provide service for the same user twice.

We analyzed all legitimate and simboxed calls with Ammit, then computed the percentage of calls in each SIM card group that were marked as simboxed. We consider a SIM to be used in a simbox if at least 25% of the calls it makes are marked as simboxed by Ammit call analysis.

6.5 Real Simbox Tests

We collect audio traces from calls made through a real simbox to validate our simulation experiments.

Figure 4 shows a schematic diagram of our experimental setup. We use 100 randomly selected audio files from the single call detection corpus (discussed in Section 6.1) to model the original call source. The call path begins at a PJSIP soft phone at a PlanetLab node located in Thai-

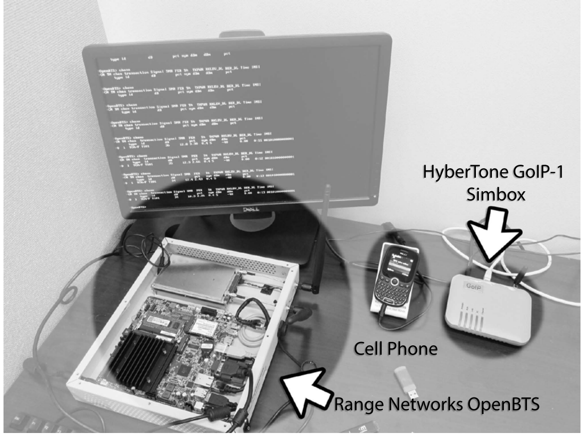

Figure 5: Our simbox experimental apparatus, including our OpenBTS GSM base station, mobile phone to model legitimate calls, and our GoIP-1 simbox.

land, a country with major simboxing problems [46][7]. This step emulates the arrival of a call to a simboxer.

The call originates from a soft phone and is routed through an Asterisk PBX[8] (not shown in the figure) to our Hybertone GoIP-1 simbox in the United States. Hybertone simboxes offer useful features to simboxing, including the ability to automatically change the IMEI number broadcast to evade filtering and detection systems like those presented in prior work [42]. Hybertone products have been advertised for sale specifically for simboxing [2], and entrepreneurs even sell value-added management consoles specifically for simboxers [1]. While the GoIP-1 supports several incoming codecs, it does not disclose which PLC algorithm it uses. We have determined experimentally that it is using a variant of the GSM-FR PLC.

The simbox delivers the call to a cellular base station under our control. Our base station is a Range Networks Professional Development Kit running the OpenBTS 5.0 open-source base station software and Asterisk 11.7. This base station is a low-power research femtocell and allows us to record call audio digitally as the base station receives it – including frame erasure information. To determine false positives, we create control calls by playing the same 100 randomly-selected audio files into a BLU Samba Jr. Plus feature phone and capturing the call audio at the base station. Figure 4 shows our base station and simbox experimental apparatus.

6.6 Technical Considerations

Our experimental setup uses both simulation and real simbox data we collect ourselves for several reasons. First, simulations provide the best way to examine the effects of codec choice, packet loss concealment, and loss rates reproducibly and accurately. Second, they allow us to build generic models of simboxes so that our detection mechanism is not tied to any particular simbox model. Third, because we use tools and models that are extensively studied, verified, and frequently used throughout the literature [25, 52, 34, 39, 7, 41], we can have confidence that our results are correct. We supplement our simulations with data collected through a commonly used simbox to support and confirm our simulation results.

The reader will note that our real simbox calls were originated in a simboxing country, not terminated there. While simboxing is a global problem [42], we wanted to focus on areas where the problem is endemic and has a substantial impact. However, logistical, economic, and legal considerations prevented us from placing our simbox and research base station abroad. Instead, we capture the exact loss and jitter characteristics of the Internet connections in a simboxing country by originating the call there while terminating the call in our lab.

Legal and privacy concerns prevent us from receiving simbox audio from mobile operators (since the audio would be from callers who could not give their consent for such use). However, we note that there are no additional privacy concerns created when an operator deploys Ammit in a real network. Operators regularly use automated techniques to monitor call quality of ongoing conversations, and Ammit does no analysis that could be used to identify either the speakers or the semantic content of the call.

Finally, we note that the use of TIMIT audio is extremely conservative; it presumes pristine audio quality before the call transits an IP link. In fact, there will be detectable degradations from the PSTN even before the VoIP transmission. Chief among these will be GSM-FR PLC applied if Alice calls from a mobile phone. Because mobile phones regularly see high loss rates[9], simboxers carrying mobile-originated traffic will be even more vulnerable to detection by Ammit than this methodology reflects.

7 Detection Results

This section demonstrates how Ammit detects simbox fraud. We first discussed Ammit's effectiveness at identifying a real simbox, followed by a discussion of the

[7] Note that Thailand is the only major simboxing country with functional PlanetLab node at the time of writing

[8] A Private Branch Exchange (PBX) is a telephony switch analogous to an intelligent router in the Internet

[9] Recall from 3GPP standard 45.005 [22] that 3% loss is considered nominal

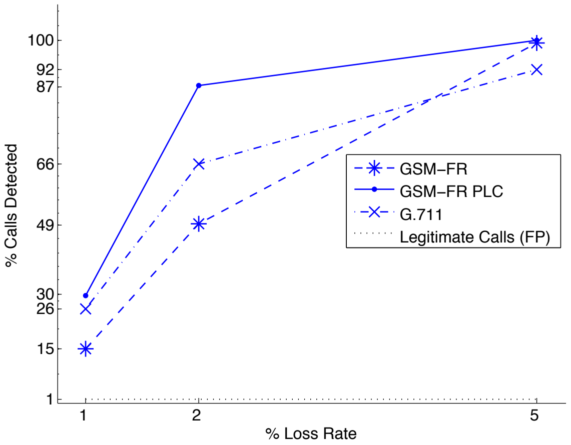

Figure 6: Ammit detection depends on the loss rate and Simbox codec used. For a 2% loss rate, Ammit detects over 55% of simboxed calls with less than a 1% false positive rate. This performance makes SIM detection (shown in Fig. 7) very reliable.

results of detecting simulated simboxed calls. We then examine how Ammit can be used to identify SIM cards used in simboxing fraud. Finally, we show that Ammit is fast enough to be effective in real networks.

7.1 Simulated Call Analysis

In this subsection, we evaluate Ammit's ability to detect individual simboxed calls and SIM cards used in simboxing.

Figure 6 presents the percentage of simboxed calls detected for three simbox types at three different loss rates. At the still plausible 5% loss rate, Ammit detects from 87% to 100% of simboxed calls. Lower detection rates for low loss rates are simply a result of fewer loss events for Ammit to detect. However, in the case of no packet loss concealment, Ammit still detects from 15–66% of the simboxed calls for 1 and 2% loss. As discussed in the previous section, these loss rates include the effect of jitter, so loss rates as low as 1% and 2% are unlikely to be encountered often in practice [40, 51].

Third, the lowest dotted line in Figure 6 shows the low (but non-zero) detection rate for the control group of simulated legitimate calls — less than 1% (0.87% to be exact).

Figure 7 shows the percentage of simbox SIM cards that can be automatically disabled at the threshold of 25% of calls. For a 5% loss rate, our policy can identify *100%* of SIM cards used in simboxes. For calls using GSM-FR with packet loss concealment our policy can also detect 100% of SIM cards. As the loss rates decrease, we identify fewer SIM cards for codecs without packet concealment. In the case of 2% loss, we identify 96% and 100% of SIMs used in GSM-FR and G.711 simboxes, respectively. In the case of 1% loss, we still identify 43% of G.711 SIMs and 28% of GSM-FR SIMs. Our threshold results in a false positive rate of 1% and was determined experimentally from a ROC curve (omitted for space reasons). To counter the effects of false positives, the operator could implement a simple policy step allowing users to reactivate canceled SIM after some verification. One possibility is requiring flagged users to verify the National ID numbers used to register the SIM card over the phone or in person at a sales agent.

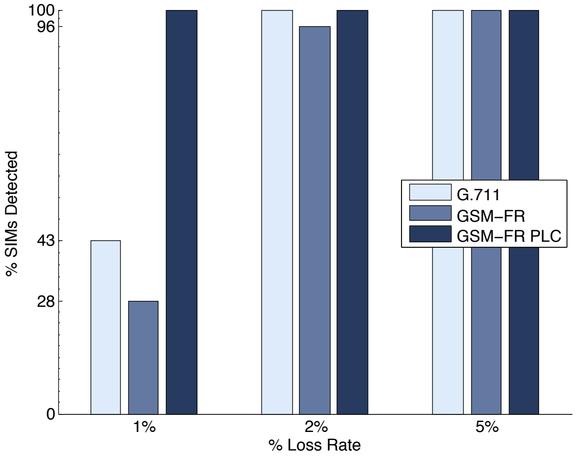

Figure 7: Even with unusually high-quality network connections, Ammit can be used to identify SIM cards used for simboxing.

7.2 Detection of Real Simboxes

We begin with the most important result that Ammit is effective at detecting real simboxes. We find Ammit can detect 87% of real simboxed calls with *zero* false positives on the call set. These figures are the result of running our GSM-FR packet loss concealment after tuning on simulated individual call data; improved detection may be possible at a cost of a low false positive rate. While simulations produce useful insights about Ammit's performance in a wide range of conditions, these results confirm our hypothesis that call audio can be used to effectively combat simbox fraud.

7.3 Discussion

We make three observations from the individual call simulations. First, the results show a clear relationship between the loss rate of a call and Ammit's ability to detect a call. Second, Figure 6 shows the counterintuitive result that using GSM-FR packet loss concealment makes calls

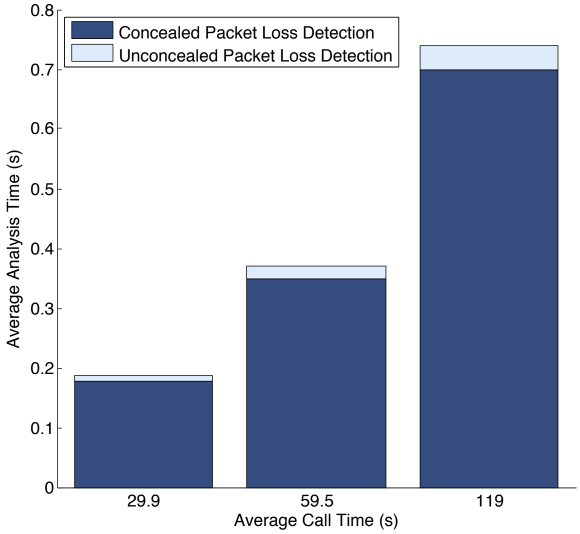

Figure 8: Ammit analyzes audio much faster than real time and is efficient enough to deploy in cell towers.

easier to detect. Even at a 1% loss rate, Ammit detects 30% of simboxed calls using GSM-FR PLC. Ammit is so effective at detecting concealed packet loss events because the GSM-FR PLC cepstral peak is distinctive and rare in speech. The corollary to this finding is that simboxers will have an incentive to disable packet loss concealment. This will noticeably impair call quality and user acceptability. Third, the non-zero false positive rate means that discretion will be required when Ammit indicates a positive simbox call.

Our SIM detection results show that Ammit can be used not only to detect single calls but as a larger initiative against simboxing. At 2% and 5% loss, we can detect and disable a single SIM card after at most 20 calls. Even at 1% loss, we can still detect and disable many SIM cards. Given that SIM cards come at a nontrivial cost (either at a legitimate point of sale or on a black market), by reducing the lifetime of a SIM card we make simboxers unable to operate.

Finally, we make two observations from the real simbox results. First, we note that our simulations were effective for tuning Ammit before applying real data. This validates our methodological strategy. Second, our simulation false positive rates were conservatively high; while we saw 1% false positives on our simulated data, we saw no false positives on our actual data.

7.4 Ammit Performance

To show that Ammit is scalable and performant, we examine the amount of time Ammit requires to analyze a call for concealed and unconcealed packet losses. Although in the previous subsections we analyzed Ammit's performance for 30 second calls, we hypothesize that longer analyses would lead to even better results, especially for lower loss rate calls. We tested Ammit's performance on a set of 10 calls of approximately 30s, 60s, and 120s; we present the averages of 10 analyses of each call in Figure 8.

We test Ammit on a late 2011 iMac with a quadcore 3.4 GHz Intel Core i7, 16GB RAM, and a 1TB solid state disk running OS X 10.9. Although this is capable hardware, the detection is done entirely with Matlab in a single thread, and the detection code is correct but far from optimal. Optimizing the Matlab code for efficiency would likely reduce analysis time. Beyond that, implementing Ammit in a more performant language like C could reduce analysis time further. For a commercial implementation, code customized for a digital signal processor could further improve performance. Ammit may be deployed directly as a BTS or BSC software update or as inexpensive standalone hardware.

As Figure 8 shows, the majority of analysis time is spent detecting concealed packet loss. Nevertheless, calls can be analyzed 150 times faster than real time, indicating that a single thread of execution could analyze approximately 150 calls per unit time. Even our unoptimized code would be able to analyze all traffic at a tower in real time.

8 Related work

Although this work is concerned with detecting simbox fraud, the techniques used belong to the long tradition of non-intrusive call quality measurement. Non-intrusive measurements are taken passively and without a reference audio; this is in opposition to intrusive measurements [4, 6] which measure the degradation of a known reference signal. Traditional call quality metrics measure listener experience, and imperceptible degradations do not significantly affect these scores. These scores have been shown to vary widely based on random conditions, language choice [48] or VoIP client [26]. The most widely used non-intrusive measurement standard is ITU specification P.563 [5], but other metrics have been developed for holistic quality measurements [32, 37, 30] and for individual artifacts like robotization [43] and temporal clipping [36]. Because call quality metrics like P.563 are only concerned with perceptible degradation and vary widely in results, they are unsuitable for detection of simbox fraud.

Telephony fraud detection is a well-studied problem, and efforts to fight telecommunications fraud have primarily depended on call records. Machine learning and data mining have been used extensively to detect fraudulent activity using call records [27, 29, 35, 45].

Given the importance of the simboxing problem in affected countries, there are a number of commercial simbox detection products, as well as two published research papers [31, 42]. Most simbox detection systems use one of two techniques: test call generation and call record analysis. A few products use hybrid techniques [14, 17]. Test call generation approaches [10, 13, 15, 16, 18] use probes widely deployed in many networks to verify that the CLI (i.e. Caller-ID) records on calls are correct — if a simbox is used, the CLI record would indicate the MSISDN (i.e. the phone number) of the SIM card routing the call and not the originating probe. Test call methods only work for certain kinds of simboxing (when a simboxer sells services to another telecom, not through the common case of selling calling cards to consumers). By contrast, call record analysis detect all types of simboxing. Those approaches rely on the fact that SIMs used in simboxes have usage patterns distinct from legitimate customers [31, 9, 11, 12, 19]. These techniques are prone to false positives and active evasion by simboxers. In recent work, Murynets et al. published a call record analysis approach that used machine learning to identify IMEIs (device identifiers) used by simboxes [42]. The authors' published accuracy rates measure identifying individual calls (not simbox devices) only after simboxes are identified, and thus are not directly comparable to the accuracy figures for Ammit. Additionally, that work identifies IMEIs (which are an asserted — and thus spoofable — identifier) of devices only after a simbox makes dozens or hundreds of calls with a single SIM card; even if the work described in that paper is deployed, simboxing will continue to be profitable. Our work is an improvement over the state of the art because we can reliably detect simboxed calls using features inherent to simboxing *at the time of the call*, thus making simboxing unprofitable.

While Ammit is the first system to combat simboxing using call audio, our system is a refinement of the ideas used in the Pindr0p system developed by Balasubramanian et al˙ [25].

The Pindr0p system combats telephony fraud by identifying callers using audio "fingerprints." These fingerprints consist of noise characteristics and indicators of different codecs used by the different PSTN and VoIP networks that route a call. For Pindr0p, capturing characteristics of end-to-end call path is essential to identify repeat callers. For Ammit, it is sufficient to hear audio that has been degraded by any prior network.

Ammit's techniques are tailored to better combat simboxing in several important ways.

First, for simbox detection, Pindr0p's greatest weakness is that it is designed to identify codec transitions. Accordingly, Pindr0p would fail to detect a simbox call that uses a single codec (i.e. the GSM codec) end to end. If Pindr0p were employed to combat simboxing, simbox operators would simply migrate to single-codec solutions. Accordingly, Ammit will detect simboxed calls that Pindr0p would fail to detect. In fact, by using loss information from the tower (and not endpoint audio) Ammit excels at this case better than any other tested.

Second, we showed that Pindr0p techniques used on individual calls may result in unacceptable false positives. This was especially true for the silence insertion detection methods proposed in that work. For Pindr0p, a classification error may prompt a call center worker to request additional authentication. For Ammit, a classification error will prompt a dropped call or suspended account — a much higher burden to the user. Ammit enhances Pindr0p by developing and verifying a SIM detection method that reduces false positives and increases confidence in classification.

Third, Pindr0p was designed to quickly fingerprint audio based on a short segment using a large number of features fed to a machine learning classifier. While we were unable to obtain access to Pindr0p for a direct comparison, we *do* show in this work that Ammit's techniques will enable real-time processing of all call audio at mobile network base stations.

9 Conclusions

Cellular networks in developing nations rely on tariffs collected at regulated interconnects in order to subsidize the cost of their deployment and operation. These charges can result in significant expense to foreign callers and create incentive for such callers to find less expensive, albeit unlawful, means of terminating their calls. Simboxes enable such interconnect bypass fraud by tunneling traffic from a VoIP connection into a provider network without proper authorization. In this paper, we develop the Ammit tool, which allows us to detect simboxes based on measurable differences between true GSM and tunneled VoIP audio. Ammit uses fast signal processing techniques to identify whether individual calls are likely made by a simbox and then to develop profiles of SIM cards. This approach allows a provider to deactivate the associated SIMs rapidly, and virtually eliminates the economic incentive to conduct such fraud. In so doing, we demonstrate that the subsidized rates that allow much of the developing world to be connected can be protected against the impact of this fraud.

10 Acknowledgments

The authors are grateful for the help of our shepherd, Srdjan Capkun, and for comments from our anonymous reviewers. Michael Good was instrumental in early work on this project that was not published in this paper, and conversations with Charles Lever were especially helpful to work out the kinks.

Abstract

Air-gapped networks are isolated, separated both logically and physically from public networks. Although the feasibility of invading such systems has been demonstrated in recent years, exfiltration of data from air-gapped networks is still a challenging task. In this paper we present *GSMem*, a malware that can exfiltrate data through an air-gap over cellular frequencies. Rogue software on an infected target computer modulates and transmits electromagnetic signals at cellular frequencies by invoking specific memory-related instructions and utilizing the multi-channel memory architecture to amplify the transmission. Furthermore, we show that the transmitted signals can be received and demodulated by a rootkit placed in the baseband firmware of a nearby cellular phone. We present crucial design issues such as signal generation and reception, data modulation, and transmission detection. We implement a prototype of GSMem consisting of a transmitter and a receiver and evaluate its performance and limitations. Our current results demonstrate its efficacy and feasibility, achieving an effective transmission distance of 1 - 5.5 meters with a standard mobile phone. When using a dedicated, yet affordable hardware receiver, the effective distance reached over 30 meters.

1. Introduction

Security-aware organizations take various steps to prevent possible theft or leakage of sensitive information. The computers responsible for storing and processing sensitive information often operate on air-gapped networks. These networks are physically disconnected from non-essential networks, primarily those in the public domain. With the growing awareness of negligent or malicious insiders compromising air-gapped networks, as evidenced in several incidents [1] [2], some organizations have begun to restrict USB access, to prevent malware infection or data leakage via USB thumb-drives [3].

Acknowledging the security risks of mobile phones equipped with cameras, Wi-Fi, or Bluetooth, some organizations has restricted their use, forbidding them in classified areas. For instance, an Intel Corporation best-practices document [4] asserts: "*Currently, manufacturing employees can use only basic corporate-owned cell phones with voice and text messaging features. These phones have no camera, video, or Wi-Fi.*" In another case, visitors at one of Lockheed-Martin’s facilities [5] are instructed as follows: "*Because ATL is a secure facility, the following items are not allowed to our floor of the building: cameras (film, video, digital), imaging equipment, tape recorders, sound recording devices. Cell phones are allowed, but camera/recording features may not be used*." Similar regulations are likely to be found in many other security-aware organizations. Clearly, the issue of information leakage associated with basic cellular phones or a phone without a camera, Wi-Fi and the like, has been overlooked in cases in which such phones are allowed in the vicinity of air-gapped computers. However, modern computers are electronic devices and are bound to emit some electromagnetic radiation (EMR) at various wavelengths and strengths. Furthermore, cellular phones are agile receivers of EMR signals. Combined, these two factors create an invitation for attackers seeking to exfiltrate data over a covert channel.

In this paper, we present an adversarial attack model in which any basic desktop computer can covertly transmit data to a nearby mobile phone. Transmission is accomplished by invoking specific memory-related CPU instructions that produce baseband compliant EMR at GSM, UMTS, and LTE frequencies. By using the functionality of multi-channel memory architecture, the signals are amplified and transmitted with increased power. These signals are received and decoded by a rootkit installed at the baseband of a standard mobile phone. To demonstrate the feasibility of the attack model, we developed *GSMem*, a bifurcated malware that consists of a transmitter that operates on a desktop computer and a receiver that runs on a GSM mobile phone. We implemented communication protocols for data modulation and channel reliability and provide extensive experimental results.

As will be explained later, the proposed method is applicable with GSM, UMTS, and LTE basebands. In this paper we focus on a prototype using a GSM mobile phone as receiver, hence the codename, *GSMem*.

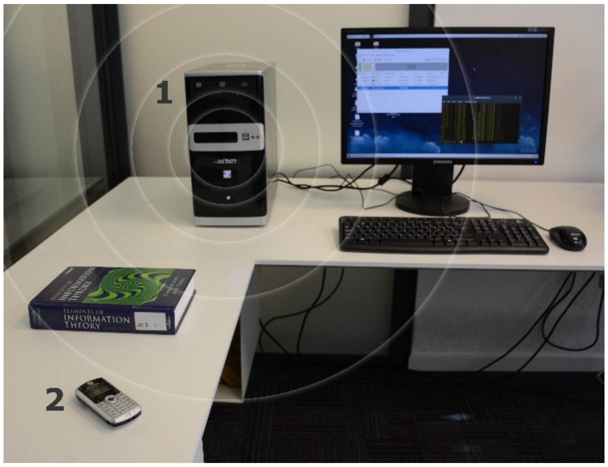

Figure 1: Demonstration of the covert channel in a working environment. Signals at GSM frequencies are emitted from the workstation and received by the nearby compromised mobile phone.

Figure 1 demonstrates the covert channel in a typical real-life scenario, in which rogue software on a computer (1) modulates sensitive information and transmits it over GSM cellular frequencies. The transmissions take place while the computer is at work, without affecting the user experience. A baseband level rootkit on the cellular phone (2) receives the signals and demodulates them, converting them into meaningful information. Note that the components exploited by the proposed model are present on virtually all computers and cellular devices, even on low-end cellular devices which are often allowed into classified environments.

1.1. The Closed Nature of the Baseband Industry

The baseband chip of a cellular device manages the low-level Radio Frequency (RF) connection with the cellular network, thereby making it an indispensable component. The baseband processor runs a real time operating system (RTOS), stored in its firmware. The code is closed to the public, and only the device manufacturer can access the baseband chip's functionality through a limited interface [6]. The RTOS source code, along with the protocol stack and other implementation details, are well-guarded trade secrets, kept off-limits by the protective baseband industry, which is led by a handful of high-ranking players that dominate the market [7]. Lacking access to this information, including documentation and implementation details, independent software vendors cannot intelligently develop new products and interfacing technologies for baseband chips.

It can be argued that the current state of affairs promotes "security through obscurity" by masking the internal workings of the baseband systems. However, this policy has only limited effectiveness. Skilled hackers working on behalf of advanced persistent attackers eventually manage to exploit baseband systems—obscure and isolated though they may be. Baseband exploitation and attacks are thoroughly discussed by Weinmann [8] [9] [10]. Welte and Markgraf [6] also point out several security problems associated with current commercial baseband technology and practices.

1.2. Paper Contributions

While emission security (EMSEC) in itself is not a new concept [11], this paper offers the following original contributions: (1) a novel method for transmitting signals at cellular frequency bands from an ordinary desktop computer, using multi-channel memory related CPU instructions without any special or additional hardware, and (2) a novel method for receiving and demodulating EMR signals using a rootkit in the baseband firmware of a mobile phone, thus turning virtually any mobile phone into an effective EMR eavesdropping device without the use of specialized equipment. We believe the proposed adversarial attack model constitutes a new security threat that security experts should be aware of.

While the bulk of this paper focuses on the mobile phone as a receiver, we also evaluate an alternative communication method in which the transmitter uses memory-related CPU instructions to emit EMR, and the receiver uses software defined radio (SDR) with dedicated, yet affordable hardware. This allows us to study the capabilities and boundaries of the transmission method on a wider scale.

The remainder of this paper is organized as follows: In Section 2 we present assorted related works, along with a concise review of our contributions. Next, in Section 3, we present the adversarial attack model. In Section 4 we present the essential technical background. Section 5 provides a detailed description of the transmitter, followed by Section 6 which describes the receiver. In Section 7 we evaluate GSMem and present the results. Next, in Section 8, we discuss possible defensive countermeasures. Finally, we conclude in Section 9.

2. Related Work

EMSEC, reviewed by Anderson [11], addresses attacks which use compromised emanations of either conducted or radiated electromagnetic signals. Concern about this issue dates back to World War I, but for decades it was relegated solely to governmental and military agencies [12]. However in 1985, van Eck [13] showed how the so-called TEMPEST exploits can be conducted using affordable equipment. He managed to reconstruct an image from electromagnetic signals produced by a video card at a considerable distance, using a modified TV set. Around 2000, Kuhn and Anderson released several publications related to TEMPEST [14] [15], demonstrating that EMR emissions originating from a desktop computer can be manipulated by appropriate software, in either a defensive or offensive manner. Public interest in EMSEC and TEMPEST was amplified by web publications, offering a glimpse into classified TEMPEST-related official standards [16], or providing 'do it yourself' tutorials related to TEMPEST exploits. Thiele [17] provides an open source program dubbed "TEMPEST for Eliza", utilizing the computer CRT monitor to modulate and transmit radio signals at AM frequencies.

Note that side-channels have a variety of possible uses, beyond intentional exfiltration of information as described in this paper. Side-channels may be used for eavesdropping, attacking sophisticated encryption methods, defensive detection of hidden malicious activities, and other uses. Furthermore, side-channels are not limited to electromagnetic radiation (EMR). Clark, Ransford et al [18] refer to power consumption as a side-channel that can reveal hidden information or activities. They present 'WattsUpDoc', a system that detects the presence of malware on medical embedded devices by measuring their power consumption. Rührmair et al [19] discuss the use of power and timing side-channels to attack physical unclonable functions (PUFs). Other researchers investigating side-channels go beyond EMR emanations. Halevy and Saxena [20], explore acoustical eavesdropping, focusing on keyboard acoustical emanations. Hanspach and Goetz [21] present so-called "covert acoustical networks". Their method is based on near-ultrasonic waves, transmitted by the speaker of one laptop computer and received by the microphone of a nearby laptop computer. Callan et al [22] provide a method for measuring the so-called "signal available to the attacker" (SAVAT), with a side-channel based on instruction-level events. Their method is based on the EMR emitted by rather generic CPU/memory operations. The receiver, however, comprises expensive dedicated equipment, and the range of explored distances is quite limited. Guri et al [23] present AirHopper, a bifurcated malware in which the transmitter exploits the EMR emanated by the VGA cable. The receiver is an FM-enabled standard cellular phone.

2.1 Comparison of Relevant Covert Channels

Current state-of-the-art covert channels methods that could be used to exfiltrate data from air-gapped networks involve various physical effects, such as FM transmissions from a display cable [23], ultrasonic acoustic emissions from a speaker [21] [24], EMR emitted by generic CPU operations [22], and thermal emission [25]. Our method, GSMem, uses emissions produced by multi-channel memory data bus. Table 1 provides a brief comparison between GSMem and other current models.

Method	Transmitter	Receiver	Distance (m)	Rate (bit/s)
AirHopper **[23]** (78MHz -108MHz)	Display cable	Cellular FM receiver	7	104-480
Ultrasonic **[21] [24]**	Speaker	Microphone	19.7	20
SAVAT **[22]** (~80KHz)	CPU/memory (laptops)	Dedicated equipment	1.0	N/A
BitWhisper [25]	Computer CPU/GPU	Computer Heat Sensors	0.4	8 bit/hour
GSMem (cellular frequencies)	RAM bus (multi-channel)	Baseband	5.5	1-2
		Dedicated equipment	30+	100-1000

Table 1: Comparison of current covert channels for air-gapped networks

As can be seen, all five methods utilize basic computer equipment as the transmitter. However, whereas a display cable or a speaker may not be present on every conceivable computer configuration [26], the CPU and memory, utilized by GSMem and SAVAT, are always present. On the receiver's end, a microphone may not be present on every computer, particularly within a classified zone [26]. A cellular FM receiver (as used by AirHopper) may not be present on every mobile phone, while the baseband processor (used by GSMem) is an integral part of any mobile phone.

In terms of bandwidth, with the dedicated hardware receiver we achieved bit rates of 100 to 1000 bit/s. However, when using a mobile phone as the receiver, the bit rate was much slower (2 bit/s) – making this equipment suitable for leaking small amount of data. It is important to note that our concept was demonstrated on a nine year old low-end phone, the only available alternative with open source firmware, given the protective nature of the baseband industry. Demonstrating the same concept on newer basebands will likely yield better results, and is left as a future research direction.

3. The Adversarial Attack Model

GSMem, viewed as a concept, contributes to the general domain of covert channels. However, we describe a particular attack model which might utilize this covert channel for the purpose of data exfiltration. The adversarial attack model is bifurcated since it requires both a contaminated computer to serve as a *transmitter* and a contaminated mobile phone to serve as a *receiver*. Infecting a computer within an air-gapped network can be accomplished, as demonstrated by the attacks involving Stuxnet [27] [28], Agent.Btz [2] and others [1] [29] [30] [31]. Compromising a mobile phone can occur via social engineering, malicious apps, USB interface, or physical access [32] [33] [34]. Once a compromised mobile phone is in the vicinity of an infected computer, it can detect, receive and decode any transmitted signals and store the relevant acquired information. Later, the phone can transmit the data to the attacker via mobile-data, SMS, or Wi-Fi (in the case of smartphones). Although this attack model is somewhat complicated, attackers have grown more sophisticated, and complex attack patterns have increasingly been proven feasible during the last few years [35] [36] [37] [38].

4. Technical Background

The exfiltration channel is based on the emission of electromagnetic signals, in the frequencies allocated to cellular bands. These signals can be picked up by a malicious component located at the baseband level of a nearby mobile phone. In this section, we provide an overview and some helpful technical background information about cellular networks and frequency bands, along with the basics of baseband components in mobile phones.

4.1. Cellular Networks

2G, and the newer 3G and 4G networks are three 'generations' of mobile networks. Each generation has its own set of standards, network architecture, infrastructure, and protocol. 2G, 3G, and 4G networks are commonly referred to as GSM, UMTS, and LTE respectively, generally reflecting, the implementation of these standards. In this paper, we use the terms GSM, UMTS, and LTE to denote the three generations.

4.1.1. Cellular Network Bands

Wireless communication between mobile-handsets (i.e., mobile phones) and the cellular network takes place through a base transceiver station (BTS), which handles the radio link protocols with the handsets. Communication with the BTS takes place over 'frequency bands' allocated for the cellular network. Various standards define the radio frequencies allocated to each band. In practice, the standard in use depends on the country, region, and support of the cellular provider. Modern mobile phones support all common frequency bands for GSM, UMTS, and LTE, although some phones are region specific. Table 2 shows the main frequency bands supported by modern mobile phones. Each band encompasses frequencies within a range surrounding (above and below) the main frequency. For example, GSM-850 has a frequency range between 824.2MHz and 894.2MHz. Lists of bands and their allocated frequencies are specified by the standards [39].

Standard	Frequency band (MHz)
GSM	850 / 900 / 1800 / 1900
UMTS	850 / 900 / 1900 / 2100
LTE	800 / 850 / 900 / 1800 / 1900 / 2100 / 2600

Table 2: The main frequency bands for GSM, UMTS and LTE cellular networks.

4.1.2. ARFCN

The communication (transmission and reception) between the mobile phone and the BTS occurs over a subset of frequencies within the entire frequency band. The absolute radio-frequency channel number (ARFCN) specifies a pair of radio carriers used for transmission (uplink) and reception (downlink) in GSM networks. For example, the GSM-850 band consists of 123 ARFCN codes (ARFCN 128 to ARFCN 251), in which the ARFCN 128 code represents the uplink frequency of 824.2MHz and the downlink frequency of 869.2MHz. In UMTS and LTE, the ARFCN are replaced with UARFCN and EARFCN respectively. The mapping of each ARFCN on the corresponding carrier frequency is given in [40].

4.2. Baseband in Mobile Phones

Modern mobile phones consist of at least two separate processors [9] [41]. The application processor runs the main operating system (e.g., Android or iOS) and is responsible for handling the graphical user interface, memory management and process scheduling. The baseband processor runs a dedicated RTOS which manages the radio communication and maintains the protocol stack. The application processor and the baseband processor work independently from one another and have separate memory space. However, it is necessary to exchange data between the two processors on a routine basis, for example, when the dialer application initiates a call (application processor to baseband processor) or when an SMS notification is received (baseband processor to application processor). Communication between the processors is commonly handled through a shared-memory segment or a dedicated serial interface [9] [41]. Unlike modern smartphones, low-end mobile phones, also referred to as feature-phones, employ a single processor to manage both user-interface and cellular communication. On feature-phones, this single processor is also referred to as a baseband processor.

4.2.1. Baseband Chip Architecture

The baseband processor is an integral part of the baseband chip. The chip consists of: (1) the RF frontend, (2) the analog baseband, (3) the digital baseband, and (4) the baseband processor [6] [41].

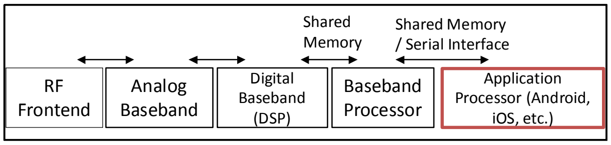

Figure 2: The baseband components and application processor in modern mobile phones. In low-end phones, an application processor doesn't exist.

The **RF frontend** handles received and transmitted signals on the physical level. This component consists of items such as: an antenna, a low-noise amplifier (LNA), and a mixer. The **analog baseband** contains, among other components, an analog to digital converter (ADC) and a digital to analog converter (DAC) to mediate between the digital baseband and the RF frontend. The **digital baseband** includes the digital signal processor (DSP) which is responsible for the lowest parts of the protocol stack (i.e., modulation/demodulation and error-correction). The **baseband processor** is responsible for handling the higher and more complex layers of the protocol stack. Communication between the DSP and the baseband processors takes place through a shared-memory interface (Figure 2).

5. The Transmitter

The physical effect underlying our transmission method is electromagnetic radiation (EMR), a form of energy emitted by certain electromagnetic processes. The emitted waves propagate through space in a radiant manner. Electromagnetic waves have two defining properties: the frequency f measured in Hertz (Hz) and the amplitude (i.e., strength) measured in decibel-milliwatts (dBm). In many cases, electronics (such as wiring, computer monitors, video cards, and communication cables) emit EMR in the radio frequency spectrum. Their frequencies and amplitudes depend on their internal currents and voltage. An exploitation of intentional and unintentional emissions from computer components has been addressed in previous research [14] [23] [13] [42].

We propose that a computer's memory bus can be exploited to act as an antenna capable of transmitting information wirelessly to a remote location. When data is exchanged between the CPU and the RAM, radio waves are emitted from the bus's long parallel circuits. The emission frequency is loosely wraps around the frequency of the RAM's I/O bus clock with a marginal span of +/-200MHz. The casual use of a computer does not generate these radio waves at significant amplitude, since it requires a major buildup of voltage in the circuitry. Therefore, we have found that by generating a continuous stream of data over the multi-channel memory buses, it is possible to raise the amplitude of the emitted radio waves. Using this observation, we are able to modulate binary data over these carrier waves by deterministically starting and stopping multi-channel transfers using special CPU instructions.

In the remainder of this section, we describe the design and implementation of the transmitter from the bottom up. First, we discuss the carrier wave (channel frequency) of the emitted radio waves. Next, we discuss a method for modulating binary data over a bus. Last, we propose a simple bit framing protocol to help the receiver demodulate the received signal. It is important to note that since the focus of this paper is the feasibility of the proposed covert channel, we do not exhaustively explore all possible signal modulations or bit framing protocols. Improvements to the communication protocol are a subject of future research.

5.1. EMR Emissions

Multi-channel memory architecture is a technology that increases the data transfer rate between the memory modules and the memory controller by adding additional buses in between them. The address space in multi-channel memory is spread across the physical memory banks, consequentially enabling data to be simultaneously transferred via multiple (two, three, or four) data buses. In this way, more data can be transferred in each read/write operation. For example, motherboards with dual-channel support have 2x64 bit data channels. Some computers support triple-channel memory and modern systems even have quadruple-channel support. Multi-channel architecture is implemented in all modern Intel and AMD motherboards.

In Figure 3, the radio emissions from an ordinary desktop workstation with dual channel memory are plotted on the frequency plane, comparing emissions from casual activity to those associated with intentional actions. When all channels are used, the radio emissions from the buses increase (red) in comparison to the emissions from casual activity (blue). We observed an increase of at least 0.1 - 0.15 dB across the frequency band 750-1000MHz, where some specific sub-bands showed an increase of about 1 - 2.1dB. A full summary of the radio emissions of different motherboards and memory technologies can be found in Table 3.

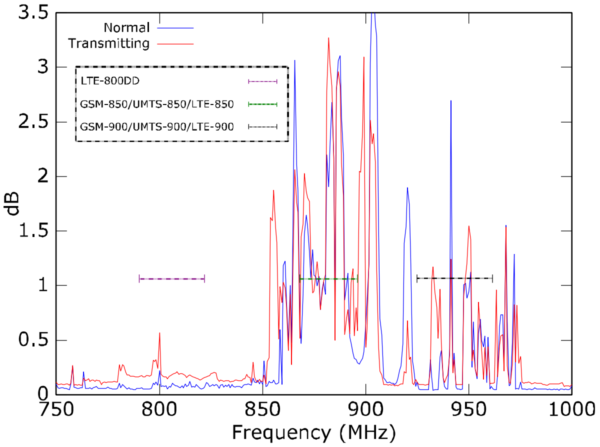

Figure 3: A plot of the amplitude of the radio waves emitted from a motherboard with an 800MHz I/O bus using DDR3-1600 RAM. Blue: casual use of the computer. Red: our transmission algorithm while using the dual channel data paths.

Based on our experiments, we have found that the use of three or four channels increases amplitude emissions across nearly the entire band depicted in Figure 3. This means that as the memory architectures mature, the quality of the proposed covert channel will increase. Note that these radio emissions fall within the frequency bands of GSM, UMTS and LTE, making them detectable by all modern basebands.

Standard Name	I/O bus clock (f_c)	EMR Range
DDR3-1600	800MHz	600MHz-1100MHz
DDR3-1866	933MHz	750MHz-1150MHz
DDR4-2133	1066MHz	750MHz-943MHz (fragmented) 1.04GHz-1.066GHz

Table 3: Summary of radio emissions from different memory buses.

5.2. Signal Modulation

In communications, modulation is the process where analog waveforms are varied to carry information over some medium. Typically, a carrier wave (for wireless a radio wave at the frequency f_c) is selected as the channel frequency, where most of the energy from the modulation can be found in the band around f_c.

There are many techniques for modulating a carrier wave to carry binary data. For simplicity and as a show of feasibility, we use a variant of the two level amplitude shift keying (B-ASK) modulation; to send a ‘1’ or ‘0’ the transmitter raises or lowers the amplitude of f_c accordingly over set time intervals T (in seconds) [43]. In other words, the time domain is partitioned into intervals of length T, and the symbol (i.e., signal amplitude) that corresponds to the current bit is transmitted over that entire interval. Our variation of B-ASK is that ‘0’ is not represented by a near zero amplitude, but rather by the average level of the casual emissions. It is assumed that the receiver can differentiate between average and high emission levels (described in detail later in Section 6). The motherboard bus’s radio emissions can be modulated to carry a B-ASK signal in the following way: to transmit a ‘1’ all memory channels are utilized for T seconds, and to transmit a ‘0’ nothing special is done (casual emissions are emitted). In this case, f_c is the motherboard’s memory clock.

5.3. Modulation Algorithm

In order to transmit a ‘1’, it is necessary to consistently utilize multiple memory channels for T seconds. To do this we generate a long random data transfer from the CPU to the main memory using the single instruction multiple data (SIMD) instruction set. SIMD utilizes special CPU registers of 64-bits and 128-bits in order to process wider chunks of data in a single instruction. SIMD instructions are usually used for vectorized calculations such as 2D/3D graphics processing, and includes instructions to load/store data between the main memory and special registers.

Algorithm 1 transmit32 (data)

```
buffer ← ALIGNED_ALLOCATE(16,4096)
tx_time ← 500000
for bit_index ← 0 to 32 do
    if (data[bit_index] = 1) then
        start_time ← CURRENT_TIME()
        while (tx_time > CURRENT_TIME() - start_time) do
            buffer_ptr ← buffer
            for i ← 0 to buffer_size do
                SIMDNTMOV(buffer_ptr, 128bit_register)
                buffer_ptr ← buffer_ptr + 16
            end for
        end while
    else
        SLEEP(tx_time)
    end if
end for
```

We implemented the B-ASK modulation algorithm using the Streaming SIMD Extension (SSE) instruction set found in Intel and AMD CPUs. The SSE specifies a set of 128-bit (quadword) registers numbered xmm0-xmm16, and includes a group of instructions for moving data between these xmm registers and the main memory [44] [45]. Using these instructions it is possible to instruct the CPU to utilize the multi-channel data paths, thereby amplifying the radio emissions.

One of the challenges we had to overcome resulted from the use of the CPU caching mechanisms. When the processor employs a cache hierarchy, transferring data between xmm registers and the main memory does not guarantee any immediate activity over the bus. This inconsistency presents an issue regarding the use of the proposed B-ASK modulation, since the symbols must start and stop precisely within the symbol interval (T).

Beginning with SSE version 2, there is a set of instructions that enable read/write operations directly to/from the main memory, while bypassing all cache levels (non-temporal). Specifically, we use the Move Double Quadword Non-Temporal instruction, MOVNTDQ *m128, xmm*. The intent of this instruction is for copying double quadwords from the xmm register to the 128-bit memory address, while minimizing pollution in the cache hierarchy.

Our implementation of the B-ASK modulation (Algorithm 1) works in the following way. The *transmit32()* method receives the outbound binary as an array of 32 bits. A temporary buffer of 4096 bytes (32x128) is allocated on the heap (lines 1-2) as a destination for the MOVNTDQ memory operations. Note that the allocated memory has to be 16-bytes aligned, as required for SSE memory operands. Next, on line 2, we set T to 500ms. Although a shorter T would provide a faster bit transmission rate, doing so directly increases the error rate. For the tested Motorola C123 phone with the Calypso baseband, a value of 500ms appears to provide satisfying results. Basebands of modern smartphones are probably capable of higher sampling quality, and therefore might require a shorter T. With specialized receiver hardware, setting T to 1-10ms provided good reception quality (Section 6).

The outer loop (line 3) iterates over the 32-bit array and performs the memory operations to generate the radio emissions. When the current bit is a '1' a loop repeatedly uses the MOVNTDQ instruction to copy data from xmm registers to the heap, until T seconds have elapsed. Conversely, when the current bit is a '0' the algorithm sleeps for T seconds.

5.4. Bit Framing

As mentioned earlier, when our variant of B-ASK modulates a '0' the amplitude of the transmitted signal is that of the bus's average casual emissions, and anything significantly higher than that (by some threshold) is considered a '1'. This incurs two issues: (1) the receiver has no prior information as to what the optimum threshold should be making it difficult for the receiver to detect activity in its area, and (2) the strength of amplitudes surrounding f_c is dependent on the distance between the transmitting desktop and the receiver; this means that if the mobile phone is moving during a transmission or other interference exists, a '1' and '0' can be decoded incorrectly.

Therefore, in order to assist the receiver in dynamically synchronizing with the transmitter, we place the data into frames. The binary stream is partitioned into sequential payloads of 12 bits, and the payloads are transmitted with a header consisting of the preamble sequence '1010' (Table 4). The preamble is used by the receiver to determine when a frame is being transmitted and to determine the amplitude levels of a '1' and a '0'. This process is discussed in depth in Section 6. The framing process takes place before data transmission. Once the frame has been built, it is passed to Algorithm 1 as the outbound data.

Preamble	*Payload*	*Preamble*	*Payload*
1010	12 bits	1010	12 bits

Table 4: The basic frame format used to send segments of a bit stream, using the *transmit32()* function.

5.5. Transmitter Stealth and Compatibility

The transmitting program has a small memory and CPU footprint, making the activities of the transmitter easier to hide. In terms of memory consumption, the program consumes merely 4K of memory allocated on the heap. In terms of CPU intake, the transmitter runs on a single, independent thread. At the OS level, the transmitting process can be executed with no elevated privileges (e.g., root or admin). Finally, the code consists of bare CPU instructions, avoiding API calls to escape certain malware scanners. In short, the transmission code evades common security mechanisms such as API monitoring and resource tracing, making it hard to detect.

As for compatibility, since 2004 SIMD instructions have been available for x86-64 Intel and AMD processors [46] [47], making the transmission method is applicable to most modern workstations and servers. Similar instructions on IBM's Power architecture have been in place since Power ISA v.2.03 was initiated [48]. The proposed transmitter has been implemented and successfully tested on several operating systems, including Microsoft Windows platform (Windows 7, 64bit), Linux Fedora 20 and 21 (64bit), and Ubuntu 12.1 (64bit).

6. The Receiver

In this section we describe how a mobile phone in close proximity to a transmitting computer can successfully receive and decode emitted signals. We implement the GSMem receiver component by modifying the firmware of a mobile phone's baseband. We present the receiver architecture and implementation, along with the modulation and decoding mechanisms. Interestingly, we found that under certain circumstances, the GSMem signals can be indirectly received by an application running on a modern Android smartphone with a non-modified baseband. This optional implementation yields rather limited effective distance of 10cm, and provides a conceptual rather than an immediate practical contribution. Therefore, to stay in line with the core of this paper, the description of this implementation is deferred to Appendix A.

6.1. Receiver Implementation

Reception of the transmitted data is accomplished in the following manner: (1) sample the amplitude of the carrier wave, (2) performs noise mitigation, (3) search for bit frame header (preamble detection), and (4) demodulate the frame's payload. We will describe each of these steps in this order after discussing the implementation framework.

6.1.1. Baseband Firmware

As discussed in Section 1, the baseband industry is highly protective, keeping information about baseband architecture, the RTOS, and the protocol stack, guarded from the public [9] [10] [49]. The secrecy and complexity of the baseband technology makes it extremely difficult to make modifications at the binary level, particularly without the availability of information such as source code [10] [49]. However, there have clearly been cases where attackers have used explicit access to the device firmware in order to perform malicious activities [29] [31] [33] [50]. Our implementation of the GSMem receiver is based on '*OsmocomBB,'* an open source GSM baseband software implementation [51].

The open source project, launched in 2010, is the only way to freely examine the implementation of a mobile's GSM baseband software. OsmocomBB provides source code for the GSM protocol stack, along with device drivers for digital and analog basebands chips. The project currently supports about 13 models of mobile phones. Most of the supported phones are OEM by Motorola and works with Calypso baseband chipsets made by Texas Instruments. For our experiments, we selected the Motorola C123 model [52] that supports 2G bands but has no GPRS, Wi-Fi, or mobile data traffic capabilities. The Motorola C123 is a limited mobile phone, supporting our attack scenario described in Section 3. It is worthwhile to note that the baseband components of modern smartphones are more advanced in terms of RF reception, sampling rate and processing power due to the improved hardware and the support in new technologies such as the LTE [6] [53]. That means that implementation of the GSMem receiver on modern device may yield better results in terms of reception quality and transfer-rates.

The GSM protocol stack at the baseband consists of three main layers [49]. Layer 1 is the most relevant layer in term of GSMem implementation. It handles the RF interface which modulates the data over the air. In OsmocomBB, the lower part of the layer 1 is handled by the DSP, while the baseband processor handles the upper layers. Layer 1 includes, among other functionalities, the power management, which is responsible for acquiring the raw signal power measurements (in dBm) of specific frequencies (ARFCNs). Note that measuring RF power levels is a basic functionality of any baseband chip [39]. The interaction between the baseband processor and the DSP is depicted in Figure 4.

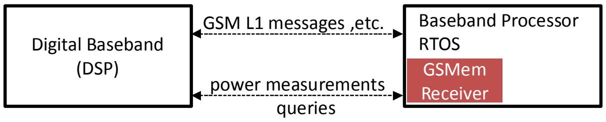

Figure 4: Interaction between the baseband processor and the DSP.

6.1.2. Firmware Modification

The receiver is implemented by patching the main event handler in the baseband RTOS. Figure 5 shows the outline of the OsmocomBB initialization and main loop. After initialization (lines 1-2), the baseband processor enters the event loop (line 3). The event loop continuously processes a sequence of event handlers, including the keypad handler, timer updates, and layers 2 and 3 handlers, interrupts from the DSP, power measurements, etc.

```
1: // baseband initialization
2: // specific receiver initialization
3: while true do
4:     // keypad handlers
5:     // layer 2/3 handlers
6:     // power management handler
7:     // ...
8:     ReceiverHandler()
9: end while
```

Figure 5: Calypso RTOS code outline

In order to implement the functionalities of the receiver, we added a routine of our own called *ReceiverHandler()* (line 8). Since it is placed in the main loop, the routine is run continuously at every iteration.

The *ReceiverHandler()* has three possible states: (1) scan for best frequency (2) search for bit frame header (preamble), and (3) B-ASK signal demodulation. Scan state is the initial state of the routine. The pseudo code for *ReceiverHandler()* is presented in Algorithm 2.

Algorithm 2 ReceiverHandler

```
1:  $dBm \leftarrow$ MEASURE($f_c$)
2:  $filtered\_signal \leftarrow$ UPDATEMOVINGAVERAGE($dBm$)
3:  if ($state = SCAN$) then
4:      $f_c \leftarrow$ SCANFREQ()
5:      SETSTATE($PREAMBLE$)
6:  end if
7:  if ($state = PREAMBLE$) then
8:      if (IDENTIFYPREAMBLE($filtered\_signal$) $= true$) then
9:          SETSTATE($RECEIVE$)
10:     end if
11: end if
12: if ($state = RECEIVE$) then
13:     $b \leftarrow$ DEMODULATEBIT($filtered\_signal$)
14:     $bitSequence$.add($b$)
15:     if ($bitSequence$.size%16 $= 0$ or SIGNALLOST($filtered\_signal$)) then
16:         SETSTATE($PREAMBLE$)
17:     end if
18: end if
```

6.1.3. Signal Sampling

The first step in detecting a GSMem transmission is to sample the amplitude of the carrier wave f_c. Note that this step takes place only after f_c has been determined in a initial scanning phase. Each time the main loop runs *ReceiverHandler(),* Algorithm 2 causes the DSP module to sample the power level (amplitude) of f_c (line 1) and stores it in a buffer (line 2). This data is used later in the demodulation routines. The function *Measure()* invokes an amplitude measurement request on the DSP using a function called *l1a_l23_rx()*. The DSP measurements are performed in bands of 0.2MHz. Our tests show that the tested Calypso baseband was able to sample power measurements at a rate of 1.8kHz, hence 1.8kbps is the fastest bit rate that this device can demodulate at. This is a much faster bit rate than we achieved due to the limited processing capabilities of the device. However, the power measurements rate is an important consideration to take into account when implementing an improved GSMem receiver on a more advanced device in the future.

6.1.4. Noise Mitigation

After the power measurement, a noise mitigation function is applied to the current sample by averaging it with the last W original samples. This operation is essentially a moving average filter, an effective technique for mitigating high frequency noise. In our experiments with the Motorola C123, we tried a W of 50-750 samples and found that the size of W directly affects the bit rate. A larger W provided better noise mitigation, while a smaller one produced a faster bit rate.

6.1.5. Detecting the Best Carrier Wave

In the *SCAN* state, the receiver searches for the best f_c to use for demodulating GSMem transmissions. Note that since the radio emissions of the transmitter fallout across the GSM-850/GSM-900 bands (Figure 3, Section 5.1), the f_c can be set in advance to any frequency in those bands. However, we observed that some frequencies have more interference than others (e.g., the channels actively used by nearby cellular base stations). Therefore, during the scanning state, the better f_c is determined as the frequency that provides the best carrier to interference ratio (CIR). This frequency is found by scanning the range of the entire GSM-850 range and selecting the frequency with the minimum average amplitude (in dBm). The assumption is that the minimum average amplitude indicates a low level of interferences, making it easier to detect a '1' using our variant of B-ASK. In our implementation, the scanning takes place after the device boots, and after every 30 seconds of noisy or lost signals. After the f_c value is set, the algorithm moves to the *PREAMBLE* state.

6.1.6. Preamble Detection and Demodulation

If state is set to *PREAMBLE*, the receiver searches for a preamble sequence (lines 7-11 of Algorithm 2). If the sequence '1010' is detected, then it is assumed to be the start of a frame, and state is changed to *RECEIVE* to complete the B-ASK demodulation process (lines 12-18). The preamble sequence allows the GSMem receiver to: (1) synchronize with the GSMem transmitter (2) identify '1' and '0' amplitude levels δ and (3) determine the signals' duration t, if unknown. Dynamically setting δ for every frame is necessary for demodulating signals while the mobile is moving. For example, a frame may be received at close proximity to the transmitter where f_c is much stronger thereby setting amplitude levels to be high. The subsequent frame may be sent while the mobile phone is farther away – where smaller amplitude would be more appropriate. Once a preamble has been detected, the payload is demodulated in a similar manner using the updated parameters.

6.1.7. Signal Loss

On line 15 in Algorithm 2, the state of the receiver returns to *PREAMBLE* if the whole payload has received, or if the signal has been lost. The function *SignalLost()* returns true if during the data reception, the measured signal power is weaker than the amplitude of the ‘0’s from the preamble for three seconds straight. In this case, any partially received data discarded or marked appropriately.

7. Evaluation

In this section we evaluate GSMem’s performance as a communication channel. We present in detail the evaluation using a tampered cellular baseband receiver. We also examine the signal reception using a dedicated hardware receiver programmed via software defined radio (SDR).

7.1. Experiment Setup

We used the Motorola C123 with the modified firmware as the receiver for all experiments in this section. As for the transmitters, we used three different models of desktop workstations (WS), each with a different configuration and different case. The details of these computers and their tested settings can be found in Table 5. Note that WS3 is a much stronger transmitter than the others since its RAM has a quad channel operation mode, which employs wider data paths. In all the experiments, the transmitter used the 4kb allocation method described in Section 5, with a T of 1.8 seconds. The receiver listened to the carrier frequency (f_c) ARFCN 25 downlink (940MHz), unless otherwise mentioned.

	WS1	**WS2**	**WS3**
OS	Linux Fedora 20		
Chassis (metal)	infinity chassis	GIGABYTE Setto 1020 GZ-AX2CBS	Silverstone RL04B
CPU	Intel i7-4790	Intel i7-3770	Intel i7-5820K
Motherboard	GIGABYTE GA-h87M-D3H	GIGABYTE H77-D3H	GIGABYTE GA-X99-UD4
RAM Type	2 x 4GB 1600MHz		4 x 4GB 2133MHz
RAM Frequencies Tested	1333/1600 MHz		1833/2133 MHz
RAM Operation Modes Tested	Single / Dual		Dual / Quad

Table 5: Configuration of the transmitting workstations.

There are several major factors that affect the quality of a wireless communication channel. Typically, the quality of a channel is measured by taking the signal to noise ratio (SNR), where $SNR \equiv 10\log(P_{signal}/P_{noise}) = P_{signal}dB - P_{noise}dB$ and P is the power level (a larger SNR is better than a smaller one). The noise power P_{noise} can originate from naturally occurring noise and from other interferences such as the emissions from nearby computers in the same office space. Therefore, in order to match our attack scenario from Section 3, the experiments in this section all take place in a regular work space with several active desktop workstations within a 10m radius.

There are many factors which can decrease the SNR of a wireless channel when the location of the receiver is changed. Because we are dealing with a low power transmission, we do not consider properties such as multipath propagation (fading). Instead, we focus on how different receiver distances and positions affect the channel’s SNR.

7.2. Channel Signal to Noise Ratio (SNR)

The first set of experiments tests the SNR of the WSs from different distances. Figure 6, Figure 7 and Figure 8 show the receiver’s maximum measured amplitudes at different distances from WSs 1, 2, and 3 respectively. Here, WSs 1 and 2 have their RAM set to dual mode at 1600MHz, and WS3 has its RAM set dual / quad mode at 1833 / 2133MHz. As illustrated by Figure 9, the SNR remains positive (more signal power than noise) even up to a distance of 160cm. This gives a good indication of the proposed covert channel’s effective distance. Given these observations, we assume that a distance of 160cm from a workstation is within the normal range where a mobile device is expected to be held while working on the workstation.

Note that WS3 in dual mode has a significant advantage in range over WSs 2 and 3. This is due to the fact that WS3 uses a higher RAM frequency than all other WSs in the workplace scenario. This means that it is subject to less interference, thereby improving its SNR. When quad channel mode is used, the range increases further, demonstrating that a higher number of active memory channels increases the signal’s amplitude.

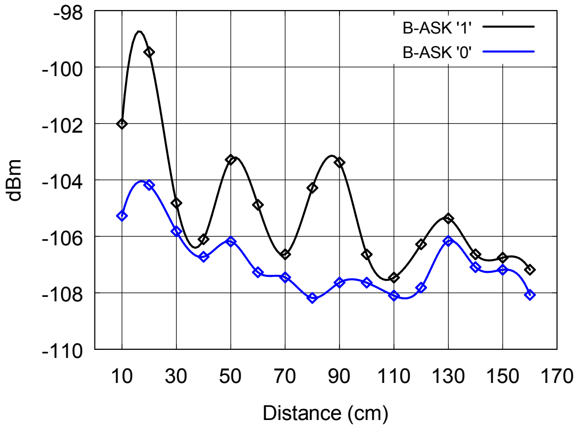

Figure 6: Signal strength received from WS2 (1600MHz, Dual) at various distances from the backside of the chassis. The blue line can also be viewed as the casual emissions (noise).

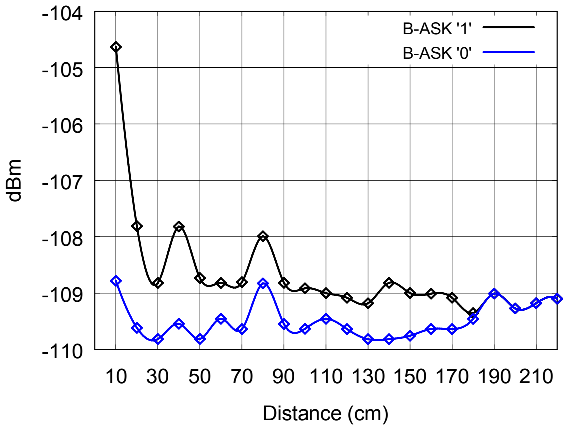

Figure 7: Signal strength received from WS1 (1600MHz, Dual) at various distances from the backside of the chassis.

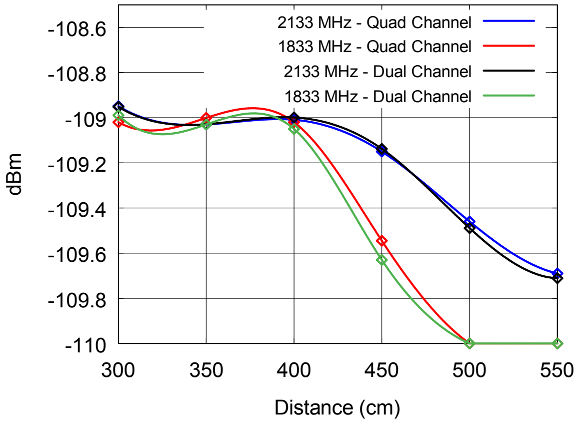

Figure 8: Signal strength received from WS3 (1833/2133MHz, dual/quad channels) at various distances from the front side of the chassis.

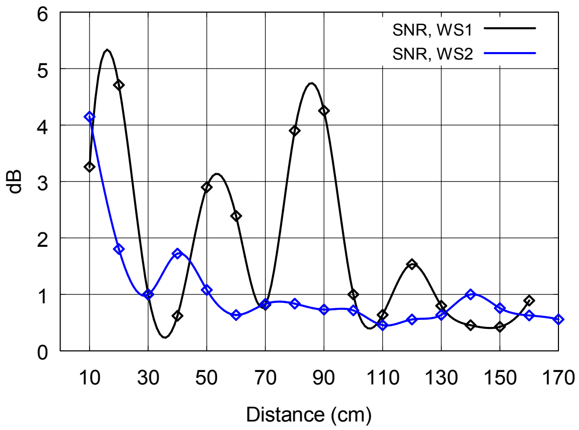

Figure 9: Receiver SNR from WS1 and WS2 (1600MHz, Dual) at various distances from the backside of the chassis.

During the experiments, we observed that the position of the receiver with respect to the transmitter has a significant impact on the SNR. For instance, using WS2, an SNR of 0.5 is achieved at a farther distance from the front of the chassis as opposed to the back. Furthermore, the best position for WS1 (using 1600MHz) is from the front, while the best position for WS2 is from the back. These differences make sense considering that each case has variations in shape and metal content. In all cases, we observed that the optimum position for the receiver to be is in front of the chassis. This may have to do with the fact that the front of an ATX case is mainly made of plastic (blocking less of the signal).

Figure 10 and Figure 11 depict the distance at which an SNR of 0.5dB can be achieved at different positions around the WSs.

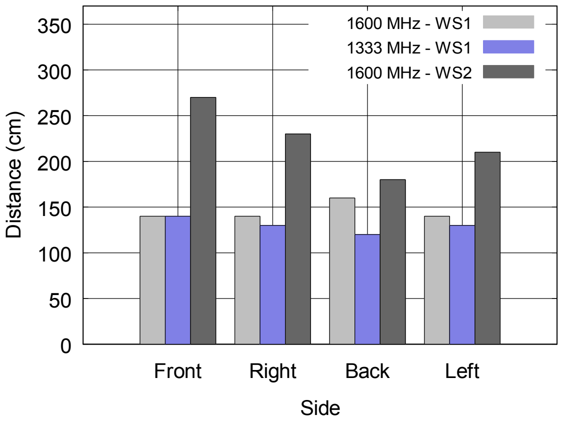

Figure 10: The distance at which an SNR of 0.5dB is achieved at various positions around the transmitters WS1 and WS2 using dual mode and different clock speeds

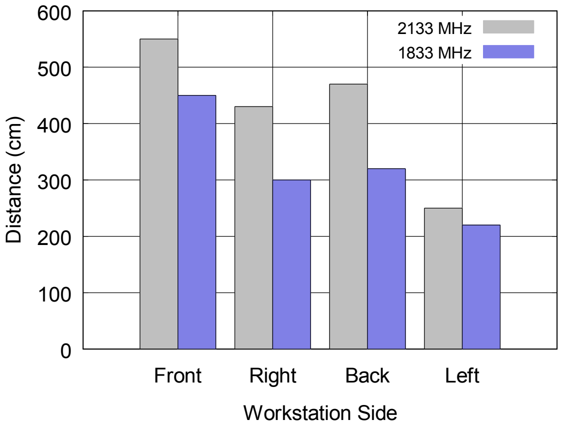

Figure 11: The distance at which at least 0.5dB of SNR is achieved at various positions around the transmitter WS3 using quad mode and different clock speeds.

7.3. Bit Rates

The GSMem receiver implemented using OsmocomBB on the nine year old mobile phone significantly limit the channel's quality. Although this device provides the advantage of GSM baseband programmability, it has limited real-time processing power and inadequate access to the DSP's full capabilities. Due to these limitations, we preferred using simple ASK type modulations over other more sophisticated options. Using the proposed B-ASK modulation with this device, we were able to receive binary data from the GSMem transmitter at a bit rate of 1 to 2 bit/s. This allows exfiltration of small amounts of information such as identifiers, passwords, and encryption keys, within several minutes. We examined the bit error rate (BER) by transmitting a set of 256-bit encryption keys from a workstation. Figure 12 depicts the BER over varying distances between the transmitting workstation and a nearby mobile phone.

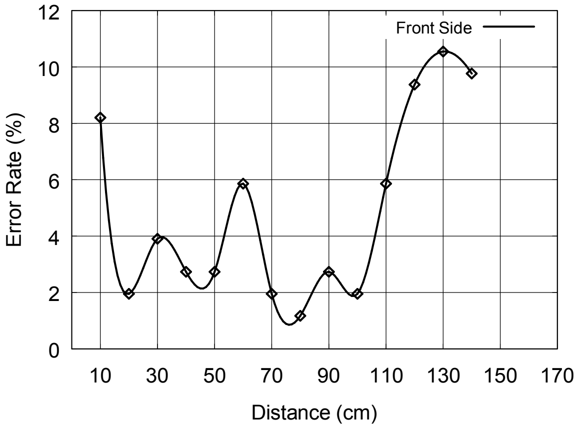

Figure 12: The Motorola C123's BER plot from a B-ASK transmission using WS1 as the transmitter.

7.4. Software Defined Radio (SDR)

Much higher bit rates - at even further distances - are achievable when more modern equipment is used and the full capabilities of the baseband component are accessible. To demonstrate this fact, we implemented a GSMem receiver using GNU-Radio software on an affordable SDR kit; the Ettus Research Universal Software Radio Peripheral (USRP) B210 [54], which is capable of capturing data at velocities up to 32 million samples per second. The USRP was connected to Lenovo ThinkPad T530 (through the USB 3.0 interface), with dedicated software suitable for capturing signals from the USRP, i.e. GNU-Radio v3.7.5.1. The OS is Linux Ubuntu 14.10 (64 bit).

Since we had full access to the DSP's capabilities, we implemented the receiver using the frequency shift keying modulation scheme (FSK) where a '1' and '0' were modulated by using two distinct frequencies. Creating two carrier waves was accomplished by adding a slight delay inside the memory transfer operation loop. Since this version of the GSMem transmitter was not implemented on a cellular device, we omit the rest of its details from the body of this paper. Using this hardware, we were able to improve the signal quality and the reception distance significantly. At a distance of 2.6m and where $T = 0.001$, we achieved a bit rate of 1000 bit/s, with a BER of approximately 0.087%. Table 6 summarizes the time needed to transfer certain pieces of sensitive information at the rates of T=0.5 (using Motorola C123) and T=0.001 (using USRP).

Data	Length (bit)	Rx Time Motorola C123	Rx Time USRP
MAC Address	48	30 sec	48 ms
Plain Password	64	40 sec	64 ms
MD5	128	1.3 sec	128 ms
GPS Coordinate	128	1.3 sec	128 ms
SHA1 Hash	160	1.6 min	160 ms
Disk Encryption Key	256	2.6 min	256 ms
RSA Private Key	2048	21.3 min	2.04 sec
Fingerprint Template	2800	29.1 min	2.8 sec

Table 6: Transmission times

In order to increase the effective distance, we used a directed printed circuit board (PCB) log periodic antenna [55], optimized for capturing signals at the range of 400 MHz – 1000 MHz. The antenna connected to the USRP via its standard connectors.

We measured the signal levels of '1' and '0' emitted from a transmitting WS3 over varying distances. The transmitter resides in a regular work space with several active desktop workstations situated within a 10m radius. As can be seen in Figure 13, the signals were received in 30 meters and beyond. This is a significant improvement when compared to the mobile phone receiver. Furthermore, these results were obtained with a rather affordable hardware receiver, using commonly available components.

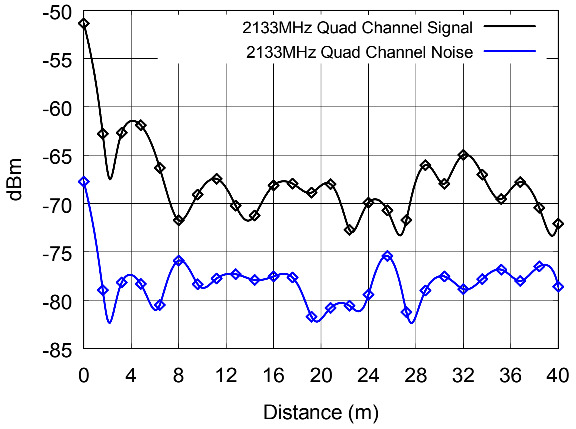

Figure 13: Signal strength received on f_{c1} as transmitted from WS3 at distances of 0-40 meters from the front side of the chassis.

8. Countermeasures

Official governmental and military standards concerning EMSEC countermeasures are mainly classified, despite some occasional leaks [16], [56]. With the exfiltration method described in this paper, the "zones" approach may be used as a countermeasure, defining spatial regions where mobile phones, including simple devices, are prohibited. As discussed earlier, however, the signal reception distance may grow when dedicated hardware receiver is being used. In this context, the insulation of partition walls may help. Structural building elements, such as reinforced concrete floors, seem to provide insulation by acting as a Faraday cage. However, enclosing each computer within a Faraday cage seems impractical. Shielding the transmitting component within the computer, i.e., the multi-channel memory bus is a challenging task, particularly when compared to shielding other emanation sources, such as monitor cables. Another defensive strategy may involve behavioral (dynamic) analysis and anomaly detection, trying to detect GSMem activities at runtime on the process level [9] [57]. However, when the baseband firmware is utilized as the GSMem receiver, it is particularly hard to detect because of the separation of the baseband component from the main operating system [49]. In this case, a meticulous forensic analysis of the device may be required.

9. Conclusion

In this paper we present GSMem, a method for exfiltrating data from air-gapped networks. Our major contributions include a unique covert channel, consisting of a feasible transmitting method, and a ubiquitous receiver that doesn’t arouse suspicion. The covert channel is based on electromagnetic waves emitted at frequency bands of GSM, UMTS and LTE cellular networks. The transmitting software exploits specific memory-related CPU instructions, utilizing the multi-channel memory bus to amplify the transmission power. Subsequently, the transmitted signals are received and demodulated by a rootkit residing at the baseband level of a cellular phone. Note that, unlike some other recent work in this field, GSMem exploits components that are virtually guaranteed to be present on any desktop/server computer and cellular phone. Furthermore, elementary cellular phones, those without Wi-Fi, camera, or other nonessential instrumentation, are often allowed into classified facilities, even in security-aware organizations. We provide essential technical background information about cellular networks and an overview of baseband components in mobile phones. Next, we discuss the design considerations of the transmitter and the receiver, regarding signal generation, data modulation, transmission detection, noise mitigation, and handling a moving receiver. Our GSMem transmission software - implemented on Windows and Linux - has a small computational footprint, which makes it hard to detect. The GSMem receiver is implemented on a mobile phone, by modifying the baseband firmware of a low-end device. We present its architecture and discuss its capabilities and limitations. We go on to evaluate the method’s using extensive configurations, settings, and various parameters. Our current results demonstrate the overall feasibility of the method, at a distance of 1-5.5 meters when using a standard cellular baseband receiver. We also evaluated the wider boundaries of GSMem using a dedicated yet affordable hardware receiver. The associated experiments yielded an effective distance of 30 meters and beyond. We believe that exposing this new covert channel will serve to raise professional awareness and academic interest.

Appendix A

Receiver Implementation (*Android Application Level*)

In this appendix we show how, under certain circumstances, the GSMem signals can be received by an application run on a modern Android smartphone with an untampered baseband. This technique is limited to close proximity to the transmitter (10cm).

Android Radio Interface Layer (RIL)

Android, as part of its open source framework, defines the upper software layers with respect to its hardware peripherals. In Android, the Radio Interface Layer (RIL) component interfaces between high level telephony services (*android.telephony*) and the baseband hardware. Each vendor supplies its own implementation for the RIL interface. The vendor RIL is closed source and shipped with the stock Android firmware as a shared object (.so) binary file.

Signal Demodulation

We developed a reception method which we refer as *'neighbor cell jamming'*. According to the GSM standard, mobile equipment must periodically listen to the broadcasted pilot channels of neighboring cells in order to provide service reliability [58]. Generally, the mobile must always be registered to a cell preferably the one with the best reception. These broadcasts are sent over logical channels called broadcast control channels (BCCH), which carry information such as that cell's ID and configuration. The GSM baseband component maintains a list of best neighboring cells along with their received power level (in dBm or equivalent units) and other information. Since GSMem operates at the same frequency as the neighboring BTSs, it is possible for a GSMem transmitter to affect a drop in the reception of a station that is rather far away. This jamming effect can be used as a side channel to detect the B-ASK modulation such a sudden drop in reception quality represent a '1' and otherwise a '0'.

Implementation

Android allow obtaining the neighboring cells' information from the baseband. E.g., by invoking the method *telephonyManager.getNeighboringCellInfo().*It includes the received signal strength indication (RSSI) of each neighboring cell. Our Android application repeated an algorithm similar to Algorithm 2 (Section 6) with a few modifications. It continuously sampled and stored the signal strength of the weakest cell out of the neighboring cells (the cell which our transmission will likely override). The modulation is inversed: low RSSI represents '1' (transmission occurred) and high RSSI represents '0' (no transmission). Figure 14 shows the reception of a single bit, as received by our application on the Samsung Galaxy S5 smartphone. The phone was located 10cm away from a transmitting workstation. The 'jammed' cell had signal strength of 23asu (equal to -67dBm) before it was jammed. At second 6, the GSMem at the workstation transmit '1', causing a drop in the RSSI measurement for that cell. The transmission stops at second 8.

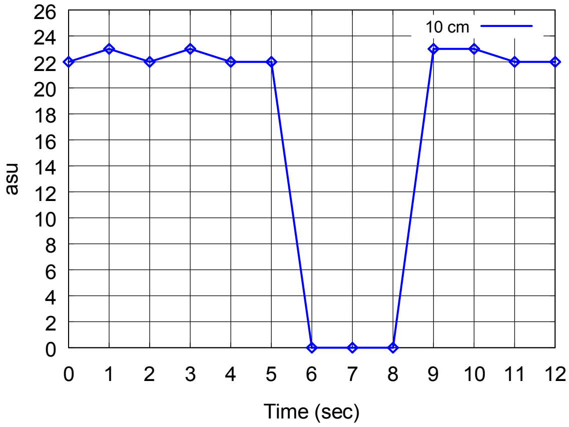

Figure 14: Neighbor cell reception level during transmission of a single bit.

Thermal Covert Channels on Multi-core Platforms

Abstract

Side channels remain a challenge to information flow control and security in modern computing platforms. Resource partitioning techniques that minimise the number of shared resources among processes are often used to address this challenge. In this work, we focus on multi-core platforms and we demonstrate that even seemingly strong isolation techniques based on dedicated cores can be circumvented through the use of thermal channels. Specifically, we show that the processor core temperature can be used both as a side channel as well as a covert communication channel even when the system implements strong spatial and temporal partitioning. Our experiments on an Intel Xeon server platform demonstrate covert thermal channels that achieve up to 12.5 bps and weak thermal side channels that can detect processes executed on neighbouring cores. This work therefore shows a limitation in the isolation that can be achieved on existing multi-core systems.

1 Introduction

Covert and side channels have for a long time remained an open threat to information flow control and isolation techniques in a variety of contexts including cloud and mobile computing [50, 71, 76]. Such channels can be used for data exfiltration from a victim [17] and be exploited by colluding applications to covertly exchange information [46].

A common technique to mitigate covert and side channel attacks that leverage co-location is to dedicate resources (e.g. processor cores, memory) to individual processes for the duration of their execution. Although seemingly inefficient, such a technique is becoming viable with the appearance of multi and many-core systems which contain hundreds of cores [12]. However, it has already been shown that, due to their architecture and use, multi-core systems do not trivially protect against all types of information leakage — covert channels have been demonstrated by exploiting shared caches [35], memory bus [34], network stacks [54], virtual memory [72], I/O devices [64], etc. These covert channels, however, still exploit the resources that particular multi-core platforms, for performance and other reasons, share among the processes. The threats arising from covert and side channel attacks led to the development of mitigation techniques such as partitioning of the shared resources when possible, for example, partitioning caches [68] and bus bandwidth [31].

In this paper, we show that even strong isolation techniques based on dedicated cores and memory can be circumvented in multi-core systems through the use of a *thermal channel*. For this, we leverage the temperature information that is exposed to processes for performance reasons on multi-core platforms and two aspects of the thermal behaviour of these systems. First, the thermal capacitance and resistance of computing platforms result in remnant heat from computations, i.e. the heat is observable even after that computation has stopped. As a result, information about one process may leak to another that follows it in the execution schedule. Second, the effects of heat resulting from processes running on one core can be observed on other cores across the chip. This leaks information about a process to its peers running on other cores in a processor chip. We demonstrate our attacks on commodity multi-core systems. So far, thermal (heat) channels have not been studied on these systems. There is a trend towards exposing thermal data to users and allowing them to make thermal management decisions based on it [21]. For example, temperature information is accessible from user-space on modern Linux systems [1]. This paper highlights the tension between building thermally-efficient systems which requires exposing high-quality temperature data to applications and securing them.

In summary, we make the following contributions: *(i)* We demonstrate the feasibility of using thermal covert channels for communication between colluding applications. We measure the throughput of such a channel on an Intel Xeon server with two processors containing 8 cores each. The challenges in building such a channel include the system's thermal capacitance, effect of cooling on multi-core systems and resolution limitations of the thermal sensors available on these platforms. Although thermal covert channels have a low throughput, sensitive data such as credit-cards (16 digits) can be transmitted within 5 seconds to 4 minutes even on systems that use resource partitioning. *(ii)* We explore the factors that influence the throughput of this covert channel — processor frequency and relative locations of the colluding applications (processes) and show the throughput varies between 0.33 bps and 12.5 bps. *(iii)* We demonstrate the existence of limited thermal side channel leakage from processes running on adjacent cores that allow identification of applications based on their thermal traces. On existing systems, heat-based leakage is non-trivial to avoid without a performance penalty; we discuss possible countermeasures to eliminate or limit the impact of such attacks.

The rest of this paper is organised as follows. In Section 2, we discuss the background and motivation for our work. Section 3 discusses the thermal behaviour of x86 platforms and Section 4 describes how these properties can be exploited to create thermal channels. In Section 5, we demonstrate the feasibility of using thermal channels for covert communication even in systems with isolation based on resource partitioning. Section 6 demonstrates that limited side channel leakage can occur through thermal channels which can be exploited for unauthorised application profiling. Section 7 and Section 8 summarise countermeasures against thermal channels and related work respectively. Finally, we conclude in Section 9.

2 Background and Motivation

In this section, we summarise the use of thermal information in modern processors and resource partitioning-based isolation techniques, as well as provide a motivation for our study.

2.1 Thermal Management

Thermal management is key to the safe and reliable operation of modern computing systems. Today, thermal sensors are incorporated into a number of system components including hard-drives, DRAM, GPU, motherboards and the processor chip itself [9]. In this work, we focus on the information available from thermal sensors that are embedded in processor chips.

Ensuring the thermal stability of a processor is becoming increasingly challenging given the rising power-density in modern processor chips. As a result, major processor vendors (e.g. Intel, AMD, VIA) incorporate thermal sensors to enable real-time monitoring of processor temperature. ARM-based processors also include thermal sensors inside the system-on-chip for power and temperature management.

Initially, thermal management was done statically in hardware and included mechanisms to power-off the processor to prevent melt-downs. This later evolved to more sophisticated dynamic frequency and voltage scaling techniques that change processor frequency to lower its temperature [13, 39]. Hybrid software- and hardware-approaches to thermal monitoring have become popular over time; operating systems today poll temperature sensors and use this to manage cooling mechanisms such as processor frequency-scaling and fan-speed [2]. More recently, there is a trend towards user-centric thermal management that exposes thermal data to users and allows them to implement customised thermal management policies. For example, Linux-based systems today enable users to configure thermal policies [14, 21].

The number and topology of thermal sensors depend on the processor vendor and family. For example, while Intel and VIA processors expose temperature data for individual cores using on-die sensors, some AMD (e.g. Opteron K10 series) processors only allow monitoring the overall temperature of the entire chip using a sensor in the processor socket [1]. Optimising the number and placement of thermal sensors on processors is an active research topic [47, 53, 55].

2.2 Resource Partitioning-based Isolation

Isolation techniques for multi-core platforms that are based on resource partitioning offer a number of benefits. First, resource management approaches that rely on partitioning reduce the size of the software Trusted Computing Base (TCB). In fact, resource partitioning is gaining popularity as a means to create multiple, isolated execution environments without the need for a software TCB in servers [6] and networked embedded systems [57]. Second, the simplicity of partitioning-based resource management eases formal verification and this is leveraged by separation kernels like Muen [23]. Third, modern processors rely on partitioning techniques to build Trusted Execution Environments (TEEs). TEE technologies such as Intel Trusted Execution Technology (TXT) [40], Intel Software Guard Extensions (SGX) [52] and ARM TrustZone [15] protect the execution of security-sensitive software from a compromised operating system. Intel TXT relies on temporal partitioning of resources such as CPU and memory between trusted and untrusted software. Intel SGX and ARM TrustZone use temporal partitioning only for the CPU and implement spatial partitioning for memory resources in the system.

Resource partitioning has already been proposed as a countermeasure against covert channels [30] and side channels [68]. This is because most covert and side channels exploit shared resources. For example, a process can modify shared resources (e.g. cache, file) to communicate covertly with another colluding process. An attacker can also exfiltrate sensitive information from a victim process by tracking the state of a shared resource such as cache. Therefore, there have been proposals for minimising shared resources to reduce the number and effectiveness of covert and side channels. Examples include partitioning of caches [68] and bus-bandwidth [31].

2.3 Motivation

The main motivation behind this work is our observation that despite its security advantages, resource partitioning on multi-core systems might not be able to completely eliminate some types of inference or communication across partitions. More specifically, we want to investigate if the exposure of core temperature information could be used to build both side channels and covert communication channels between processes that execute on different cores within a multi-core system. Our goal is to study these channels primarily in terms of their feasibility and throughput.

Thermal channels are particularly interesting in the context of multi-core systems for two main reasons: *(i)* today, these platforms expose the information from thermal sensors to users and *(ii)* thermal channels can be tested for their effectiveness under the resource partitioning-based isolation mechanisms that multi-core systems can support. To build thermal channels, it is necessary to understand the type and quality of temperature data available on systems today. One must also account for the nature of temperature variations on such systems and the factors that affect them. We focus on Intel x86 platforms for our study given their wide spread use.

3 Thermal Behaviour of x86 Platforms

In this section, we present theoretical and empirical aspects of the thermal behaviour of x86 systems. More specifically, we first discuss recent attempts to analyse, model, and simulate the thermal behaviour of the state-of-the-art processors. Then, we discuss the on-die thermal sensors available on Intel processors and the thermal behaviour of these platforms under a CPU-intensive load.

3.1 Models of Thermal Behaviour

The most common abstraction of the thermal behaviour of processors is the resistor-capacitor mesh network model. This model is based on the well-known duality between thermal and electrical phenomenon [36]. Each physical layer of the processor is modelled separately as a resistor-capacitor mesh. The heat flow between the layers itself and eventually to the environment is represented by connecting the various meshes using additional resistors and capacitors. Such an approach [28] assumes that it is possible to approximate the thermal properties of a processor using a linear model. It also captures factors such as high thermal resistivity of silicon, heat-sinks and fan cooling that affect overall processor temperature.

Alternative empirical approaches that approximate thermal behaviour using measurements from on-die thermal sensors and machine learning techniques have also been explored (e.g. [60]). The advantage of such an approach over using traditional models is that it does not need information such as detailed design parameters (e.g. floorplan of the processor) which are usually not readily available.

Given the complexity of modern commodity processors and the lack of public information required to accurately model them, in this paper, we focus on a more empirical approach. We use measurements from the on-die thermal sensors to understand the thermal behaviour of commodity systems.

3.2 Temperature Sensors in Intel Processors

Intel labels each of its processors with a maximum *junction temperature* which is the highest temperature that is safe for the processor's operation. If the processor's temperature exceeds this level, permanent silicon damage may occur. To avoid such processor melt-down, Intel facilitates processor temperature monitoring by incorporating one digital thermal sensor (DTS) into each of the cores in a processor. The layout of the cores within a processor chip can be identified using `lstopo` [7] on a Linux machine. For example, on the Xeon server used in our experiments, the cores are arranged along a line (as shown in Section 5.1). Each DTS reports the difference between the core's current temperature and the maximum junction temperature [3]. The accuracy of the DTS varies across different generations of Intel processors. They typically have a resolution of $\pm 1^\circ$C.

The absolute value of a core's temperature in °C is computed in software by subtracting the thermal sensor reading from the maximum junction temperature. Thermal data from a sensor can be obtained using special CPU registers of the corresponding core. The data from

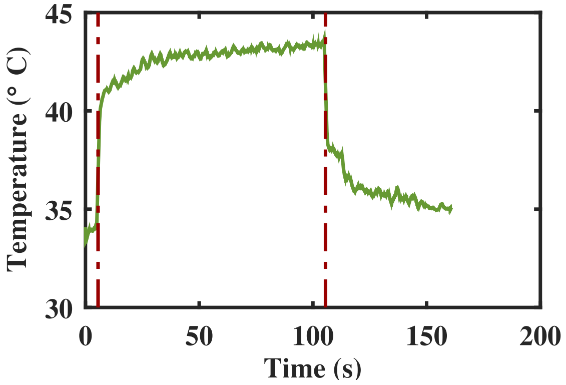

Figure 1: **Thermal Response of a CPU Intensive Application.** Temperature trace resulting from the execution of an application that does RSA decryption in a loop for 100 s. The start and end times of the application's execution are indicated using the two red lines. Temperature increases rapidly initially and saturates over time as an application runs. Similarly, it falls rapidly as soon as the core becomes idle and gradually returns to the ambient temperature.

all sensors is exposed using the `coretemp` kernel module [1] on Linux systems. This information is accessible from user space through the `sysfs` filesystem which is refreshed every 2 ms.

3.3 Example Temperature Trace

To illustrate how computations affect the temperature of a core, we ran a CPU intensive application – more specifically, one that does an RSA decryption continuously in a loop. We ran the application on core 3 of an octa-core processor (for setup details, refer to Section 5.1). Figure 1 shows the recorded temperature trace of core 3 during the execution of the application for 100 s (between the dotted red lines) on it and for about 50 s thereafter when the core cools. We observe that 25 ms after the application begins execution, the temperature rises by 5°C from approximately 35 °C to 40 °C. Following this rapid rise, the temperature increases very slowly and saturates at 43°C. As soon as the application stops executing, the temperature falls rapidly to 38 °C in about 25 ms and takes an additional 11 s to reach 35 °C.

The exponential nature of the temperature rise and fall is a result of the system's thermal capacitance and resistance. The temperature fall curve shows that the temperature changes caused by such an application's execution can be observed for sometime after it has stopped.

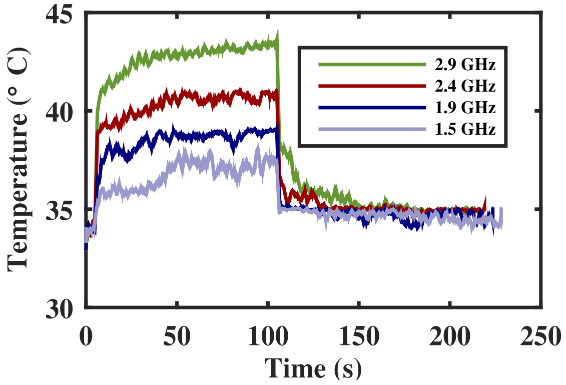

Figure 2: **Effect of Processor Frequency on Thermal Behaviour.** Temperature profiles produced by running a CPU intensive application on a core at different processor frequencies for 100 s.

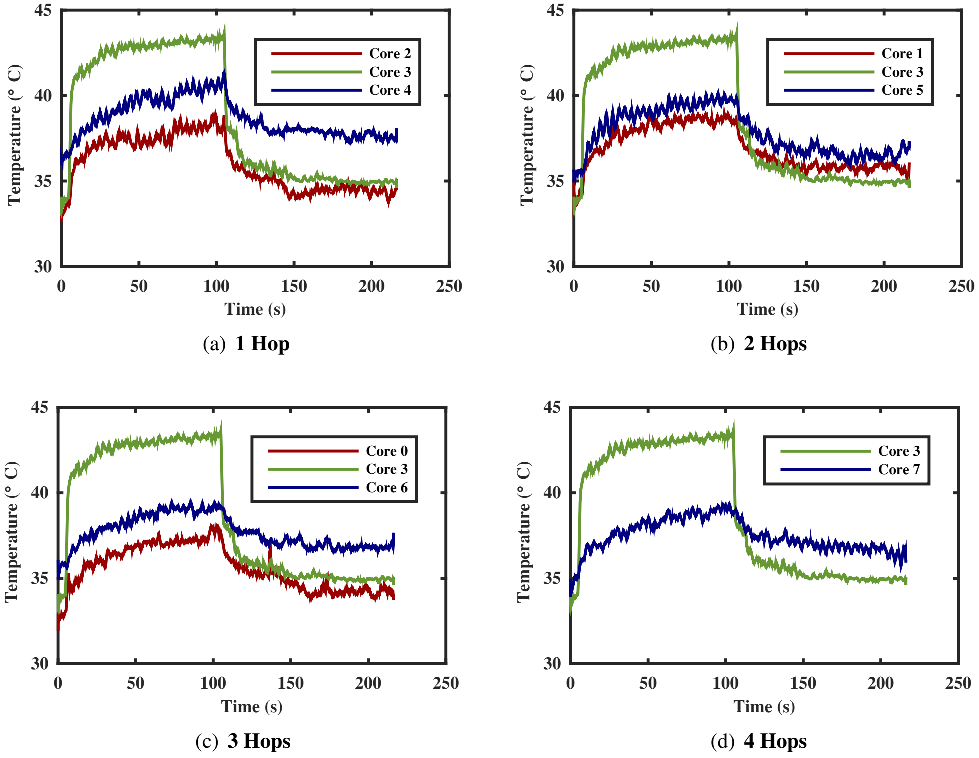
3.4 Factors Influencing a Core's Temperature

The major factors affecting the temperature at a particular core are the fan speed, processor frequency and heat propagation from neighbouring cores. Since, in our experiments, we do not control the server fan speed (see Section 5.1), we only discuss the effect of the processor frequency and heat propagation on a specific core's temperature below.

CPU Frequency. Most Intel processors are designed to run at a set of discrete frequencies for optimising power consumption. For example, in our setup (Section 5.1), the Xeon server can run at frequencies between 1.2 GHz and 2.9 GHz. All cores within a single processor chip run at the same frequency. Changes in frequency at a given core are reflected across all the other cores. The actual frequency can be controlled either by the user or by the kernel; for example, Ubuntu systems allow users to control this using the `sysctl` interface.

Figure 2 shows how the processor frequency affects temperature when a CPU-intensive application runs for 100 s. We can observe that higher frequencies result in more heat and higher saturation temperatures. This is because processor operation at a higher frequency results in a larger power density and therefore, more heat.

Heat Propagation From a Neighbour. The heat resulting from computations on one core will propagate to neighbouring cores. As a result, the temperature at a certain core depends not only on that core's workload (type of computation and schedule) but also those of its neighbours.



(a) **1 Hop**

(b) **2 Hops**

(c) **3 Hops**

(d) **4 Hops**

Figure 3: **Heat Propagation from a Neighbouring Core.** Effect of running a CPU-intensive application on core 3 of an octa-core processor for 100 s on the temperature sensors of its adjacent cores.

Figure 3 shows the effects of a CPU-intensive application executing on a central core (core 3) of an octa-core processor for 100 s. We notice that the computation on core 3 affects the temperature sensors of its neighbouring cores which remain idle all through. Additionally, we observe that the saturation temperature of a neighbouring core decreases with increasing distance from core 3. This effect is not symmetric as one would expect on either side of core 3. We suspect that this is due to an asymmetrically located processor hotspot or asymmetrically positioned thermal sensor.

4 Exploiting Thermal Behaviour

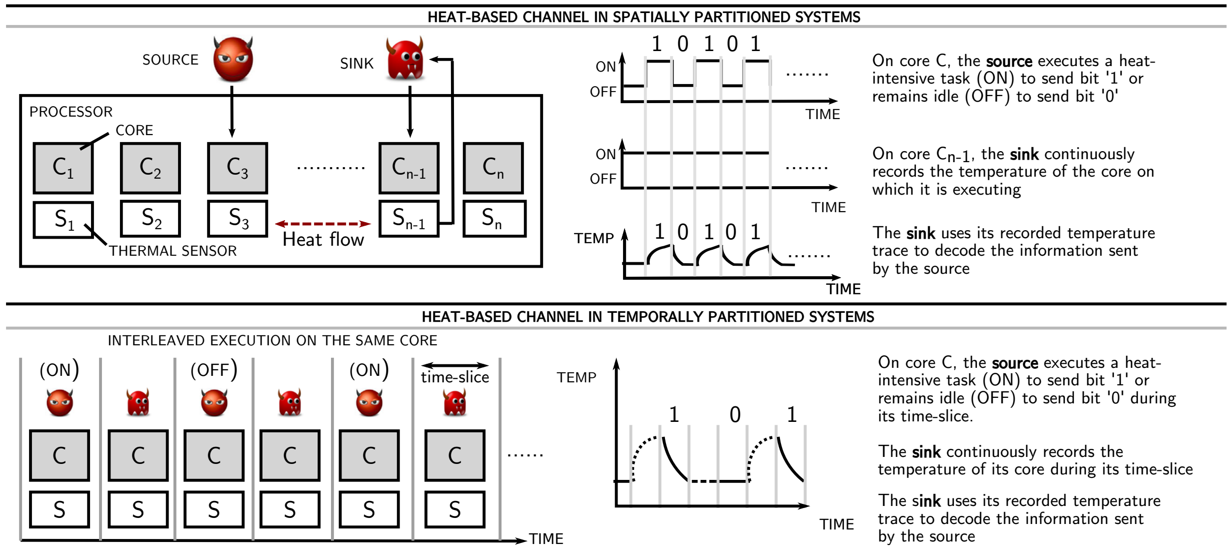
In this section, we present the intuition underlying the construction of thermal channels on multi-core systems.

4.1 Isolation based on Spatial and Temporal Partitioning

Isolation techniques that rely on resource partitioning are becoming increasingly popular and there have been a number of proposals for using such partitioning to prevent covert and side channels [31, 68]. In our work, we consider two most common types of process isolation and partitioning techniques: Spatial and Temporal as shown in Figure 4. In spatially partitioned systems, processes are isolated by being assigned exclusive computation resources, i.e. no two processes share cores or memory. Such an approach prevents certain types of side channels between processes that execute concurrently. For example, cache-partitioning prevents any information leakage that may occur based on the state of the cache-lines in a processor (e.g. how many cache-lines are full). In such systems, processes do not share any processor temperature sensors because they do not use any common CPU resources.

In temporally partitioned systems, the processes share the same resources but run in a time-multiplexed manner. For example, this technique is used by TEEs like Intel TXT in which only one of two partitions (trusted or untrusted) are active at a time but have access to common cores and memory. In systems that employ temporal partitioning, processes that share one or more cores have access to the corresponding temperature sensor(s) during their execution time-slice.

Thermal channels that leverage system thermal behaviour can be used to circumvent both these types of isolation techniques as we describe below.



On core C, the **source** executes a heat-intensive task (ON) to send bit '1' or remains idle (OFF) to send bit '0'

On core Cn-1, the **sink** continuously records the temperature of the core on which it is executing

The **sink** uses its recorded temperature trace to decode the information sent by the source

On core C, the **source** executes a heat-intensive task (ON) to send bit '1' or remains idle (OFF) to send bit '0' during its time-slice.

The **sink** continuously records the temperature of its core during its time-slice

The **sink** uses its recorded temperature trace to decode the information sent by the source

Figure 4: **Covert communication using Thermal Channels.** We demonstrate that the temperature sensors on commodity multi-core platforms can be misused for covert communication by two colluding processes in spatially and temporally isolated systems.

4.2 Constructing Thermal Channels

Based on our discussion in Section 3, we make two observations that can be used to construct thermal channels.

Remnant Heat. Since temperature variations that result from a computation can be observed even after it stops, these variations leak information regarding the computation to the process that follows it in the execution schedule especially if they share the same core. This remnant heat can be exploited as a thermal side channel and may allow a process to exfiltrate sensitive information from its predecessor thereby violating temporal partitioning. Furthermore, it can also be used for communication between two colluding processes that time-share a core. Note that while it is possible to *reset* most resources (e.g. CPU registers, caches) to prevent other types of channels before switching between applications, the remnant heat from a computation (and hence, a thermal channel) is hard to eliminate.

Heat Propagation to a Neighbouring Core. The thermal conductivity of the processor results in heat propagation between cores, i.e, the heat that results from a computation not only affects its underlying core's temperature but also its neighbouring cores. This heat flow can be exploited as a thermal channel by an attacker to make inferences about a potentially sensitive computation at a neighbouring core. Colluding processes can also use the heat flow to communicate covertly. Since it is hard to eliminate heat flows within processors, thermal channels are a viable threat even in spatially partitioned systems.

There are several challenges involved in the construction of thermal channels. First, the nature of temperature changes makes it hard to control the effect that an application's execution will have on the temperature of its own core and its neighbours. Second, the limited resolution of the temperature sensors available on current x86 platforms prevents fine-grained temperature monitoring. Finally, fan-based cooling mechanisms affect the rate and extent of temperature variations.

5 Covert Communication Using Thermal Channels

In this section, we present the feasibility and throughput of communication using thermal covert channels in spatially and temporally partitioned multi-core systems. We first describe our experimental setup that implements such isolation mechanisms. Throughout, we refer to the data sender as the *source* and the recipient as the *sink*.

5.1 Experimental Setup

Our setup is based on an Intel server containing two octa-core Xeon processor chips and running an Open SUSE installation (Figure 5). We use *cpusets* [4] to implement spatial and temporal partitioning. Using cpusets, we restrict the OS to one of the processor chips (Processor 2) and isolate it from the rest of the system. We achieve spatial partitioning by running the source and the sink on

Figure 5: **Our Experimental Setup.** Our framework consists of an Intel Xeon-based server platform running Suse Linux. We use *cpusets* to achieve spatially or temporally isolated source and sink applications. We wrote a custom source application that uses RSA decryption operations to generate heat and a sink application that records its own core's temperature continuously.

separate cores on the Processor 1 with minimal interference from the OS. To realise temporal partitioning, our system incorporates a scheduler that controls the duration and cores on which the source and sink execute.

We wrote a custom application that performs an RSA decryption (using PolarSSL [10]) continuously in a loop and we use it as the source application of the covert channel. We chose a compute intense benchmark like RSA because thermal sensors are typically located in the processor's region which is most likely to experience very high temperatures, such as the ALU [53]. Hence, this benchmark can quickly increase CPU temperature. This choice of benchmark also complies with popular thermal benchmarks (e.g. CStress [5], mprime [8]), that contain applications which extensively use the CPU register file and ALU.

We rely on the server fan for cooling the cores. Our server allows the fan-speed to be configured only through the BIOS. We set the fan-speed to the maximum allowed value (15000 rpm) for our entire study. We chose this setting because it is the most likely setting for servers which run computationally intensive tasks. Our server is currently in a room whose ambient temperature is around 22°C. We also implemented a custom sink application that records the temperature of the core on which it executes continuously.

Our experimental framework is implemented using C. It allows configuration of run-time parameters like the processor frequency, set of applications to run, their schedule and mapping to cores. Initialisation and tear down of the measurement framework is performed using a set of Perl and Bash scripts. Our setup allows us to achieve spatial and temporal isolation; this makes it an ideal platform for our investigation of thermal channels.

5.2 Covert Communication in Spatially Partitioned Systems

This section addresses the construction of thermal channels in the scenario where the source and sink applications run on dedicated cores and execute concurrently. The sink has access only to its own core's temperature sensor and not that of the source as described in the upper part of Figure 4. To communicate covertly in such a scenario, the source exploits the heat propagation from its own core to the sink that runs on a neighbouring core. In this section, we demonstrate the feasibility of achieving this on a commodity multi-core platform and evaluate the throughput of such a communication channel. Below, we first present the encoding scheme that we use for data transmission and then describe the experiments that realise covert communication using the thermal channel.

Encoding and Decoding. The source and sink use *On-Off Keying* for their communication. To send bit '1', the source application runs RSA decryption operations to generate heat and to transmit bit '0', it remains idle. It is important that the source application runs long enough to affect the sink's temperature sensor on a neighbouring core to send bit '1', i.e. it must generate enough heat to raise the temperature of the sink's core above the ambient temperature. We denote the minimum duration for which the source application needs to execute to transmit a '1' bit to the neighbouring cores as T_b. The source remains idle for the same duration to send a '0' bit. We assume that the source and sink *a priori* agree on T_b and a fixed preamble to mark the start of the data.

The sink that records the temperature of its own core continuously does the following to decode the data. It first searches the recorded temperature trace for a fixed preamble. We choose a preamble starting with bit '1' because it can clearly be identified by the sink. To detect the start of the preamble, the sink searches for a '1' bit by detecting the first rising edge, i.e. a temperature increment $\geq$ 2°C given its ambient temperature. We use this threshold because the resolution of the sensors on the platform is ±1°C. It then tries to decode the bits following this to see if they match the preamble. The source repeats this until it recovers the preamble from the temperature trace. It then decodes the remaining bits using a simple edge detection mechanism in which a rising edge indicates bit '1', a falling edge indicates bit '0' and a no-change implies that the value is the same as the previous bit.

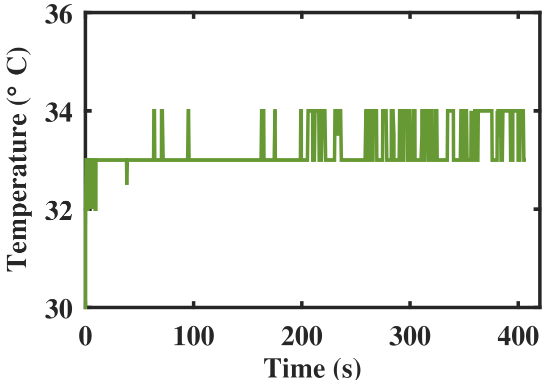

Figure 6: **Temperature Drift due to the Sink's Execution.** The temperature drift caused by the execution of the sink itself is very slow as shown here. This trace was recorded over 400 s by running the sink application on core 3 with all the other cores idle. Note that the resolution of the sensor is ±1°C.

T_b(ms)	Bit Error (%)	
	Core 2 (1-hop)	Core 1 (2-hop)
250	18	–
500	14	–
750	13	–
1000	11	24
1250	9	26
1500	8	15

Table 1: **Calibration of T_b in Spatially Partitioned Systems.** We send a block of 100 bits consisting of alternating ones and zeroes using different T_b values from the source (core 3) to the sink that runs at one and two hop distances from it. The processor frequency was set to 2.9 GHz and this table shows the resulting bit-error rates ('–' indicates that the data could not be decoded). We observe when $T_b \geq$ 500 ms, we can decode data with less than 15% error at one hop but this does not improve much by increasing T_b to 1500 ms. We also notice that the required T_b increases with greater distance from the source. At a one hop distance, setting T_b = 750 ms and using Hamming(7,4) error correction code results in a channel throughput of up to **0.33 bps**.

Temperature Drift due to the Sink's Execution. The sink relies on the source to affect its core's temperature sensor for communication. However, to do this, it is necessary to isolate any temperature drifts that may be caused by the sink's execution itself on its own temperature sensor.

To understand these drifts better, we run the sink for a long time and observe its temperature. Figure 6 shows the temperature trace of core 3 when the sink is running on it for 400 s and the other cores are idle. The core's temperature remains stable at around 33°C for 200 s and later drifts slowly towards 34°C. Therefore, we conclude that the temperature changes caused by the execution of the sink process itself is negligible over a long duration of time (e.g., 200 s).

Calibration of T_b. Before the actual transmission of data, we have to determine the optimal value of T_b, i.e. the duration for which the source executes or remains idle to send bit '1' and bit '0' respectively. Note that the actual value of T_b depends on the relative locations of the source and the sink. This is because the effect of the source's execution affects the cores farther away from it to a lesser extent (see Section 3). For our first experiments, we fix the source to execute on a core 3 because it is a central core and the sink to execute on core 2. We later describe the effects of increasing the distance between the source and the sink on T_b.

To estimate T_b, we first set it to a value between 50 ms and 1500 ms. We then attempt to send 100 data bits from the source on core 3 to the sink on core 2 and observe the resulting temperature traces on core 2. We do this by configuring the source application to be active and idle for T_b alternately. Our data consist of 50 alternating ones and zeros. We choose this data sequence because it is important to ensure that the chosen T_b consistently results in the desired temperature increment on core 2.

We were unable to decode data when T_b was smaller than 250 ms. We observe that data transmission using $T_b \geq$ 500 ms results in about 10% bit errors (Table 1). Furthermore, we notice that the bit error rate does not improve much by increasing T_b from 500 ms to 1500 ms. Figure 7 shows the temperature traces of the two cores during the data exchange using a T_b = 750 ms. The data shown here has been post-processed to remove noise using a smoothing function. We observe that the temperatures of core 3 and core 2 are well-correlated (correlation co-efficient $\simeq$ 0.55, p-value = 0).

Error Rate. To understand the nature of errors in thermal channels, we send a pseudorandom sequence of a 1000 bits in 100-bit blocks. Each block begins with a preamble to enable the sink to detect the start of data transmission.

From our initial experiments, we observe that the temperature traces of core 2 and core 3 are well-correlated in time over a sequence of alternating ones and zeros (Figure 7). Therefore, we choose a preamble of five alternating ones and zeroes (10 bits in total). The source and sink synchronise in 9 out of 10 tests and the average error rate is 13.22 % (± 5.19) for a T_b value of 500 ms. On increasing T_b to 750 ms and 1000 ms, the source and

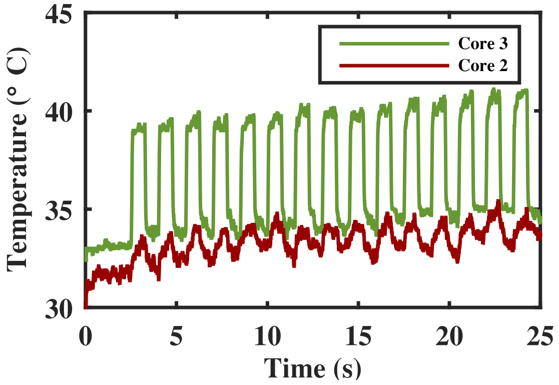

Figure 7: **Thermal Communication in Spatially Isolated Systems.** Temperature traces recorded during the transmission of the 30 bits (15 ones and 15 zeroes) from the source (core 3) to the sink (core 2) using a T_b = 750 ms.

sink synchronise over all 10 tests and the average error rate is 11.3% (± 2.83) and 11% (± 3.83) respectively.

Varying the Sink's Location. We repeat similar experiments by running the sink on core 1 and core 0 which are two and three hops away from the core 3 to see how the error rate varies with increasing distance from the source. At a two hop distance, we observe that for a given T_b, the error rate is higher than in the case of the one hop (Table 1). At a three hop distance, we were unable to decode data at 1500 ms. However, increasing the value of T_b sufficiently will allow data transmission at a 3-hop distance. For example, Figure 3(c) shows an extreme case in which T_b is set to 200 s to transmit bit '1'.

The increased error rate and deterioration in the ability to decode data is expected. This is because heat resulting from computations at a given core affects the cores closer to it more than the cores farther away. We repeated the experiments to estimate the error rate from the source (core 3) to a sink running on core 1 at a two hop distance. We observe that the source and sink synchronise successfully in 9 out of 10 tests. We can transmit data at the rate of 1 bit in 1.5 s (T_b = 1500 s) with an error rate of 18.33% (±4.21).

T_b(ms)	Bit Error (%)	
	2.9 GHz	2.4 GHz
250	18	–
500	14	23
750	13	24
1000	11	23
1250	9	14
1500	8	14

Table 2: **Effect of Processor Frequency on Required T_b.** We send a block of 100 bits consisting of alternating ones and zeroes using different T_b values from the source (core 3) to the sink (core 2). The table shows the resulting bit-error rates at different processor frequencies ('–' indicates that the data could not be decoded). We observe that when the processor runs at lower frequencies, T_b has to be increased to achieve lower bit-error rates.

Effect of Frequency on T_b. To understand the effect of processor frequency on T_b, we repeated our experiments for 1-hop communication at lower frequencies, namely, 2.4 GHz and 1.9 GHz. As shown in Table 2, for a given T_b, the error rate increases at lower processor frequencies. When the processor frequency is set to 1.9 GHz, we could not decode data even at 1500 ms. We note that using a larger value for T_b would solve this problem and can be done using the same methodology we used for our experiments. This deterioration in error rates and the ability to decode data itself is expected because lower frequencies result in lesser heat generation from a given computation. Therefore, the rise in temperature may not be significant enough to detect a bit '1' .

We repeated the data transmission experiments when the processor frequency is set to 2.4 GHz. We transmit a pseudo-random sequence of 1000 bits in 100-bit blocks. Each block is preceded by a preamble and is sent from the source (core 3) to the sink (core 2) using T_b = 1250 ms and 1500 ms. In both cases, the source and sink synchronise in all 10 tests. The observed error rates in both cases is similar, i.e. 14.9% (± 3.9) and 15.9% (± 6.08) for T_b = 1250 ms and T_b = 1500 ms respectively.

Throughput Estimation. From the above discussion, we conclude that the throughput of thermal covert channels in spatially partitioned systems depends on number of factors. This includes the time required to transmit one bit of information (T_b) and error rates. Both these parameters in turn depend on the processor frequency and the distance between the colluding processes.

At 1-hop distances, given a T_b of 750 ms, the throughput would be 1.33 bps in the ideal case without any errors. However, due to the 11% errors that we observe in the experiments, actual communication would require error correction to be implemented. When we analysed the nature of the errors, we found that for every four bits, with a probability of over 0.9, there was one or no errors. Therefore, we could use a Hamming (7,4) error-correction code to correct for these errors. This would result in 75% overhead and hence, an effective throughput of 0.33 bps. When the frequency is changed to 2.4 GHz, the throughput is about 0.2 bps using a Hamming (7,4) error correction code. A similar trend was observed on

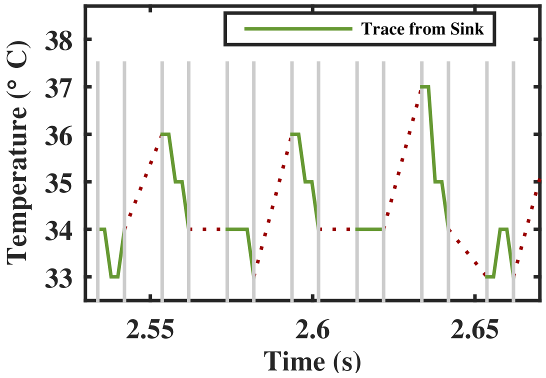

Figure 8: **Thermal Communication in Temporally Isolated Systems.** Temperature traces recorded during the transmission of the 6 bits (3 ones and 3 zeroes) from the source to the sink. The source and the sink execute in alternate time-slots of 10 ms (marked in grey) on core 3. The thick lines are the actual temperature traces recorded by the sink and the dotted lines represent the temperature changes that occur as a result of the source's execution.

increasing the distance between the source and sink. Although the thermal channel's throughput is low, it still allows the transfer of sensitive data like credit-card information (16 digit) in a few minutes. We discuss other factors that affect the thermal channel's throughput in Section 5.4.

5.3 Covert Communication in Temporally Partitioned Systems

Temporal partitioning schemes securely multiplex the same resources (e.g. cores, memory) between several applications. Systems that use this technique mitigate information leakage through side channels by clearing caches, registers, etc. while switching between processes. However, the thermal footprint of an application (the source) remains intact for observation by the other application that executes after it on the same core (the sink). This is a result of the thermal capacitance and resistance of processors and can be exploited to communicate covertly as our experiments demonstrate.

Scheduling, Encoding and Decoding Schemes. In temporally partitioned systems, a scheduler determines the order in which different partitions execute on a core. Therefore, we implement a scheduler (Figure 5) that realises this functionality. Since the sink and source share the same core, they run in an interleaved manner and the sink has access to the temperature sensors only during its execution time-slice (t_s). Note that t_s is controlled by the system's scheduler while T_b is controlled by the applications. If the execution time-slice (t_s) $\leq T_b$, then communication becomes difficult because the source cannot generate enough heat to transmit '1' bits. However, if $t_s \geq T_b$, then the source can choose to execute for long enough to cause a temperature change that the sink notices. Note that temperature variations over the course of the source's execution within one time-slice are not visible to the sink; instead the sink only has access to the final temperature after the source's execution time-slice. Therefore, in our implementation, the source sends a single bit per time-slice (using the temperature at the end of that time-slice) to the sink over a thermal covert channel, i.e. $T_b = t_s$. We use the same On-Off keying technique as before in Section 5.2.

T_b(ms)	Bit Error (%)		
	2.9 GHz	2.4 GHz	1.9 GHz
10	0	4	0
15	0	1	1
20	0	0	1
25	0	0	0
30	0	0	0

Table 3: **Effect of Processor Frequency on Required T_b.** We send a block of 100 bits consisting of alternating ones and zeroes using different T_b values from the source (core 3) to the sink that runs on the same core. The table shows the resulting bit-error rates at different processor frequencies. We observe that the error rates do not change much even at lower processor frequencies. Setting the frequency to 2.9 GHz, T_b to 10 ms and using Hamming(7,4) error correction code leads to the channel throughput of up to **12.5 bps**.

Calibration of T_b. We consider the scenario in which the sink and the source share a core and run in a round-robin fashion. The source heats up the processor (bit '1') or stays idle (bit '0') to send one bit of information to the sink application that runs immediately after.

In order to understand how fast one can transmit bits over such a channel, we do the following. We try to send an alternating sequence of 50 ones and 50 zeroes from the source to the sink. We vary T_b between 10 ms which is the minimum value that our framework allows and 30 ms. The source and sink run on core 3 in our experiments. Figure 8 shows an example temperature trace that the sink records during its execution. Note that the sink has access to the shared core's temperature sensor only during its own time-slice. We observed no errors in the data that the sink decodes for $T_b \geq 10$ ms and therefore, use this value for further experiments. We also repeated the experiment on the cores at the corners (core 0 and core 7) and noticed similar results.

Error Rate. To understand the nature of errors in this channel, we send a pseudorandom stream of 1000 bits in 100-bit blocks using T_b = 10 ms. We send 10 bits for synchronisation at the beginning of every block similar to the experiments in Section 5.2. The synchronisation using the preamble was successful in all cases and the data transmission resulted in error rates of 7.6% (± 1.9), 9.5% (± 4.86) and 7.1% (± 2.23) for experiments on cores 0, core 3 and core 7 respectively.

Effect of processor frequency on T_b. We repeated our experiments at two lower processor frequencies to understand how it may affect the required T_b for reliable communication. In the T_b calibration experiments, the error rates remain low despite the decrease in frequency (Table 3). In the actual data transmission tests (of 1000 bits in 100 bit blocks) at 2.4 GHz, the source and the sink successfully synchronise in all 10 tests and the error rate is about 6.5% (±3.58). At 1.9 GHz however, the synchronisation succeeds only 5 out of 10 times and the error rate is 9.5% (±2.55). This indicates that a higher T_b value is required for more reliable communication at this lower processor frequency.

Throughput Estimation. The throughput of the thermal channel in temporally partitioned systems depends on the execution schedule of the applications and the time required to send one bit of information ($T_b = t_s$). We note that typical Linux systems have a time-slice of about 100 ms which is 10 times bigger than the one we need for implementing thermal covert channels.

When T_b is 10 ms, we would expect the throughput of the thermal channel would be 50 bps. However, since the communication is error prone and results in up to 10% error, the encoding scheme would have to incorporate error correction codes. On analysing the nature of the errors during the transmission of a 1000 bits, we see that with a probability of over 0.9, there is 1 or no errors in every four data bits. Therefore, we can use a Hamming(7,4) code to overcome these errors and this results in an effective throughput of about 12.5 bps. This throughput is independent of which particular core the source and sink share (core 0/3/7). A T_b of 10 ms results in low error rates even at a processor frequency of 2.4 GHz and hence, the throughput is roughly 12.5 bps. We note that this data rate would allow the transmission of sensitive information such as credit-card details (16 digits) in about 5 s.

5.4 Other Factors Affecting Throughput

We have explored how factors like processor frequency and relative locations of the source and sink affect the throughput of the thermal covert channel. Below we discuss additional parameters that affect the throughput. An exhaustive evaluation of these factors is beyond the scope of the paper and is intended as part of future work.

Noise from Other Workloads. On a given system, the throughput of a thermal communication channel will depend on the actual workloads running on that platform. In the case of thermal channels in spatially partitioned systems, the exact effect of a concurrent workload on the throughput will likely depend on the nature of the workload and its relative distance from the sink's core. On the one hand, a workload that saturates its own core's temperature is only likely to increase the sink's temperature by a constant amount without disturbing the actual communication patterns. On the other hand, a workload that runs in the opposite schedule as the source (i.e. it is active whenever the source is idle and vice-versa) is likely to result in increased errors at the sink's core. Analogous discussions hold in the case of temporal channels. Finally, if the attacker controls more than one core on the platform, then he could potentially generate more heat and build faster channels but this requires further exploration.

Other Encoding and Error-Correction Schemes. In our experiments, we used the On-Off keying technique to transmit data. Instead, to improve throughput, one could borrow techniques from signal processing and telecommunications such as multi-level encoding. One could alternatively use bi-phase encoding schemes such as Manchester-coding that would lower the data rate (e.g. by half) but also result in fewer errors. Furthermore, in order to detect and correct more than single-bit errors, one could implement alternative error correction schemes such as Reed-Solomon [62] or BCH [18]. For example, a Reed-Solomon RS(32,28) code encodes a 28-word data into a 32-word codeword and is capable of correcting errors up to 2-words in length.

We note that our experiments were performed in conditions that minimise any noise that may arise from other concurrent workloads such as the OS. Given this and the low resolution of the thermal sensors (±1°C), we believe that an order of magnitude improvement in the throughput is unlikely.

6 Thermal Channels for Unauthorised Profiling

In this section, we present a preliminary study of how thermal side channels enable unauthorised thermal profiling of processes even in systems that implement strong isolation mechanisms like spatial resource partitioning. In contrast to thermal covert channels in which the source and the sink collude to exchange data, thermal side channels allow an attacker to exfiltrate information from a *victim* without requiring any cooperation from the victim.

The heat generated from an application (which we refer to as the victim) can be observed from its neighbours. This may leak information regarding the nature of its computation to processes at other cores. More specifically, if the attacker has reference thermal traces for victim applications, he can recognise if and when such an application executes on a neighbouring partition. For example, identifying that a sensitive or potentially vulnerable application is running on a neighbouring core may aid an attacker in preparing or launching an attack. Application identification based on temperature traces has not been addressed previously in literature. Below we present a first study that tries to understand its effectiveness as an attack vector.

Goal and Intuition of the Attack. We assume that an attacker has access to a reference thermal trace of the victim application (say RSA decryption). Such a trace can be obtained by the attacker if he has access to a similar platform as the one he is attacking. The attacker's goal is to verify if the temperature trace of his core is a result of the victim application's execution on a neighbouring core. Note that the attacker does not have access to the temperature trace of its neighbouring core(s) but only to that of his own core. For simplicity, we assume that only the attacker and the victim are active during the attack and that they are collocated on adjacent cores. The attacker continuously monitors his own core's temperature and then, correlates it with a reference trace of the victim application. A strong correlation indicates that the attacker's temperature trace was a result of the execution of the victim application with high probability.

Experiments and Analysis. We chose a set of five CPU-intensive applications including RSA decryption and four applications from a benchmark suite, MiBench [32] (ADPCM, Quick Sort, BitCount, BasicMath) and use them as the universal set of applications that a victim core (core 3) executes. We intentionally chose similar applications all of which stress the ALU and register file region of the core. This choice makes our task harder than distinguishing between applications with very distinct thermal behaviour, for example, an idle application vs. a thermal benchmark. A deeper exploration of the thermal behaviour of different classes of applications (memory intensive, I/O intensive, etc.) and their distinguishability is out of the scope of this work.

To understand the feasibility of identifying these applications, we ran each of them for 200 s on core 3 of our setup (Section 5.1) and collected the temperature traces of a neighbouring core (core 2). We repeated this five times for each of the applications and Figure 9 shows one such trace for each of them. We observe that the saturation temperature for the RSA decryption application is higher than the rest.

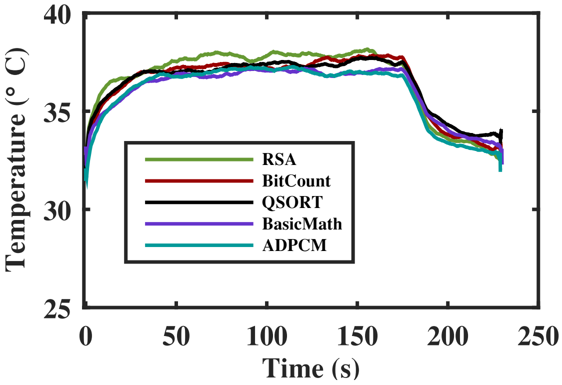

Figure 9: **Example Temperature Traces of Different Applications.** We used a set of five CPU intensive applications (RSA decryption, BitCount, QSort, BasicMath, ADPCM) from a popular MiBench benchmark suite [32]. We ran each application for 200 s separately and recorded the resulting temperature traces on a neighbouring core.

We use simple correlation as a metric to measure similarity/differences between pairs of applications. We first correlated the traces from the RSA application. Since there are 5 runs, we have 10 pairs to correlate. We observe that the correlation is higher than 85% in seven out of ten occasions. Using this same correlation threshold of 85% also results in 28% false positives when the RSA application is correlated with the others from the benchmark suite. In general, traces belonging to the same application have high correlation values ($\geq$ 80%). However, traces belonging to different applications also show high correlation because they are all CPU intensive and stress similar parts of the CPU ($\geq$ 75%). Therefore, we conclude that using a simple correlation metric would only allow distinguishing applications that behave very differently. More sensitive metrics (such as thermal models [60] or machine-learning based classifiers) are required for better accuracy in other cases.

Finally, more fine-grained data exfiltration such as deducing AES or RSA keys on commodity x86-systems using the thermal side channel is an open, unexplored problem. A key challenge is the limited resolution of the temperature sensors which is ±1°C and the rate at which the sensors are refreshed (currently, once every 2 ms).

7 Discussion

In this section, we present possible countermeasures against thermal channels and discuss their limitations. We also discuss a potential security application for thermal channels.

Countermeasures. Since we leveraged the temperature information exposed to software to construct thermal channels, a natural solution to this problem would be to restrict access to temperature sensors on the system. However, such information cannot always remain hidden. For example, centralised control and monitoring of thermal states does not scale well with the advent of many-core processors [41]. Such processors contain hundreds of cores and host a large number of autonomous processes on separate cores. In fact, research prototypes like Intel's SCC platform [41] already allow subsets of cores to administer their frequency and voltage independently for power-efficiency; temperature information is a vital input to this decision process. The software at each core should track thermal information to schedule intelligently and to detect if any of its threads are misbehaving. *Therefore, there is a tension between securing platforms and improving their energy-efficiency by exposing thermal data to software applications.*

Even if one restricts access to the temperature sensors, related parameters may still leak information about the system's thermal state. Examples of such parameters are clock skew, fan speed and even processor frequency in systems that allow dynamic frequency scaling. Since all these parameters are usually common across cores or subsets of cores within a processor chip, they can still provide a signalling mechanism. Finally, while it may be possible to separate processes temporally and spatially to limit the effectiveness of thermal channels, such resource allocation strategies are wasteful and result in low resource utilisation.

Thermal Fingerprinting For Security. So far we discussed only how thermal behaviour of systems can be exploited by attackers. The same properties could be used for achieving better security. Since temperature changes resulting from computations are difficult to avoid, we hypothesise that thermal profiling techniques can also be used to detect any anomalous behaviour in the execution of an application. More specifically, it is highly likely that run-time compromise of an application results in a temperature trace that does not match its original *thermal fingerprint*. It has been shown to be possible to extract thermal models by monitoring the application under controlled conditions [60, 61]. By comparing the actual execution trace to the expected trace, it may be possible to detect run-time compromise of software applications.

More generally, understanding the capacity of thermal channels using information theory will help assess the throughput of covert communication. Similarly, a theoretical estimation of the entropy of such channels will help bound fingerprint accuracy and hence, side channel leakage. A more detailed study along these lines is an interesting direction for future work.

8 Related Work

We review previous work on covert and side channels on x86 systems and on thermal channels in general. We also provide examples of existing literature on optimising computing systems for thermal efficiency because it highlights the advantages of exposing thermal data as opposed to the other work that misuses this data to undermine security.

Thermal Channels and Attacks. There is no previous work that demonstrates the feasibility of thermal covert and side channels on commodity multi-core systems as we do in this paper. Previously, two works discussed and one implemented thermal covert channels on FPGA boards [19, 38, 51]. There have also been attempts to transmit data between two processes by changing fan-speed [20]. The ability to remotely monitor a system's clock-skew (influenced by the changes in the system temperature) has also been exploited in the past for exposing anonymous servers [56, 75] and covert communication with a remote entity [74]. We note that although some of these works [20, 74] use the term thermal channel, none of them use the thermal information available on modern systems to covertly communicate between processes on the same host as we do in this paper.

More recently, it has been shown that it is possible to use temperature variations to induce processor faults [59] which can in turn be also be used to extract sensitive information like RSA keys [37]. Thermal information can also be used for coarse-grained data-exfiltration. For example, since temperature directly reflects the intensity of computation, it can be used to estimate the load or resource utilisation of a machine. This was illustrated by Liu et al. who computed the resource utilisation of servers in Amazon's EC2 using the temperature data that is exposed to virtual machines [49].

Previous research has identified other security risks that arise from hardware and software thermal management techniques on modern systems. For example, malicious processes may cause a denial-of-service by slowing down the processor [33] or permanently damaging hardware by causing thermal hotspots [27]. Such processes could exploit the fact that certain architecture components (e.g. instruction cache) are ignored by thermal optimisation approaches on processors [45].

Covert and Side Channels on x86-Systems. Originally defined by Lampson as part of the confinement problem [46], today, several covert channels have been identified and explored in the context of x86 systems. Covert channels can be classified either as timing or storage channels. Timing covert channels transmit information in terms of the timing of certain events. Examples of timing covert channels include cache-based and memory bus-based channels both of which were first demonstrated by Hu [34, 35]. Wang et al. identify more timing channels that arise out of processor extensions such as multi-threading and speculative execution [68]. Wu et al. achieve improved data rates on bus-based channels [71]. Covert timing channels that use other types of shared resources like virtual memory deduplication [72] and input devices such as keyboards [64] have also been studied.

In contrast to timing channels, storage channels rely on the source writing the data (indirectly) into a shared resource which the sink reads at a later point in time. Lampson's file system based covert channel [46] and covert channels that exploit CPU registers (e.g. FPU registers that signal exceptions) [65] are examples of such channels. Interestingly, certain types of covert channels such as those based on the hard-disk [70] and processor cache [22, 35] can be used to realise timing and storage channels. We could classify the thermal covert channels as storage channels because they use the CPU registers to (indirectly) exchange information.

While covert channels rely on two colluding entities for data exfiltration, side channels can be used to extract information from a unsuspecting victim without any co-operation from it. Side channels can be classified as access-driven channels, trace-driven channels and timing-driven channels. Access-driven side channels rely on a victim's modifications to a shared resource (e.g. cache) to extract sensitive information (e.g. AES keys [76]). Trace-driven channels require measuring a certain aspect of the system such as power (e.g. [43]) or electromagnetic emanations (e.g. [29]) continuously as the victim executes. Finally, timing-based side channels measure the time consumed by sensitive operations (e.g. cryptographic functions) to extract information (e.g. such as AES keys [17]). In general, side channels are used for cryptanalysis. Example attacks include extraction of AES keys [11, 17, 42, 76], DES keys [58] and RSA keys [22, 43, 44]. They can also be used to extract more coarse-grained information such as co-residency [63], existence of files [67], etc. The thermal side channel can be viewed as a trace-driven side channel that continuously tracks temperature to identify the computation at a neighbouring core.

One way to mitigate timing channels (both covert and side channels) in general is to expose less accurate timing information [34]. This technique is unlikely to be effective against thermal channels because they do not exploit timing information. Another general approach against side and covert channels is to partition system resources. This is for example used to mitigate cache-based channels [68] and bus-based channels [31]. However, such partitioning techniques will not eliminate temperature-based channels completely as demonstrated in this paper.

Thermal Monitoring of Processors. Temperature management of computing systems has gained importance over the last few years due to the increasing on-chip temperatures of modern processors. This has resulted in efforts to design and implement better thermal management techniques for processors. Examples include optimisation of sensor placement (e.g. [53, 55]), improving algorithms for dynamic temperature management (e.g. [73]) and cooling techniques [25]. There are also ongoing efforts to develop frameworks to thermally profile applications [61], build temperature-aware schedulers [24, 26] and micro-architectures [48, 66]. Thermal profiling can further be used to detect compromised process in embedded systems [69] and design schedulers such that they do not leak information through thermal fingerprints of applications [16].

9 Conclusion

In this paper, we demonstrated the feasibility and potential of thermal channels on commodity multi-core systems. We showed that such channels can be built by exploiting the thermal behaviour of current platforms. Thermal channels can be used to circumvent strong isolation guarantees provided by temporal and spatial partitioning techniques. Our experiments indicate that it is possible to use them for covert communication between processes and achieve a throughput of up to 12.5 bps. We also demonstrated that thermal channels can be exploited to profile applications running on a neighbouring core. Our work points to a limitation in the isolation guarantees that resource partitioning techniques can provide.

Attacks based on thermal channels are further facilitated by the increasing trend towards exposing system temperature information to users. This would enable users to make thermal management decisions for efficient system operation. This paper highlights the tension between designing systems to support user-centric thermal management for efficiency and security.

Abstract

Sensing and actuation systems contain sensors to observe the environment and actuators to influence it. However, these sensors can be tricked by maliciously fabricated physical properties. In this paper, we investigated whether an adversary could incapacitate drones equipped with Micro-Electro-Mechanical Systems (MEMS) gyroscopes using intentional sound noise. While MEMS gyroscopes are known to have resonant frequencies that degrade their accuracy, it is not known whether this property can be exploited maliciously to disrupt the operation of drones.

We first tested 15 kinds of MEMS gyroscopes against sound noise and discovered the resonant frequencies of seven MEMS gyroscopes by scanning the frequencies under 30 kHz using a consumer-grade speaker. The standard deviation of the resonant output from those gyroscopes was dozens of times larger than that of the normal output. After analyzing a target drone's flight control system, we performed real-world experiments and a software simulation to verify the effect of the crafted gyroscope output. Our real-world experiments showed that in all 20 trials, one of two target drones equipped with vulnerable gyroscopes lost control and crashed shortly after we started our attack. A few interesting applications and countermeasures are discussed at the conclusion of this paper.

1 Introduction

Sensors are devices that detect physical properties in nature and convert them to quantitative values for actuators and control systems. In many sensing and actuation systems, actuations are determined on the basis of information from sensors. However, these systems can malfunction because of physical quantities that sensors fail to measure or measure insensitively. Furthermore, most sensors cannot distinguish between normal and abnormal physical properties. Therefore, sensors can measure malicious inputs that are intentionally crafted by an attacker in addition to the physical stimuli that the sensors should detect. Because providing detection capabilities for attacks against sensors increases production costs, most commercial devices with sensors are not equipped with any ability to detect or protect against such attacks.

Recently, many sensor-equipped devices, such as smartphones, wearable healthcare devices, and drones, have been released to make the devices easier and more convenient to use. In particular, commercial and open-source drones have been widely used for aerial photography, distribution delivery [2, 3], and private hobbies. These drones have multiple sensors, such as gyroscopes, accelerometers, and barometers. A gyroscope measures changes in tilt, orientation, and rotation based on angular momentum. It is thus a core sensor for flight attitude control and position balancing.

To make the flight control modules of drones small, lightweight, and inexpensive, Micro-Electro-Mechanical Systems (MEMS) gyroscopes are used. MEMS gyroscopes are designed as Integrated Circuit (IC) packages. Each design has a unique mechanical structure in the IC package. Depending on the structure of the MEMS gyroscope, resonance occurs as a result of sound noise at resonant frequencies [37, 38, 39, 49]. This resonance causes performance degradation of the gyroscope.

The resonant frequencies of MEMS gyroscopes are usually designed to be higher than the audible frequency band to prevent malfunctioning of the sensing and actuation systems. However, in our experiments, we discovered that some MEMS gyroscopes that are popularly used in commercial drones resonate at audible frequencies as well as ultrasonic frequencies. Our experiments were designed and conducted to analyze how drones are affected by this phenomenon from an adversary point of view. The flight control software of our target drone was also analyzed to examine the propagation of this phenomenon through the whole system. The results of our real-world experiments and a software simulation show that this phenomenon could be exploited to launch incapacitating attacks against commercial drones.

The contributions of this research to the field can be summarized as follows:

- We found, using a consumer-grade speaker, that the resonant frequencies of several popular MEMS gyroscopes are not only in the ultrasonic frequency band but also in the audible frequency band, and we analyzed their resonant output.

- We investigated the effect of the resonant output of MEMS gyroscopes on the flight control of drones via software analysis and simulations.

- We developed a novel approach to attacking drones equipped with vulnerable MEMS gyroscopes using intentional sound noise, and we demonstrated the consequences of our attack in real-world experiments [1]

This paper is organized as follows: Section 2 outlines security research to date on sensor systems. Section 3 provides background information on drone systems and MEMS gyroscopes. Section 4 describes the analyses and experiments conducted in this study to investigate the effects of sound noise on MEMS gyroscopes. Analysis of the flight control software, real-world experiments, and simulations for attacking drones are described in Section 5. A discussion of the results and conclusion drawn from the results are presented in Sections 6 and 7, respectively.

2 Related Work

The security of sensors recently started to draw attention with the introduction of consumer-grade sensing and actuation systems. As this study was focused on input spoofing attacks on gyroscopes, we review in this section previous researches on 1) privacy issues related to gyroscopes, 2) resonant frequencies of gyroscopes, 3) security analyses of commercial drones, and 4) input spoofing attacks on sensing circuitry.

Privacy Issues Related to Gyroscopes: Embedded devices can be used to record the private information of users without their recognition. Because a gyroscope can be used to measure changes in tilt, orientation, and rotation, it can be used to steal a smartphone user's keystroke information, such as unlock passwords, banking passwords, and credit card numbers [36, 47]. By exploiting the capability of the gyroscopes of smartphones to measure acoustic vibrations at a low frequency band, a new attack was proposed to eavesdrop speech [59]. The focus of these studies differed from that of this paper in that they examined the use of gyroscopes to extract private information, without affecting actuation.

Resonant Frequencies of Gyroscopes: Resonant frequency has been identified as a problem that causes the performance degradation of MEMS gyroscopes. In general, the vibrating structures of MEMS gyroscopes have resonant frequencies. Resonance can occur as a result of sound noise [37, 38, 39]. Some mechanisms for mitigating interference from sound have been proposed. Roth suggested a simple and cheap defense technique that involves surrounding the gyroscope with foam [49]. Soobramaney proposed the use of an additional structure in a gyroscope that responds only to the resonant frequency to cancel out the resonant output from the gyroscope [52]. Using an additional feedback capacitor connected to the sensing electrode, the resonant frequency and the magnitude of the resonance effect can be tuned [35, 43]. It is widely believed that most consumer-grade MEMS gyroscopes have resonant frequencies. However, these resonant frequencies are often considered to be commercial secrets or are designed to be just higher than the audible frequency range.

Security Analysis of Commercial Drones: There were a couple of works on hacking commercial drones. Samland et. al. showed that *AR.Drone* [5] was vulnerable to network attacks due to unencrypted Wireless LAN (WLAN) communication and the lack of authentication for Telnet and FTP [50]. Kamkar showed that a drone can be hijacked by another drone using similar vulnerabilities [44]. Attacks such as these are focused on hijacking network connections or system privileges.

Input Spoofing Attacks on Sensing Circuitry: All sensing and actuation systems have sensing circuitry that is composed of the sensor itself and a wire that connects the sensor to other components of the system. Kune et. al. showed that an adversary can inject an Electro Magnetic Interference (EMI) signal into the wire connecting an analog sensor and Analog-to-Digital Converter (ADC) to fake a sensing signal [45]. By injecting fake waveforms, the researchers were able to inhibit pacing or induce defibrillation shocks in Cardiac Implantable Electrical Devices (CIEDs). Without affecting the sensor itself, they were able to spoof the sensing signal by injecting an EMI signal into the sensing circuitry.

It is also possible to affect the sensor itself. For example, biometric imaging sensors have frequently been targeted in sensor spoofing attacks. Tsutomu et al. showed that a verification rate of more than 68 % could be achieved against 11 different fingerprint systems using artificial fingers [46]. Galbally et al. fabricated fake

[1] A demo video of our attack against the target drone in the real world is available at `https://sites.google.com/site/rockingdrone/`.

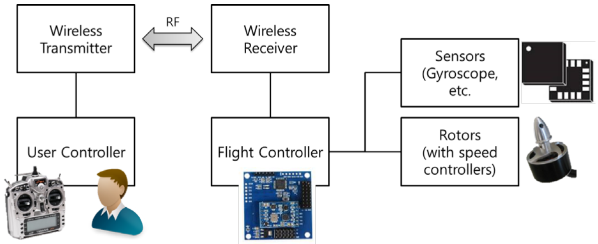

Figure 1: Block diagram of a typical drone system

fingerprints from standard minutiae templates, and more than 70 % of the fake fingerprints were accepted by the system tested [42]. In addition, a method for bypassing the user authentication of facial cognitive biometric systems was proposed as an example of sensor input spoofing against the imaging sensor systems of commercial laptops [40].

We were able to find only one notable and relevant study not related to biometric image sensors. Shoukry et al. injected magnetic fields to spoof the wheel speed of vehicles by placing a magnetic actuator near the Anti-lock Braking System (ABS) wheel speed sensor of which is also a magnetic sensor also [51]. In other words, the researchers used the same physical property as that intended to be sensed through the sensing channel of the target sensor for their spoofing attack. This work is similar to ours in that it explored intentional interference with sensors to cause malfunctioning of actuators However, we investigated whether intentional sound noise at the resonant frequency of a gyroscope can incapacitate a drone. This means that our attack is an interference attack through a channel other than the sensing channel that has to be insensitive for the gyroscope. Note that a MEMS gyroscope is *the most basic sensor used in maintaining a drone in an upright position* without any external torque.

3 Background

In this section, we explain the operation and characteristics of the drone considered in this study, its flight control system and a MEMS gyroscope.

3.1 Drone (Multicopter)

A drone is a kind of Unmanned Aerial Vehicle (UAV). Drones are used not only for military purposes but also for various non-military purposes such as delivery services, aerial photography, search and rescue (S&R), crop-dusting, and hobbies. Because of accessibility reasons, military drones were not considered in this paper. Many commercial drones have been released in recent years as the non-military drone market has grown [2, 3]. Both finished drones and DIY drones with open-source drone projects for the flight control software are commercially available. *AR.Drone* [5] is a popular commercial finished drone product. *Multiwii* [24] and *ArduPilot* [7] are open-source flight control software used widely with both DIY and commercial drones. These drones are also known as multicopters (quadcoptors if they have four rotors) because they usually have multiple rotors.

Typically, a drone system consists of multiple rotors, one flight controller, one wireless receiver, and one wireless transmitter (remote controller). Figure 1 shows a block diagram of a drone system. The flight controller receives control signals from the wireless transmitter through the receiver, and manipulates the speed of the rotors in accordance with the user's control supported by the flight controller.

3.2 Flight Attitude Control

It is very important for the drone flight controller to adjust each rotor's speed for horizontally leveling off in the air, because multiple rotors are not always exactly the same and the center of mass cannot always be ensured. To stabilize a drone's balance automatically, a flight attitude control system is implemented in the flight control software. This flight attitude control system computes the proper control signal for multiple rotors with algorithms based on the data from Inertial Measurement Units (IMUs), including gyroscopes.

IMUs, which consist of sets of sensors, are fundamental components of flight control systems for aircraft, spacecraft, and UAVs, including drones. An IMU measures the orientation, rotation, and acceleration of a drone, using a combination of a gyroscope and an accelerometer, and in some cases also a magnetometer and a Global Positioning System (GPS) [55]. MEMS gyroscopes are thus necessary components of drones and must be robust to control drones successfully.

In the case of open-source flight control software [7, 24], the most common algorithm for flight attitude control is Proportional-Integral-Derivative (PID) control. The PID control algorithm is a control loop feedback mechanism that minimizes the difference between the desired control and the current status. It is made up of three terms: the proportional, the integral, and the derivative terms, denoted by *P*, *I*, and *D*, respectively. The *P* term applies control to the system in proportion to the difference (error) between the current state and the desired state to the system. The *I* term is used to reduce the steady-state error through proportional control of the accumulation of past errors. The *D* term is used to reduce overshoot and increase stability through proportional control of the changing rate of errors. Each term has a gain (G_P, G_I, and G_D) for tuning the control system, and users can change each gain for stability and sensitivity of drones of various types, sizes, and weights.

3.3 MEMS Gyroscope

3.3.1 Operation

The principle underlying the MEMS gyroscope [1, 9] is the law of physics known as the Coriolis effect or Coriolis force. The Coriolis effect is the deflection of a moving object in a rotating reference frame. This effect appears only to an observer in the same rotating reference frame. In the observer's view, the path of the moving object is observed to be bent by a fictitious force, i.e. the Coriolis force. In other words, when an object is moving in a rotating container or package, the path of the moving object is bent in a direction different from the moving direction. Therefore, the observer on the container or package can sense this bending. Figure 2 illustrates the concept of a MEMS gyroscope structure for one axis. To sense motion with respect to one axis such as Z-axis rotation, there is a mechanical structure called a sensing mass in a MEMS gyroscope. While a sensing mass is continuously vibrating at a certain frequency with respect to the X-axis, the Coriolis force is applied in the Y-axis direction as a result of the Z-axis rotation. The amount of rotation is proportional to the amount of bending.

Figure 3 shows an example of a MEMS gyroscope structure with three axes. This gyroscope is manufactured by *STMicroelectronics* [10]. In Figure 3, M1 through M4 correspond to continuous vibrations of the sensing masses. Bending occurs in the direction orthogonal to both the vibrating axis and the rotating axis when this structure rotates with respect to each axis [10].

MEMS gyroscopes support digital interfaces such as Inter-Integrated Circuits (I^2Cs) and Serial Peripheral Interfaces (SPIs) that communicate with the processors of application systems. By reading registers of the gyroscopes that contain the sensed values, a system's processor can calculate the amount of rotation that occurs. The maximum sampling frequency for reading the registers of the MEMS gyroscopes varies from a few hundred to a few thousand samples per second. This means that gyroscopes cannot sense and recover correctly from fast changes in rotation over a few kHz without additional signal processing, according to the sampling theorem. The sampling theorem defines the minimum sampling frequency as a frequency higher than $2 \times B$ Hz when the given signal contains no frequency components higher than B Hz. If this condition is not satisfied, distortion occurs in the frequency response. This is referred to as aliasing. Because of the aliasing problem, a frequency analysis of the gyroscope output is not very useful.

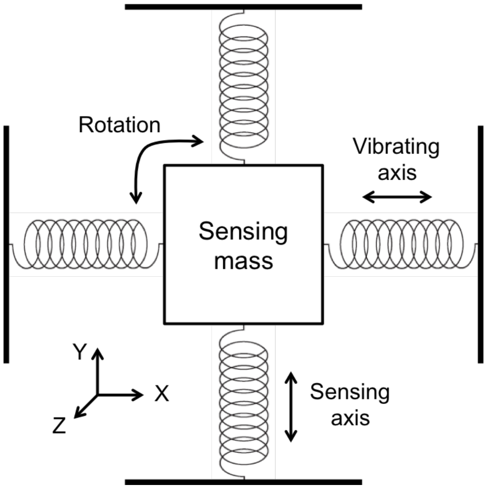

Figure 2: Concept of MEMS gyroscope structure for one axis

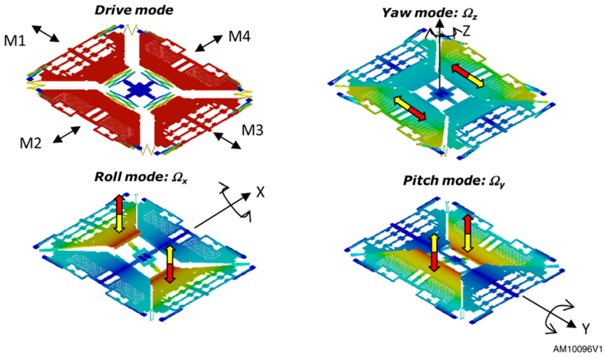

Figure 3: Operation of a three-axis MEMS gyroscope [10] (the X-, Y-, and Z-axes are defined as the pitch, roll, and yaw, respectively.)

3.3.2 Acoustic Noise Effect

The accuracy degradation of MEMS gyroscopes by harsh acoustic noise is well known to researchers who have studied the performance of MEMS sensors [37, 38, 39, 49]. A MEMS gyroscope has a resonant frequency that is related to the physical characteristics of its structure, and high-amplitude acoustic noise at the resonant frequency can produce resonance in the MEMS structure. As a result of this resonance, the MEMS gyroscope generates an unexpected output that may cause the related systems to malfunction. To minimize the resonance effect of acoustic noise in daily life, MEMS gyroscopes are typically designed with resonant frequencies above the audible frequency limit (i.e., above 20 kHz).

However, we found that some MEMS gyroscopes have resonant frequencies in both the audible and ultrasonic frequency ranges, and these sensors generate ghost outputs with injected sound noise by an attacker. In addi-

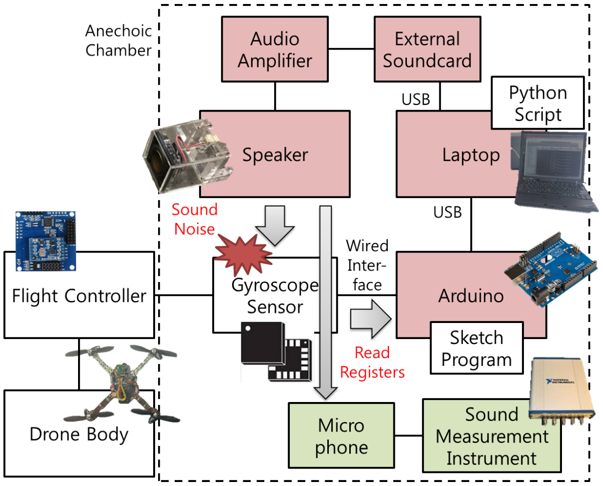

Figure 4: Overview of our experiment

tion, these MEMS gyroscopes are widely used in drone flight controllers and smartphones. The accuracy degradation problem of MEMS gyroscopes has only been considered in the context of performance issues, but this phenomenon can be used as a new attack vector. Therefore, it is important to study this phenomenon as a vulnerability that can cause critical loss of control of MEMS gyroscope application systems, such as drones.

4 Analysis of Sound Noise Effects

To explore the effects of sound noise on drones, it is necessary to identify the resonant frequencies of MEMS gyroscopes used for drones precisely. However, the datasheets of some MEMS gyroscopes do not include information on their exact resonant frequencies, and the resonant frequencies are even classified in some cases. A simple and reliable way to find the resonant frequency of a MEMS gyroscope is exhaustive search, i.e., scanning with pure single-tone sound over a chosen frequency band. In this section, the measurement and analysis of the effect of sound noise on MEMS gyroscopes are described.

4.1 Overview

An overview of our experiment is shown in Figure 4. Python scripts to generate sound noise with a single frequency and to collect data from the target gyroscopes are run on a laptop computer. A consumer-grade speaker connected to the laptop is used as the noise source and is set 10 cm above the top of the target gyroscope. We used Arduino [6], a programmable microprocessor board, to read and write registers of the target sensors. A single-tone sound noise scanning the sound frequency range was maintained until 1,000 samples had been collected from the target gyroscopes. We generated single-tone noises at frequencies from 100 Hz to 30 kHz at intervals of 100 Hz. In other words, this experiment was performed using not only audible noise (below 20 kHz) but also ultrasonic noise (above 20 kHz).

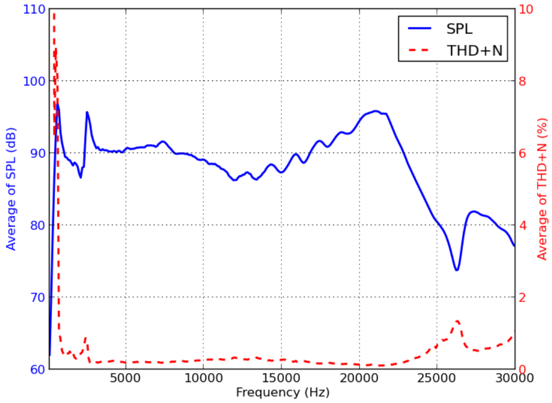

Figure 5: SPL and THD+N measurement using sound measurement instrument (National Instruments USB-4431)

We evaluated 15 kinds of MEMS gyroscopes manufactured by four vendors, which are readily available on online websites. Most of the target gyroscopes were from *STMicroelectronics* and *InvenSense*, two leading vendors of MEMS gyroscopes [22]. Each kind of gyroscope requires a different application circuit and register configuration for proper operation. We therefore implemented simple application circuits and Arduino codes for the target gyroscopes by referring to their datasheets. The effects produced on each gyroscope by sound noise were measured in an anechoic chamber (indicated by the dotted line box in Figure 4).

4.2 Sound Source

We considered the loudness and linearity of the sound source to select a sound source for further analysis.

A common noise measurement unit for the loudness of sound is the Sound Pressure Level (SPL), because sound is a pressure wave in a medium such as air or water. To show the noise level generated by our sound source [12], a consumer-grade speaker, SPL values were measured with no weighting using a professional sound measurement instrument [26] and a microphone [8]. The speaker was placed 10 cm from the microphone, and single-tone noises were generated from 100 Hz to 30 kHz at intervals of 100 Hz. We used an audio amplifier to make the sound noise sufficiently loud. In addition, we set the sampling

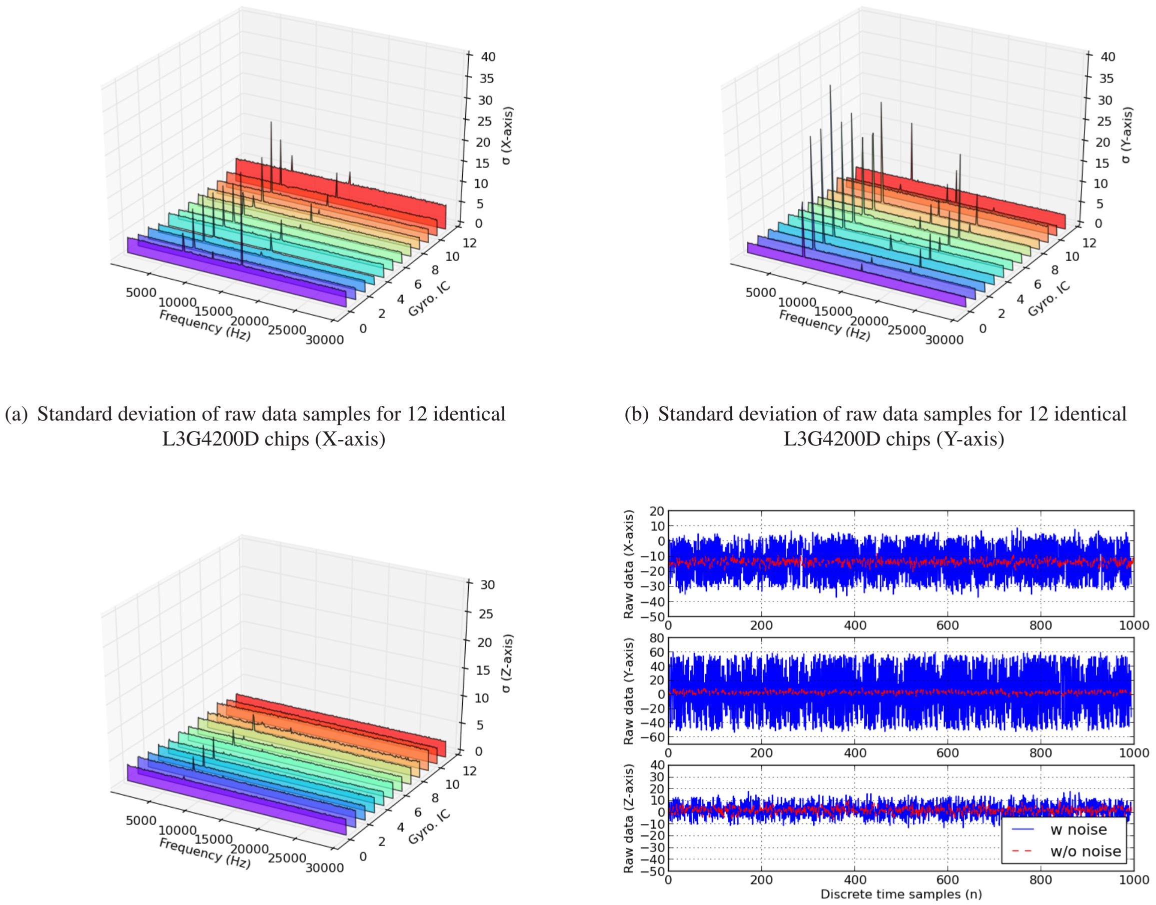
rate of the sound source to 96 kHz rather than 48 kHz to remove aliasing of the generating sound signal.

Another important property of a sound source is Total Harmonic Distortion plus Noise (THD+N), which is the ratio of the power of the harmonics and noise components to that of a fundamental component, expressed as a percentage. Every speaker has a nonlinear characteristic to its frequency response. This nonlinearity leads to harmonic distortions and noise of output sound at frequencies that are different from a fundamental frequency. If the power of these harmonics and noise is high (i.e., high THD+N), it is hard to regard the identified response as the effect from a single frequency. However, it is not necessary for low THD+N of the sound source to attack.

Figure 5 shows the average values of both the SPL and THD+N for all of the experiments. In most frequency bands, the SPL values were above 80 dB and the THD+N values were less than 2 %. Because the sound source we used was a tweeter that is usually used for high-frequency sound, the performance was not good in the low-frequency region (below 1 kHz). It is usually difficult to hear sound noise at frequencies above approximately 15 kHz, although we set the maximum volume at those frequencies. The measured SPL in our experiment was equivalent to the noise level (around 90 dB SPL) of a hand drill, hair dryer, heavy city traffic, noisy factory, and subway in the real world.

4.3 Effect of Sound Noise

Raw data samples from the registers of the target gyroscopes were collected for use in this analysis. The target gyroscopes were fixed on a stable frame in an ane-



(a) Standard deviation of raw data samples for 12 identical L3G4200D chips (X-axis)

(b) Standard deviation of raw data samples for 12 identical L3G4200D chips (Y-axis)

(c) Standard deviation of raw data samples for 12 identical L3G4200D chips (Z-axis)

(d) Raw data samples of one L3G4200D chip with the single tone sound noise at 8,000Hz

Figure 6: Sound noise effect on L3G4200D gyroscopes (all samples were collected as raw data stored in the gyroscope's register)

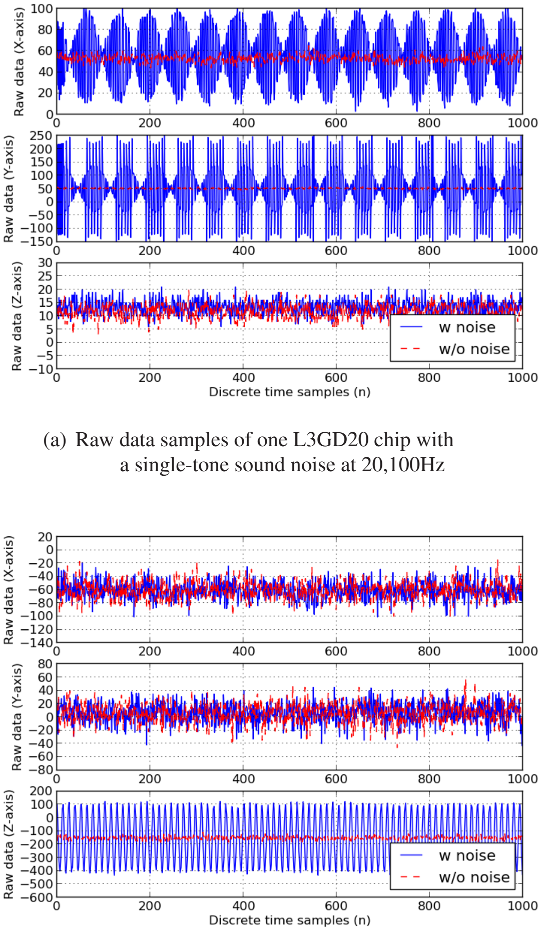
choic chamber, with and without sound noise. Because the standard deviation of the raw data samples should ideally be zero without sound noise when the target gyroscopes are on the frame, we consider the difference in the standard deviations with and without sound noise as a criterion for the resonance of the target gyroscopes.

The results of the experiment are summarized in Table 1. The third and fourth columns indicate the degrees of freedom and the interface type of each gyroscope, respectively. The resonant frequencies [2] and axes from the datasheets [4, 13, 14, 15, 16, 17, 18, 19, 25, 28, 29, 30, 31, 32] are listed in the fifth column, and the resonant frequencies identified in our experiment are listed in the last column.

Our results show that seven of these gyroscopes (i.e., vulnerable gyroscopes) resonated at their own resonant frequencies in response to sound noise. Three of the vulnerable gyroscopes were manufactured by *STMicroelectronics*, and the others were manufactured by *InverSense*. No documentation on the resonant frequencies of the tested gyroscopes was available from vendors other than *InvenSense* and *Analog Devices*. We figured out that the gyroscopes manufactured by *STMicroelectronics* had resonant frequencies in the audible range (almost below 20 kHz), and that they were affected considerably more along the X-axis and Y-axis than along the Z-axis. In contrast, the gyroscopes manufactured by *InvenSense* resonated in the ultrasound range (above 20 kHz) and were affected in the Z-axis direction only.

Both keeping resonant frequencies secret and raising them to the higher-frequency region are good ways to

[2] These are described as mechanical frequencies in the datasheets for the *InvenSense* gyroscopes.



(a) Raw data samples of one L3GD20 chip with a single-tone sound noise at 20,100Hz

(b) Raw data samples of one MPU6000 chip with a single-tone sound noise at 26,800Hz

Figure 7: Sound noise effects on two vulnerable MEMS gyroscopes (all samples were collected as raw data stored in the gyroscope's register)

reduce resonance due to sound noise. However, as our results show, resonance can be induced by a malicious attacker, as long as resonant frequencies exist in gyroscopes. Additionally, the standard deviations of the output data from these gyroscopes are largely increased without any rotation or tilt when the resonance occurs as a result of intentional sound noise. This abnormal output can potentially make gyroscope application systems malfunction.

We did not detect resonance effects for the other eight gyroscopes evaluated in our experiments. Particularly, for five of these gyroscopes, no resonant frequencies were observed, even though their resonant frequencies are described in their datasheets. We obtained additional measurements with the frequency resolution enhanced by a factor of two (50 Hz), but resonant frequencies were not found. It might be possible that the frequency intervals (100 Hz and 50 Hz) used in our tests were not sufficiently narrow. The fact that resonant frequencies were not detected in our experiments does not necessarily mean that they do not exist in the frequency range below 30 kHz.

A comparison between the standard deviations (σ_{axis}) with and without sound noise for the seven vulnerable gyroscopes is presented in Table 2. To validate our attack method, 12 individual gyroscope chips were tested for L3G4200D, L3GD20, and MPU6000, whereas only two chips were tested for the others. All of the values shown in Table 2 are average for all outputs from the same kind of vulnerable gyroscopes. The standard deviations of the gyroscope outputs with sound noise at the resonant frequencies are relatively large. The ratios of the standard deviations with sound noise to those without sound noise are summarized in the last three columns. The standard deviations changed by factors up to dozens, with the greatest change being by a factor of 31.04 (for the Y-axis of L3GD20).

Figures 6(a), 6(b), and 6(c) show the standard deviations of the raw data samples for each axis from the 12 individual L3G4200D chips. The different L3G4200D chips have different output characteristics because of manufacturing variances. However, every L3G4200D chip has a peak in the range of 7,900 to 8,300 Hz. To investigate what happens at these frequencies in more detail, the raw data samples for one L3G4200D gyroscope with and without sound noise at 8,000 Hz were compared, as shown in Figure 6(d). This graph clearly shows that resonances occur for all axes, and the amplitudes are dozens of times larger than the normal output. These amplitudes are equivalent to the output produced by sudden and fast shaking of the gyroscope or the target drone's body by hands or rapidly changing winds. Raw data samples of two other vulnerable gyroscopes, L3GD20 and MPU6000, are shown in Figure 7. L3G4200D and MPU6000, two of the vulnerable gyroscopes in our experiments, were used in the target drones described in the next section.

It should be noted that a speaker generates sound from a vibrating membrane fixed to the enclosure of the speaker, and thus vibration from the enclosure itself was unavoidable in the experiments. However, our experimental results indicate that vibration had very little effect on the identification of the resonant frequencies of the target gyroscopes. Because we tested all of the gyroscopes in the same environment, there should have been consistent resonance frequencies for all of the gyroscopes if any enclosure vibration had influenced the motion of the gyroscopes. In addition, some of the gyroscopes listed in Table 1 exhibited no resonance (i.e., almost constant standard deviation), which would not have

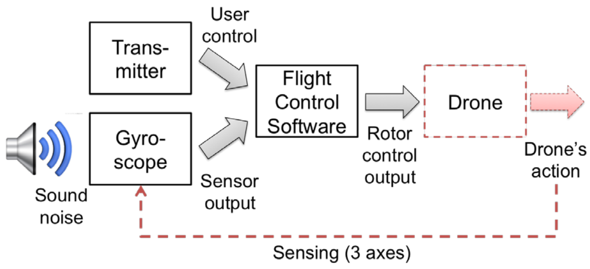


Figure 8: Propagation of the effect of sound noise

been possible if there had been a strong vibration due to vibration of the enclosure.

5 Attacking Drone

As described in the previous section, the outputs of MEMS gyroscopes fluctuate with the sound noise at the gyroscopes' own resonant frequencies. This section describes the impact of this fluctuation on the control of a drone. To understand this, we first need to understand how the user input from a remote controller and the input from the gyroscope propagate to the operation of a drone. Figure 8 shows each step in this propagation. The flight control software calculates each control signal for four rotors based on the user input and gyroscope output. This control signal mechanically controls the speed of each rotor, which determines the tilt, orientation, and rotation of the drone in turn. This section describes the analysis of how sound noise at the resonant frequency of a gyroscope affects control of target drones.

We took the following three steps. 1) To understand the reaction of the target drones as actuators to the fluctuation of the gyroscope output as abnormal sensing, the flight control software was analyzed statically. 2) We then launched our attack on two target drones under real-world conditions to assess the effect of the maximum sound noise against them. 3) To identify cost-efficient parameters for our attack, we performed software simulations with gyroscope outputs varying from 1% to 100 % of the maximum noise.

5.1 Target Drones

For this experiment, two DIY drones were built for use as the target drones, and they were equipped with L3G4200D and MPU6000 respectively, two of the vulnerable gyroscopes. This approach was taken because the gyroscopes on most finished drones are not user selectable, and it was necessary to evaluate the effect of sound noise in the sensing and actuation systems. The main specifications of the two target drones are given in Table 3. All DIY drones require calibration for stable operation. Following the instructions in the manual for the flight control software, we calibrated the IMU sensors and four rotor controllers, and we adjusted the PID gains (see Section 3.2) for stable flight.

5.2 Software Analysis

Target drone A's flight control software, *Multiwii* [24], supports various gyroscopes. However, the main routine of this software is essentially the same for all gyroscopes except with respect to the way the sensors are prepared and the way the raw data are accessed. The main processor reads the raw data from the gyroscope's registers through an I^{2}C interface, along with the raw data from the transmitter controlled by the user. Each raw data sample for each axis was stored in two 8-bit registers. These raw data were the main inputs to the flight control software, and the outputs were the rotor control data calculated by the PID control algorithm. The PID controller seeks to minimize the difference between the measured control and the desired control for the control systems. While PID controller implementation and PID gains vary depending on their application and the gyroscope used, the fundamental algorithm remains the same.

Algorithm 1 describes a high-level implementation of the default PID control algorithm in this flight control software. The details of the software are omitted for simplicity. Conceptually, the P, I, and D terms influence the target drone's control as follows:

- P is proportional to the present output of the gyroscope, and if the present output value ($gyro[axis]$) of the gyroscope is abnormally large, the desired control from the transmitter ($txCtrl[axis]$) can be ignored (line 7).
- I is proportional to the accumulated error between the output from the transmitter and the gyroscope (line 10), which can be ignored, because the default value of the I term gain (G_I) for the target drone is very small.

Table 3: Specifications of two target drones for the real world attacking experiment

Spec.	Target Drone A	Target Drone B
Processor	STM32F103CBT6	ATMEGA2560
Gyroscope	L3G4200D	MPU6000
Flight Ctrl. Software	Multiwii [24]	ArduPilot [7]
Diagonal Frame Size	45 cm	55 cm
Propeller Size	10 × 4.5	10 × 4.5

Algorithm 1: Simplified PID algorithm of *Multiwii* flight controller (calculating the rotor control data according to the output of the gyroscope)

```
Input: The sensed data from the MEMS gyroscope
Input: The received data from the transmitter
Output: The data to control the rotor
1  initialization;
2  $G_P$, $G_I$, and $G_D$: pre-configured P, I, and D gain by
   user (configured as the default values);
3  while True do
4      read data from the gyroscope for 3 axes;
5      receive data from the transmitter for 4 channels
       (3 axes and throttle);
6      for axis do
7          $P = txCtrl[axis] - gyro[axis] \times G_P[axis]$;
8          $error = txCtrl[axis]/G_P[axis] - gyro[axis]$;
9          $error_{accumulated} = error_{accumulated} + error$;
10         $I = error_{accumulated} \times G_I[axis]$;
11         $delta = gyro[axis] - gyro_{last}[axis]$;
12         $delta_{sum}$ = sum of the last three delta values;
13         $D = delta_{sum} \times G_D[axis]$;
14         $PIDCtrl[axis] = P + I - D$;
15     end
16     for rotor do
17         for axis do
18             $rotorCtrl[rotor] =$
               $txCtrl[throttle] + PIDCtrl[axis]$;
19         end
20         limit $rotorCtrl[rotor]$ within the pre-defined
           MIN (1,150) and MAX (1,850) values;
21     end
22     actuate rotors;
23 end
```

- D is proportional to the changes ($delta_{sum}$) between the previous and present output values of the gyroscope (line 13).

These three terms directly affect the PID control values ($PIDCtrl[axis]$) for each axis (line 14). If the values of P and D are abnormally large, the PID control values will also increase abnormally. The desired throttle control ($txCtrl[throttle]$) can thus be ignored (line 18). In the end, all rotor control values are constrained by the pre-defined minimum and maximum values (line 20). Throughout the process, the raw data from the gyroscope were not checked, filtered, or verified. In other words, the target drone system fully trusted the integrity of the gyroscope output in its sensing and actuation. Therefore, the control of the target drone could be directly affected by our attack.

We also analyzed the flight control software of *ArduPilot* [7] for target drone B. A manual software analysis shows that the PID algorithm used in *ArduPilot* is essentially the same as that used with target drone A. The only difference between two algorithms is in slight changes of the gains that are multiplied to each of the P, I, and D terms. This can be considered a discrepancy in the configuration values of the sensors.

5.3 Real-World Experiment

While the software analysis described in the previous section led us to believe that the $PIDCtrl[axis]$ values would fluctuate when the gyroscope outputs fluctuated, this information was not sufficient to answer the following questions: 1) Given user inputs $txCtrl[throttle]$ and fluctuating $PIDCtrl[axis]$, how much does $rotorCtrl[rotor]$ change? 2) How does a change in $rotorCtrl[rotor]$ affect the behavior of the drone? To answer these questions, we decided to launch our attack in the real world with sound noise causing the fluctuation.

Attack Setup: In this experiment, we attached a small Bluetooth speaker above the target system's gyroscope at a distance of 10 cm to serve as an attacking sound source. The SPL of the fundamental frequency component was 113 dB with the maximum volume of the speaker. Low THD+N was not a consideration for the sound source used in the attack. The sound noise was turned on while the target drones were stably maintained in the air. To observe the status of the target drones before, during, and after the attack, sound noise at the resonant frequency was turned off, turned on (attack), and turned off again for every 10 seconds.

Attack Results: The results of our attack experiment are summarized on two target drones (A and B) in Table 4. Our attacks successfully disrupted control of target drone A, but it did not affect target drone B. The reason of attack failure on target drone B is that the gyroscope of target drone B resonated only along the Z-axis. The Z-axis of target drone B corresponds to the horizontal orientation that is also sensed by the magnetometer on the board.

We also attached a sonar device to gauge the altitude

Table 4: Result of attacking two target drones

Item	**Target Drone A**	**Target Drone B**
Resonant Freq. (Gyroscope)	8,200 Hz (L3G4200D)	26,200 Hz (MPU6000)
SPL at Resonant Freq.	97 dB	95 dB

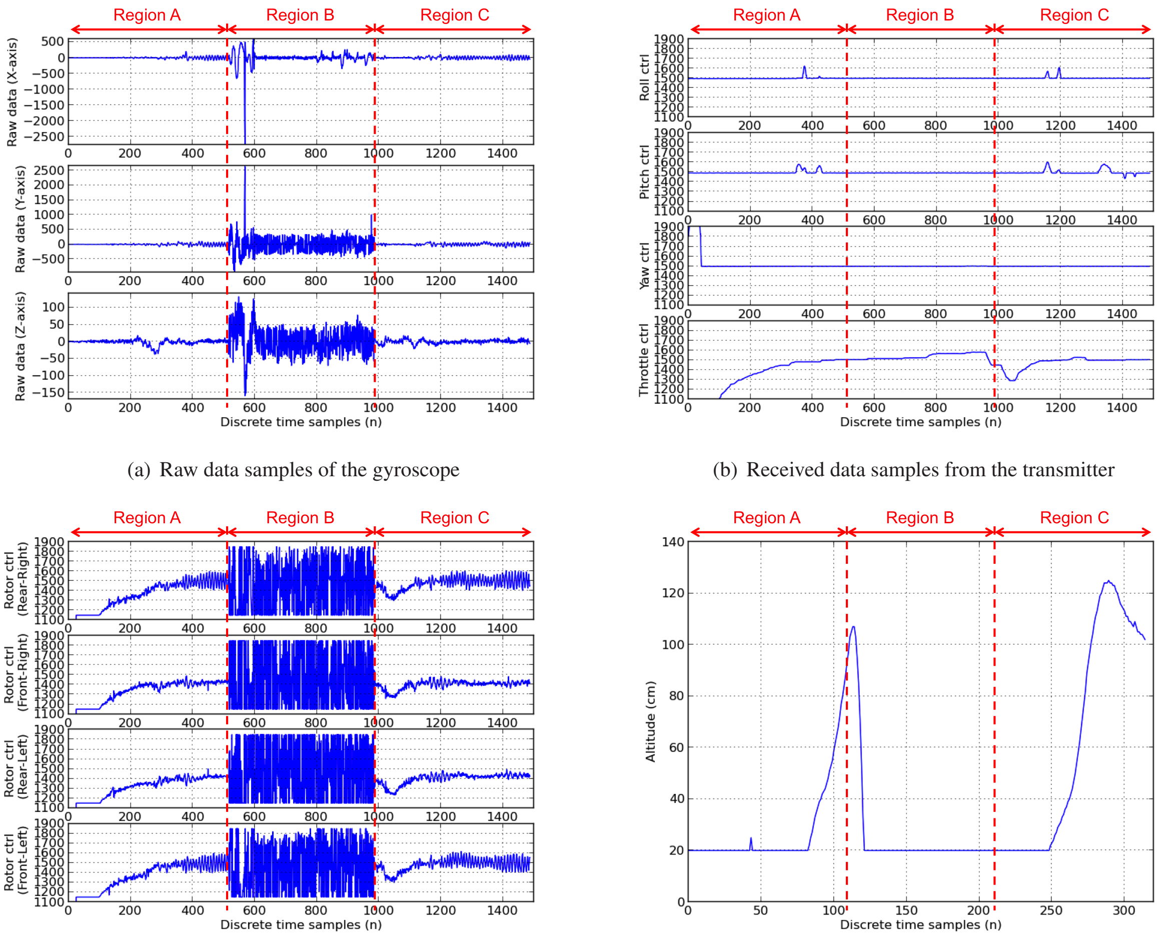
Attack Result	Fall down	Not affected



(a) Raw data samples of the gyroscope

(b) Received data samples from the transmitter

(c) Rotor control data samples (from the flight control software)

(d) Altitude data samples from sonar

Figure 9: The results of our attack against target drone A in a real-world experiment (sound noise turned off, on, and off every 10 seconds; note that the sonar's sampling rate was different from that for the data in other figures)

and two Bluetooth-to-UART (Universal Asynchronous Receiver/Transmitter) modules to collect real-time data from target drone A. The Bluetooth-to-UART modules were connected to a UART interface on target drone A's flight controller board and the sonar module. Using this UART interface, we were able to communicate with a computer for configuration purpose. We were also able to monitor the status of target drone A, including the raw data from the sensors and the rotor control data, using the *Multiwii* [24] Graphical User Interface (GUI) program. By analyzing the *Multiwii* source code, we were able to understand the protocol used for the UART communication. Each request or response message consists of a 3-bytes fixed header, 1 byte for the data length (n), a 1-byte command, n bytes of data, and a 1-byte checksum. Using this protocol and the Bluetooth-to-UART modules, we were able to record the resonant outputs of the gyroscope, the control data from the transmitter, the rotor control data of the flight control software, and the altitude data from target drone A in the air. Note that the altitude data were sampled at a different rate than the other data because of a technical limitation of the sonar module, and the minimum sensing distance of the sonar was 20 cm.

Figure 9 shows the detailed results of the attack against target drone A in the real-world experiment. Region A in Figure 9 corresponds to the period before the attack. The user gradually raised the throttle (Figure 9(b)), and the speeds of the four rotors were increased correspondingly (Figure 9(c)). In response, target drone A rose over 100 cm in the air (Figure 9(d)). When the attack was started (Region B), the output of the gyroscope fluctuated because of the sound noise at the resonant frequency (Figure 9(a)). According to the resonant output of the gyroscope, the rotor control data fluctuate between the maximum and minimum values (Region B in Figure 9(c)).

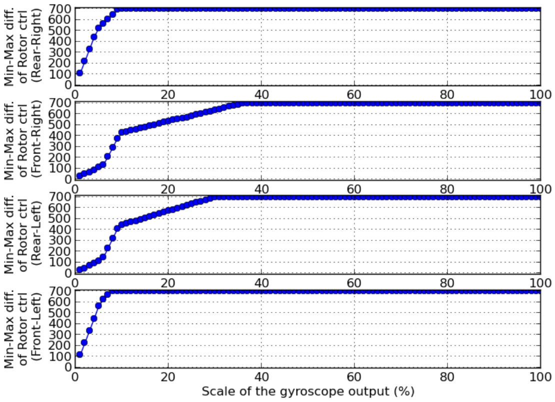


Figure 10: Rotor control outputs from our software simulation (the maximum change of the rotor control output was 700)

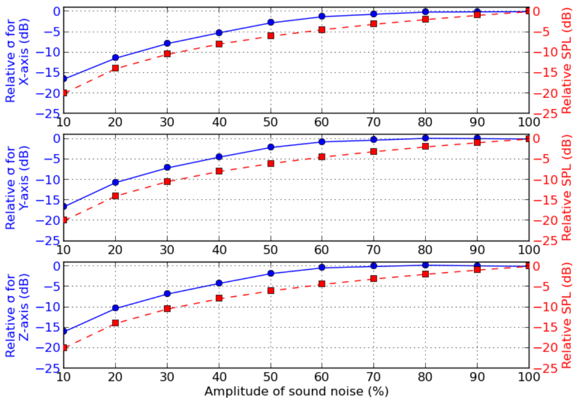

Figure 11: Sound noise effect on one L3G4200D gyroscope versus sound noise amplitude with theoretical relative SPL (data averaged for ten identical experiments and 1,000 raw data samples collected per experiment)

When the attack started, target drone A dropped instantaneously. During the attack, target drone A could not ascend or recover its control, even though throttle control was maintained to allow it to ascend slowly (Figure 9(b)). After the attack was stopped (Region C), target drone A ascended normally again and recovered its control. We attacked target drone A 20 times in the real-world experiments, and it lost control and crashed shortly after our attack in every test.

To assess the effectiveness and practicality of our attack, more real-world attack experiments are required. However, there are obstacles such as the damage to the target drone (e.g., broken arms) and the repetitive recalibration required after each crash, because the unpredictable changes in the drone's balancing are fed back into the gyroscope by our attack (see the dotted line and box in Figure 8).

5.4 Attack Distance

Our real-world experiments showed that an acoustic attack can completely incapacitate a target drone equipped with a gyroscope vulnerable to X-axis and Y-axis resonance due to sound incidence. We also want to determine the conditions or bounds of a cost-effective attack. For example, we need to find out possible attack distance or sound level of a sound source required to destabilizing a target drone in the air.

We may try to conduct tests at various distances to discover either the approximate minimum distance or the sound level required to incapacitate target drone A in the air. However, it would disrupt the stability of the target drone to attach a longer structure with the sound source on the target drone. It is also difficult to take aim at the target drone with sound noise from outside during its flight without attaching any structure to it.

Therefore, to minimize the number of trials and overcome the practical limitations mentioned above, we first ran a simulation using the functions of Algorithm 1, which were extracted from the source code for target drone A. Based on the results of this simulation, we found out the effective fluctuation (i.e., standard deviation) of the gyroscope output with a few real-world tests. Then, we measured the standard deviations of target drone A on a desk exposed to sounds of various amplitudes. By combining the results of this simulation and our measurements, we were able to identify an approximate range of sound amplitude for testing the target drone in the air. We then derived the feasible attack distance theoretically using the SPL value that we had measured in our attack with the effective amplitude of the sound noise.

Simulation: For the software simulation, the recorded gyroscope output and the control data from the transmitter in the real-world attack experiments were used as the inputs. The recorded gyroscope output was linearly scaled from 1 % to 100 % in increments of 1 %, and the control data from the transmitter were the same as in the real-world experiment. Figure 10 shows the results of the simulation. Because the rotor control output was bounded between 1,150 and 1,850 in Algorithm 1, the maximum change of the rotor control output was 700. The minimum scale of the gyroscope output that could achieve the maximum change in all rotor controls was 37 % in our simulation (Figure 10).

Indoor Measurements: The standard deviation of the gyroscope output with respect to the sound noise amplitude was measured for the L3G4200D gyroscope of target drone A on a desk. Figure 11 shows the relative standard deviation of the gyroscope output measured at a 10 cm distance, which decreases logarithmically as the sound level decreases. Theoretically, the relationship between the sound amplitude and SPL is described by Equation 1 [27]. At the point of the reference SPL (SPL_{ref}), the amplitude of the sound noise signal is A_{ref}.

$$SPL = SPL_{ref} + 20\log\left(\frac{A}{A_{ref}}\right) \tag{1}$$

The relative SPL obtained by changing the amplitude is the second term in Equation 1, and it is illustrated in Figure 11, along with the measured relative standard deviations. The decreasing trend in our measurements is similar to that for the theoretical relative SPLs, but the amount of decrease in our measurements was smaller than that for the theoretical relative SPLs from the amplitude range over 70 %. This mismatch is the typical output characteristic of consumer-grade speakers at high amplitude levels, which is caused by the nonlinear distortion that also leads to the leakage of sound energy into harmonic and subharmonic frequencies.

Distance Analysis: The amplitude of the sound noise corresponding to 37 % (-8.64 dB) of the standard deviation in Figure 11 is approximately 27 %, because the standard deviation of the gyroscope output is proportional to the scale of the gyroscope output. Accordingly, the sound noise greater than 27 % in amplitude can induce the maximum changes in all rotor controls for target drone A, if the drone is tested at the same environment as that of our real-world attack.

In the real-world experiments, we changed the amplitude of the sound noise in the same environment and observed that around 30 % sound amplitude is the lower bound for making target drone A crash. The SPL measured at this 30 % sound amplitude was 108.5 dB. Using the following relationship between the distance and SPL [58], we can derive a possible attack distance of a remotely located sound source, where the reference distance (d_{ref}) and SPL (SPL_{ref}) are those measured from the real-world attack experiments.

$$SPL = SPL_{ref} - 20\log\left(\frac{d}{d_{ref}}\right) \tag{2}$$

According to this prediction, the possible attack distance is approximately 16.78 cm using the same sound source that we used for the real-world attack with the maximum volume (113 dB). This attack distance range might not be sufficient for a malicious attacker. However, attackers can overcome this distance limitation by using a more powerful and directional source (e.g., a loudspeaker array) than the single speaker used in our experiments. For instance, *SB-3F* [23] from *Meyersound* can generate sound of 120 dB at 100 m, and *450XL* [21] from *LRAD* and *HyperShield* [33] from *UltraElectronics* can produce 140 dB at 1 m, which is equivalent to 108.5 dB at 37.58 m. Therefore, the possible attack distance is 37.58 m, if an attacker uses a sound source that can generate 140 dB of SPL at 1 m.

6 Discussion

In this section, we present a discussion of potential attack scenarios and countermeasures.

6.1 Potential Attack Scenarios

The attack model used in this paper seems to be too strong in two ways: 1) Use of audible sound can be easily detected, and 2) the speaker is close to the drone body. However, the more practical attack can be designed to weaken this attack model from the analysis result of this study.

First, several gyroscopes listed in Table 1 have resonant frequencies in the inaudible band (i.e., above 20 kHz). If the resonant frequency is above 20 kHz, a successful attack is possible using an ultrasonic sound generator and transducer. In addition, sound at frequencies higher than 15 kHz is difficult for humans to hear.

Second, the distance analysis shows that various remote attacks are also possible using different types of sound generators. Some of promising ways for the remote attack are described below.

Compromising the Sound Source: It is not hard to imagine drones with speakers (consider police and military operations or search-and-rescue operations). If one can compromise the source of the sound from the speaker, the effect will be the same as that of our original attack model. For example, insecurity of the Hybrid Broadcast-Broadband Television (HbbTV) standard and implementation would allow an adversary to control the TV stream [48].

Drone to Drone Attack: In 2013, Kamkar demonstrated the 'SkyJack' attack, in which an adversary drone hijacks a victim drone using a wireless denial-of-service attack [44]. A similar attack could involve following and taking a picture of a moving object, which could become a popular drone application. An adversary drone equipped with a speaker could steer itself toward a victim drone and generate a sound with the resonant frequency of the victim's gyroscope to drag it down. Of course, in this case, the resonant frequency of the adversary's gyroscope has to be different from that of the victim.

Long Range Acoustic Device: Long Range Acoustic Device (LRAD) [56] could be used as a sonic weapon [57] or Acoustic Hailing Device (AHD) [54]. Sonic weapons can cause damages to human organs by inducing intense sound waves at certain frequencies, even if the sound source is not in contact with opponents [41, 53]. AHDs are specially designed loudspeakers that communicate over longer distances than normal loudspeakers [21, 23, 33]. In both cases, the most important requirement is a high SPL in a specific frequency band. Obviously, these technologies could be used to increase the range of our attack.

Sonic Wall/Zone: Because drones can be made small, they can be difficult to detect using radar. Therefore, it might be desirable to enforce no-fly zones for drones, as illustrated by recent drone incidents [11, 34]. One might consider building a sonic wall or a zone that radiates continuous sound noise (at various frequencies) in a specific area to enforce the no-fly zone.

6.2 Countermeasures

Several researches that have been conducted to improve the performance of MEMS gyroscopes in harsh acoustic environments are discussed below.

Physical Isolation: The simplest way to mitigate our attack is to provide physical isolation from the sound noise. This is the same concept as shielding against Electro Magnetic Interference (EMI). For example, the iPhone 5S, which is equipped with an L3G4200D gyroscope [20], would not be affected by our attack, because of the compact casing of the hardware circuit. Surrounding the gyroscope with foam would also be a simple and inexpensive countermeasure. Foam that is 1 inch thick has approximately 120 dB insertion loss in SPL [49].

Figure 12 shows the result of physical isolation experiments conducted using four different materials: a paper box, an acrylic panel, an aluminum plate, and foam. We put these materials between the sound source and the target gyroscope. The isolation performances of the different materials were not very different. Using these materials, the effect of the sound noise on one L3G4200D gyroscope was decreased to 23.78%, 16.25%, and 60.49% for the three axes.

Differential Comparator: While physical isolation is a passive approach to mitigation, use of a differential comparator is an active approach to mitigation. Using an additional gyroscope with a special structure that responds only to the resonant frequency, the application systems can cancel out the resonant output from the main gyroscope [52]. The concept of this countermeasure was introduced by Kune et al. [45] to detect and cancel out analog sensor input spoofing against CIEDs.

Resonance Tuning: In the operation of MEMS gyroscopes, the bending mentioned in Section 3.3.1 changes the capacitance between the sensing mass and the sensing electrode, and this capacitance change is sensed as the output of the gyroscope. By using an additional feedback capacitor connected to the sensing electrode, the resonant frequency and the magnitude of the resonance effect can be tuned [35, 43].

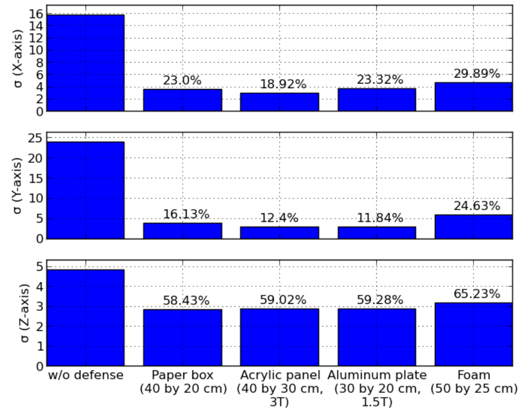

Figure 12: Physical isolation test for one L3G4200D gyroscope with four different materials (data averaged for ten identical experiments and 1,000 raw data samples collected per experiment)

These countermeasures may be used to mitigate our attack. However, physically surrounding the gyroscope sensor with certain materials could cause several problems, such as affecting other sensors or components and raising the temperature of the board. These problems may cause malfunctions of the drone control systems. In addition, use of a differential comparator with another gyroscope implies an additional cost. The resonance tuning countermeasure also has the limitation that the resonant frequency does not disappear as a result of tuning. Because the resonant frequency still exists, an attack at that frequency remains possible.

7 Conclusions and Future Work

Many sensing and actuation systems trust their measurements, and actuate according to them. Unfortunately, this trust can lead to security vulnerabilities that cause critically unintended actuations. We found that the sound channel can be used as a side channel for MEMS gyroscopes from a security point of view. In our experiment, we tested 15 kinds of MEMS gyroscopes, and seven of them were found to be vulnerable to disruption using intentional sound noise. The output of the vulnerable MEMS gyroscopes was found using a consumer-grade spaeker to fluctuate up to dozens of times as a result of sound noise.

To demonstrate the effects of this vulnerability, we implemented an attack against two target drones equipped with different kinds of vulnerable MEMS gyroscopes.

As a result of a firmware analysis of the target drones and a simulation of the flight control software output, the control signals of four rotors were found to fluctuate up to the maximum value and down to the minimum value by the injected gyroscope output. One of the target drones, which was equipped with with a small speaker, lost control and crashed in all 20 real-world attack experiments. We found in these experiments that an attacker with only 30% of the amplitude of the maximum sound noise could achieve almost the same effect at the same distance.

The countermeasures that are mentioned in the last subsection have limitations and require hardware modifications and additional materials. Because these mitigations would increase the production costs, it is necessary to develop a low-cost, software-based defense mechanism against sensor attacks for various types of embedded devices.

Some MEMS gyroscopes are integrated with accelerometers in the same IC package. In our experiments, we found that some accelerometers are also affected by high-power sound noise at certain frequencies. It would be interesting to further investigate this finding.

Cache Template Attacks:
Automating Attacks on Inclusive Last-Level Caches

Daniel Gruss, Raphael Spreitzer, *and* Stefan Mangard
Graz University of Technology, Austria

Abstract

Recent work on cache attacks has shown that CPU caches represent a powerful source of information leakage. However, existing attacks require manual identification of vulnerabilities, i.e., data accesses or instruction execution depending on secret information. In this paper, we present *Cache Template Attacks*. This generic attack technique allows us to profile and exploit cache-based information leakage of any program automatically, without prior knowledge of specific software versions or even specific system information. Cache Template Attacks can be executed online on a remote system without any prior offline computations or measurements.

Cache Template Attacks consist of two phases. In the profiling phase, we determine dependencies between the processing of secret information, e.g., specific key inputs or private keys of cryptographic primitives, and specific cache accesses. In the exploitation phase, we derive the secret values based on observed cache accesses. We illustrate the power of the presented approach in several attacks, but also in a useful application for developers. Among the presented attacks is the application of Cache Template Attacks to infer keystrokes and—even more severe—the identification of specific keys on Linux and Windows user interfaces. More specifically, for lower-case only passwords, we can reduce the entropy per character from $\log_2(26) = 4.7$ to 1.4 bits on Linux systems. Furthermore, we perform an automated attack on the T-table-based AES implementation of OpenSSL that is as efficient as state-of-the-art manual cache attacks.

1 Introduction

Cache-based side-channel attacks have gained increasing attention among the scientific community. First, in terms of ever improving attacks against cryptographic implementations, both symmetric [4, 6, 16, 39, 41, 53] as well as asymmetric cryptography [3, 7, 9, 54], and second, in terms of developing countermeasures to prevent these types of attacks [31, 34]. Recently, Yarom and Falkner [55] proposed the Flush+Reload attack, which has been successfully applied against cryptographic implementations [3, 17, 22]. Besides the possibility of attacking cryptographic implementations, Yarom and Falkner pointed out that their attack might also be used to attack other software as well, for instance, to collect keystroke timing information. However, no clear indication is given on how to exploit such vulnerabilities with their attack. A similar attack has already been suggested in 2009 by Ristenpart et al. [44], who reported being able to gather keystroke timing information by observing cache activities on an otherwise idle machine.

The limiting factor of all existing attacks is that sophisticated knowledge about the attacked algorithm or software is necessary, i.e., access to the source code or even modification of the source code [7] is required in order to identify vulnerable memory accesses or the execution of specific code fragments manually.

In this paper, we make use of the Flush+Reload attack [55] and present the concept of *Cache Template Attacks*,[1] a generic approach to exploit cache-based vulnerabilities in any program running on architectures with shared inclusive last-level caches. Our attack exploits four fundamental concepts of modern cache architectures and operating systems.

1. Last-level caches are shared among all CPUs.
2. Last-level caches are inclusive, i.e., all data which is cached within the L1 and L2 cache must also be cached in the L3 cache. Thus, any modification of the L3 cache on one core immediately influences the cache behavior of all other cores.
3. Cache lines are shared among different processes.
4. The operating system allows programs to map any other program binary or library, i.e., code and static data, into their own address space.

[1] The basic framework can be found at `https://github.com/IAIK/cache_template_attacks`.

Based on these observations, we demonstrate how to perform Cache Template Attacks on any program automatically in order to determine memory addresses which are accessed depending on secret information or specific events. Thus, we are not only able to attack cryptographic implementations, but also any other event, e.g., keyboard input, which might be of interest to an attacker.

We demonstrate how to use Cache Template Attacks to derive keystroke information with a deviation of less than 1 microsecond from the actual keystroke and an accuracy of almost 100%. With our approach, we are not only able to infer keystroke timing information, but even to infer specific keys pressed on the keyboard, both for GTK-based Linux user interfaces and Windows user interfaces. Furthermore, all attacks to date require sophisticated knowledge of the attacked software and the executable itself. In contrast, our technique can be applied to any executable in a generic way. In order to demonstrate this, we automatically attack the T-table-based AES [10, 35] implementation of OpenSSL [37].

Besides demonstrating the power of Cache Template Attacks to exploit cache-based vulnerabilities, we also discuss how this generic concept supports developers in detecting cache-based information leaks within their own software, including third party libraries. Based on the insights we gained during the development of the presented concept, we also present possible countermeasures to mitigate specific types of cache attacks.

Outline. The remaining paper is organized as follows. In Section 2, we provide background information on CPU caches, shared memory, and cache attacks in general. We describe Cache Template Attacks in Section 3. We illustrate the basic idea on an artificial example program in Section 4 and demonstrate Cache Template Attacks against real-world applications in Section 5. In Section 6, we discuss countermeasures against cache attacks in general. Finally, we conclude in Section 7.

2 Background and Related Work

In this section, we give a basic introduction to the concept of CPU caches and shared memory. Furthermore, we provide a basic introduction to cache attacks.

2.1 CPU Caches

The basic idea of CPU caches is to hide memory accesses to the slow physical memory by buffering frequently used data in a small and fast memory. Today, most architectures employ set-associative caches, meaning that the cache is divided into multiple cache sets and each cache set consists of several cache lines (also called ways). An index is used to map specific memory locations to the sets of the cache memory.

We distinguish between virtually indexed and physically indexed caches, which derive the index from the virtual or physical address, respectively. In general, virtually indexed caches are considered to be faster than physically indexed caches. However, the drawback of virtually indexed caches is that different virtual addresses mapping to the same physical address are cached in different cache lines. In order to uniquely identify a specific cache line within a cache set, so-called tags are used. Again, caches can be virtually tagged or physically tagged. A virtual tag has the same drawback as a virtual index. Physical tags, however, are less expensive than physical indices as they can be computed simultaneously with the virtual index.

In addition, there is a distinction between inclusive and exclusive caches. On Intel systems, the L3 cache is an inclusive cache, meaning that all data within the L1 and L2 caches are also present within the L3 cache. Furthermore, the L3 cache is shared among all cores. Due to the shared L3 cache, executing code or accessing data on one core has immediate consequences for all other cores. This is the basis for the Flush+Reload [55] attack as described in Section 2.3.

Our test systems (Intel Core i5-2/3 CPUs) have two 32 KB L1 caches—one for data and one for instructions—per core, a unified L2 cache of 256 KB, and a unified L3 cache of 3 MB (12 ways) shared among all cores. The cache-line size is 64 bytes for all caches.

2.2 Shared Memory

Operating systems use shared memory to reduce memory utilization. For instance, libraries used by several programs are shared among all processes using them. The operating system loads the libraries into physical memory only once and maps the same physical pages into the address space of each process.

The operating system employs shared memory in several more cases. First, when forking a process, the memory is shared between the two processes. Only when the data is modified, the corresponding memory regions are copied. Second, a similar mechanism is used when starting another instance of an already running program. Third, it is also possible for user programs to request shared memory using system calls like mmap.

The operating system tries to unify these three categories. On Linux, mapping a program file or a shared library file as a read-only memory with mmap results in sharing memory with all these programs, respectively programs using the same shared library or program binary. This is also possible on Windows using the LoadLibrary function. Thus, even if a program is statically linked, its memory is shared with other programs which execute or map the same binary.

Another form of shared memory is content-based page deduplication. The hypervisor or operating system scans the physical memory for pages with identical content. All mappings to identical pages are redirected to one of the pages while the other pages are marked as free. Thus, memory is shared between completely unrelated processes and even between processes running in different virtual machines. When the data is modified by one process, memory is duplicated again. These examples demonstrate that code as well as static data can be shared among processes, even without their knowledge. Nevertheless, page deduplication can enhance system performance and besides the application in cloud systems, it is also relevant in smaller systems like smartphones.

User programs can retrieve information on their virtual and physical memory using operating-system services like `/proc/<pid>/maps` on Linux or tools like `vmmap` on Windows. The list of mappings typically includes all loaded shared-object files and the program binary.

2.3 Cache Attacks

Cache attacks are a specific type of side-channel attacks that exploit the effects of the cache memory on the execution time of algorithms. The first theoretical attacks were mentioned by Kocher [28] and Kelsey et al. [26]. Later on, practical attacks for DES were proposed by Page [41] as well as Tsunoo et al. [50]. In 2004, Bernstein [4] proposed the first time-driven cache attack against AES. This attack has been investigated quite extensively [36].

A more fine-grained attack has been proposed by Percival [42], who suggested to measure the time to access all ways of a cache set. As the access time correlates with the number of occupied cache ways, an attacker can determine the cache ways occupied by other processes. At the same time, Osvik et al. [39] proposed two fundamental techniques that allow an attacker to determine which specific cache sets have been accessed by a victim program. The first technique is Evict+Time, which consists of three steps. First, the victim program is executed and its execution time is measured. Afterwards, an attacker evicts one specific cache set and finally measures the execution time of the victim again. If the execution time increased, the cache set was probably accessed during the execution.

The second technique is Prime+Probe, which is similar to Percival's attack. During the Prime step, the attacker occupies specific cache sets. After the victim program has been scheduled, the Probe step is used to determine which cache sets are still occupied.

Later on, Gullasch et al. [16] proposed a significantly more powerful attack that exploits the fact that shared memory is loaded into the same cache sets for different processes. While Gullasch et al. attacked the L1 cache, Yarom and Falkner [55] presented an improvement called Flush+Reload that targets the L3 cache.

Flush+Reload relies on the availability of shared memory and especially shared libraries between the attacker and the victim program. An attacker constantly flushes a cache line using the `clflush` instruction on an address within the shared memory. After the victim has been scheduled, the attacker measures the time it takes to reaccess the same address again. The measured time reveals whether the data has been loaded into the cache by reaccessing it or whether the victim program loaded the data into the cache before reaccessing. This allows the attacker to determine the memory accesses of the victim process. As the L3 cache is shared among all cores, it is not necessary to constantly interrupt the victim process. Instead, both processes run on different cores while still working on the same L3 cache. Furthermore, the L3 cache is a unified inclusive cache and, thus, even allows to determine when a certain instruction is executed. Because of the size of the L3 cache, there are significantly fewer false negative cache-hit detections caused by evictions. Even though false positive cache-hit detections (as in Prime+Probe) are not possible because of the shared-memory-based approach, false positive cache hits can still occur if data is loaded into the cache accidentally (e.g., by the prefetcher). Nevertheless, applications of Flush+Reload have been shown to be quite reliable and powerful, for example, to detect specific versions of cryptographic libraries [23], to revive supposedly fixed attacks (e.g., Lucky 13) [24] as well as to improve attacks against T-table-based AES implementations [17].

As shared memory is not always available between different virtual machines in the cloud, more recent cache attacks use the Prime+Probe technique to perform cache attacks across virtual machine borders. For example, Irazoqui et al. [20] demonstrated a cross-VM attack on a T-Table-based AES implementation and Liu et al. [32] demonstrated a cross-VM attack on GnuPG. Both attacks require manual identification of exploitable code and data in targeted binaries. Similarly, Maurice et al. [33] built a cache-index-agnostic cross-VM covert channel based on Prime+Probe.

Simultaneous to our work, Oren et al. [38] developed a cache attack from within sandboxed JavaScript to attack user-specific data like network traffic or mouse movements. Contrary to existing attack approaches, we present a general attack framework to exploit cache vulnerabilities automatically. We demonstrate the effectiveness of this approach by inferring keystroke information and, for comparison reasons, by attacking a T-table-based AES implementation.

3 Cache Template Attacks

Chari et al. [8] presented template attacks as one of the strongest forms of side-channel attacks. First, side-channel traces are generated on a device controlled by the attacker. Based on these traces, the template—an exact model of signal and noise—is generated. A single side-channel trace from an identical device with unknown key is then iteratively classified using the template to derive the unknown key.

Similarly, Brumley and Hakala [7] described cache-timing template attacks to automatically analyze and exploit cache vulnerabilities. Their attack is based on Prime+Probe on the L1 cache and, thus, needs to run on the same core as the spy program. Furthermore, they describe a profiling phase for specific operations executed in the attacked binary, which requires manual work or even modification of the attacked software. In contrast, our attack only requires an attacker to know how to trigger specific events in order to attack them. Subsequently, Brumley and Hakala match these timing templates against the cache timing observed. In contrast, we match memory-access templates against the observed memory accesses.

Inspired by their work we propose *Cache Template Attacks*. The presented approach of Cache Template Attacks allows the exploitation of any cache vulnerability present in any program on any operating system executed on architectures with shared inclusive last-level caches and shared memory enabled. Cache Template Attacks consist of two phases: 1) a profiling phase, and 2) an exploitation phase. In the profiling phase, we compute a Cache Template matrix containing the cache-hit ratio on an address given a specific target event in the binary under attack. The exploitation phase uses this Cache Template matrix to infer events from cache hits.

Both phases rely on Flush+Reload and, thus, attack code and static data within binaries. In both phases the attacked binary is mapped into read-only shared memory in the attacker process. By accessing its own virtual addresses in the allocated read-only shared memory region, the attacker accesses the same physical memory and the same cache lines (due to the physically-indexed last level cache) as the process under attack. Therefore, the attacker completely bypasses address space layout randomization (ASLR). Also, due to shared memory, the additional memory consumption caused by the attacker process is negligible, i.e., in the range of a few megabytes at most.

In general, both phases are performed online on the attacked system and, therefore, cannot be prevented through differences in binaries due to different versions or the concept of software diversity [12]. However, if online profiling is not possible, e.g., in case the events must be triggered by a user or Flush+Reload is not possible on the attacked system, it can also be performed in a controlled environment. Below, we describe the profiling phase and the exploitation phase in more detail.

3.1 Profiling Phase

The profiling phase measures how many cache hits occur on a specific address during the execution of a specific event, i.e., the *cache-hit ratio*. The cache-hit ratios for different events are stored in the Cache Template matrix which has one column per event and one row per address. We refer to the column vector for an event as a *profile*. Examples of Cache Template matrices can be found in Section 4 and Section 5.1.

An *event* in terms of a Cache Template Attack can be anything that involves code execution or data accesses, e.g., low-frequency events, such as keystrokes or receiving an email, or high-frequency events, such as encryption with one or more key bits set to a specific value. To automate the profiling phase, it must be possible to trigger the event programmatically, e.g., by calling a function to simulate a keypress event, or executing a program.

The Cache Template matrix is computed in three steps. The first step is the generation of the cache-hit trace and the event trace. This is the main computation step of the Cache Template Attack, where the data for the Template is measured. In the second step, we extract the cache-hit ratio for each trace and store it in the Cache Template matrix. In a third post-processing step, we prune rows and columns which contain redundant information from the matrix. Algorithm 1 summarizes the profiling phase. We explain the corresponding steps in detail below.

Algorithm 1: Profiling phase.

```
Input: Set of events $E$, target program binary $B$,
       duration $d$
Output: Cache Template matrix $T$

Map binary $B$ into memory
foreach event $e$ in $E$ do
    foreach address $a$ in binary $B$ do
        while duration $d$ not passed do
            simultaneously
                Trigger event $e$ and save event trace $g_{a,e}^{(E)}$
                Flush+Reload attack on address $a$
                    and save cache-hit trace $g_{a,e}^{(H)}$
        end
        Extract cache-hit ratio $H_{a,e}$ from $g_{a,e}^{(E)}$
            and $g_{a,e}^{(H)}$ and store it in $T$
    end
end
Prune Cache Template matrix $T$
```

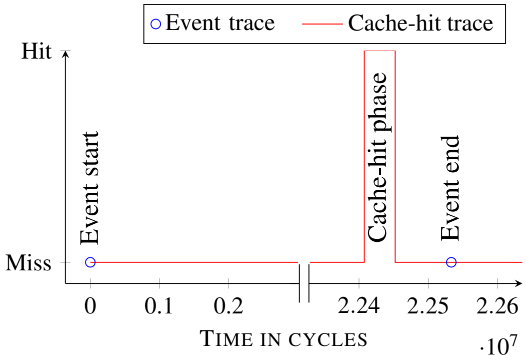

Figure 1: Trace of a single keypress event for address 0x4ebc0 of libgdk.so.

Cache-Hit Trace and Event Trace. The generation of the cache-hit trace and the event trace is repeated for each event and address for the specified duration (the while loop of Algorithm 1). The cache-hit trace $g_{a,e}^{(H)}$ is a binary function which has value 1 for every timestamp t where a cache hit has been observed. The function value remains 1 until the next timestamp t where a cache miss has been observed. We call subsequent cache hits a cache-hit phase. The event trace $g_{a,e}^{(E)}$ is a binary function which has value 1 when the processing of one specific event e starts or ends and value 0 for all other points.

In the measurement step, the binary under attack is executed and the event is triggered constantly. Each address of the attacked binary is profiled for a specific duration d. It must be long enough to trigger one or more events. Therefore, d depends only on the execution time of the event to be measured. The more events triggered within the specified duration d, the more accurate the resulting profile is. However, increasing the duration d increases the overall time required for the profiling phase.

The results of this measurement step are a cache-hit trace and an event trace, which are generated for all addresses a in the binary and all events e we want to profile. An excerpt of such a cache-hit trace and the corresponding event trace is shown in Figure 1. The start of the event is measured directly before the event is triggered. As we monitor library code, the cache-hit phase is measured before the attacked binary observes the event.

The generation of the traces can be sped up by two factors. First, in case of a cache miss, the CPU always fetches a whole cache line. Thus, we cannot distinguish between offsets of different accesses within a cache line and we can deduce the same information by probing only one address within each cache-line sized memory area.

Second, we reduce the overall number of triggered events by profiling multiple addresses at the same time. However, profiling multiple addresses on the same page can cause prefetching of more data from this page. Therefore, we can only profile addresses on different pages simultaneously. Thus, profiling all pages only takes as long as profiling a single page.

In case of low-frequency events, it is possible to profile all pages within one binary in parallel. However, this may lead to less accurate cache-hit traces $g_{a,e}^{(H)}$, i.e., timing deviations above 1 microsecond from the real event, which is only acceptable for low-frequency events.

Hit-Ratio Extraction. After the cache-hit trace and the event trace have been computed for a specific event e and a specific address a (the while loop of Algorithm 1), we derive the cache-hit ratio for each event and address. The cache-hit ratio $H_{a,e}$ is either a simple value or a time-dependent ratio function. In our case it is the ratio of cache hits on address a and the number of times the event e has been triggered within the profiling duration d.

To illustrate the difference between a cache-hit ratio with time dependency and without time dependency, we discuss two such functions. The cache-hit ratio with time dependency can be defined as follows. The event traces contain the start and end points of the processing of one event e. These start and end points define the relevant parts (denoted as *slices*) within the cache-hit trace. The slices are stored in a vector and scaled to the same length. Each slice contains a cache-hit pattern relative to the event e. If we average over this vector, we get the cache-hit ratio function for event e.

The second, much simpler approach is to define the cache-hit ratio without time dependency. In this case, we count the number of cache hits k on address a and divide it by the number of times n the event e has been triggered within the profiling duration d. That is, we define $H_{a,e} = \frac{k}{n}$. In case of a low-noise side channel and event detection through single cache hits, it is sufficient to use a simple hit-ratio extraction function.

Like the previous step, this step is repeated for all addresses a in the binary b and all events e to be profiled. The result is the full Cache Template matrix T. We denote the column vectors $\vec{p}_e$ as *profiles* for specific events.

Pruning. In the exploitation phase, we are limited regarding the number of addresses we can attack. Therefore, we want to reduce the number of addresses in the Cache Template. We remove redundant rows from the Cache Template matrix and merge events which cannot be distinguished based on their profiles $\vec{p}_e$.

As cache hits can be independent of an event, the measured cache-hit ratio on a specific address can be independent of the event, i.e., code which is always executed, frequent data accesses by threads running all the time, or code that is never executed and data that is never accessed. In order to be able to detect an event e, the set of events has to contain at least one event e' which does not include event e. For example, in order to be able to detect the event "user pressed key A" we need to profile at least one event where the user does not press key A.

The pruning happens in three steps on the matrix. First, the removal of all addresses that have a small difference between minimum and maximum cache-hit ratio for all events. Second, merging all similar columns (events) into one set of events, i.e., events that cannot be distinguished from each other are merged into one column. The similarity measure for this is, for example, based on a mean squared error (MSE) function. Third, the removal of redundant lines. These steps ensure that we select the most interesting addresses and also allows us to reduce the attack complexity by reducing the overall number of monitored addresses.

We measure the reliability of a cache-based side channel by true and false positives as well as true and false negatives. Cache hits that coincide with an event are counted as true positive and cache hits that do not coincide with an event as false positive. Cache misses which coincide with an event are counted as true negative and cache misses which do not coincide with an event as false negative. Based on these four values we can determine the accuracy of our Template, for instance, by computing the F-Score, which is defined as the harmonic mean of the cache-hit ratio and the positive predictive value (percentage of true positives of the total cache hits). High F-Score values show that we can distinguish the given event accurately by attacking a specific address. In some cases further lines can be pruned from the Cache Template matrix based on these measures. The true positive rate and the false positive rate for an event e can be determined by the profile $\vec{p}_e$ of e and the average over all profiles except e.

Runtime of the Profiling Phase. Measuring the cache-hit ratio is the most expensive step in our attack. To quantify the cost we give two examples. In both cases we want to profile a 1 MB library, once for a low-frequency event, e.g., a keypress, and once for a high-frequency event, e.g., an encryption. In both cases, we try to achieve a runtime which is realistic for offline and online attacks while maintaining a high accuracy.

We choose a profiling duration of $d = 0.8$ seconds for the low-frequency event. During 0.8 seconds we can trigger around 200 events, which is enough to create a highly accurate profile. Profiling each address in the library for 0.8 seconds would take 10 days. Profiling only cache-line-aligned addresses still takes 4 hours. Applying both optimizations, the full library is profiled in 17 seconds.

In case of the high-frequency event, we attack an encryption. We assume that one encryption and the corresponding Flush+Reload measurement take 520 cycles on average. As in the previous example, we profile each address 200 times and, thus, we need 40–50 microseconds per address, i.e., $d = 50\mu s$. The basic attack takes less than 55 seconds to profile the full library for one event. Profiling only cache-line-aligned addresses takes less than 1 second and applying both optimizations results in a negligible runtime.

As already mentioned above, the accuracy of the resulting profile depends on how many times an event can be triggered during profiling duration d. In both cases we chose durations which are more than sufficient to create accurate profiles and still achieve reasonable execution times for an online attack. Our observations showed that it is necessary to profile each event at least 10 times to get meaningful results. However, profiling an event more than a few hundred times does not increase the accuracy of the profile anymore.

3.2 Exploitation Phase

In the exploitation phase we execute a generic spy program which performs either the Flush+Reload or the Prime+Probe algorithm. For all addresses in the Cache Template matrix resulting from the profiling phase, the cache activity is constantly monitored.

We monitor all addresses and record whether a cache hit occurred. This information is stored in a boolean vector $\vec{h}$. To determine which event occurred based on this observation, we compute the similarity $S(\vec{h}, \vec{p}_e)$ between $\vec{h}$ and each profile $\vec{p}_e$ from the Cache Template matrix. The similarity measure S can be based, for example, on a mean squared error (MSE) function. Algorithm 2 summarizes the exploitation phase.

Algorithm 2: Exploitation phase.

```
Input: Target program binary $b$,
Cache Template matrix $T = (\vec{p}_{e_1}, \vec{p}_{e_2}, ..., \vec{p}_{e_n})$
Map binary $b$ into memory
repeat
    foreach address $a$ in $T$ do
        Flush+Reload attack on address $a$
        Store 0/1 in $\vec{h}[a]$ for cache miss/cache hit
    end
    if $\vec{p}_e$ equals $\vec{h}$ w.r.t. similarity measure then
        Event $e$ detected
    end
```

The exploitation phase has the same requirements as the underlying attack techniques. The attacker needs to be able to execute a spy program on the attacked system. In case of Flush+Reload, the spy program needs no privileges, except opening the attacked program binary in a read-only shared memory. It is even possible

```
int map[130][1024] = {{-1U},...,{-130U}};
int main(int argc, char** argv) {
  while(1) {
    int c = getchar(); // unbuffered
    if (map[(c % 128) + 1][0] == 0)
      exit(-1);
} }
```

Listing 1: Victim program with large array on Linux

to attack binaries running in a different virtual machine on the same physical machine, if the hypervisor has page deduplication enabled. In case of Prime+Probe, the spy program needs no privileges at all and it is even possible to attack binaries running in a different virtual machine on the same physical machine, as shown by Irazoqui et al. [20]. However, the Prime+Probe technique is more susceptible to noise and therefore the exploitation phase will produce less reliable results, making attacks on low-frequency events more difficult.

The result of the exploitation phase is a log file containing all detected events and their corresponding timestamps. The interpretation of the log file still has to be done manually by the attacker.

4 Attacks on Artificial Applications

Before we actually exploit cache-based vulnerabilities in real applications in Section 5, we demonstrate the basic working principle of Cache Template Attacks on two artificial victim programs. These illustrative attacks show how Cache Template Attacks automatically profile and exploit cache activity in any program. The two attack scenarios we demonstrate are: 1) an attack on lookup tables, and 2) an attack on executed instructions. Hence, our ideal victim program or library either contains a large lookup table which is accessed depending on secret information, e.g., depending on secret lookup indices, or specific portions of program code which are executed based on secret information.

Attack on Data Accesses. For demonstration purposes, we spy on simple events like keypresses. In our victim program, shown in Listing 1, each keypress causes a memory access in a large array called `map`. These key-based accesses are 4096 bytes apart from each other to avoid triggering the prefetcher. The array is initialized with static values in order to place it in the data segment and to guarantee that each page contains different data and, thus, is not deduplicated in any way. It is necessary to place it in the data segment in order to make it shareable with the spy program.

In the profiling phase of the Cache Template Attack, we simulate different keystroke events using the X11 automation library `libxdo`. This library can be linked statically into the spy program, i.e., it does not need to be installed. The Cache Template matrix is generated as described in Section 3. Within a duration of $d = 0.8$ seconds we simulated around 700 keypress events. The resulting Cache Template matrix can be seen in Figure 2 for all number keys. We observe cache hits on addresses that are exactly 4 096 bytes apart, which is due to the data type and the dimension of the `map` array. In our measurements, there were less than 0.3% false positive cache hits on the corresponding addresses and less than 2% false negative cache hits. The false positive and false negative cache hits are due to the high key rate in the keypress simulation.

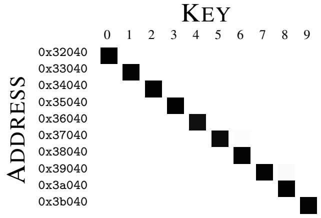

Figure 2: Cache Template matrix for the artificial victim program shown in Listing 1. Dark cells indicate high cache-hit ratios.

For verification purposes, we executed the generated keylogger for a period of 60 seconds and randomly pressed keys on the keyboard. In this setting we measured no false positives and no false negatives at all. This results from significantly lower key rates than in the profiling phase. The table is not used by any process other than the spy and the victim process and the probability that the array access happens exactly between the reload and the flush instruction is rather small, as we have longer idle periods than during the profiling phase. Thus, we are able to uniquely identify each key without errors.

Attack on Instruction Executions. The same attack can easily be performed on executed instructions. The source code for this example is shown in Listing 2. Each key is now processed in its own function, as defined by the `CASE(X)` macro. The functions are page aligned to avoid prefetcher activity. The `NOP1024` macro generates 1024 `nop` instructions, which is enough to avoid accidental code prefetching of function code.

Our measurements show that there is no difference between Cache Template Attacks on code and data accesses.

Performance Evaluation. To examine the performance limits of the exploitation phase of Cache Template Attacks, we evaluated the number of addresses which can

```
#define NOP1024 /*1024 times asm(”nop”);*/
#define CASE(X) case X:\
  { ALIGN(0x1000) void f##X() { NOP1024 };\
    f##X(); break; }
int main(int argc, char** argv) {
  while (1) {
    int c = getchar(); // unbuffered
    switch (c) {
      CASE(0);
      // ...
      CASE(128);
} } }
```

Listing 2: Victim program with long functions on Linux

be accurately monitored simultaneously at different key rates. At a key rate of 50 keys per second, we managed to spy on 16 000 addresses simultaneously on an Intel i5 Sandy Bridge CPU without any false positives or false negatives. The first errors occurred when monitoring 18 000 addresses simultaneously. At a key rate of 250 keys per second, which is the maximum on our system, we were able to spy on 4 000 addresses simultaneously without any errors. The first errors occurred when monitoring 5 000 addresses simultaneously. In both cases, we monitor significantly more addresses than in any practical cache attack today.

However, monitoring that many addresses is only possible if their position in virtual memory is such that the prefetcher remains inactive. Accessing several consecutive addresses on the same page causes prefetching of more data, resulting in cache hits although no program accessed the data. The limiting effect of the prefetcher on the Flush+Reload attack has already been observed by Yarom and Benger [54]. Based on these observations, we discuss the possibility of using the prefetcher as an effective countermeasure against cache attacks in Section 6.3.

5 Attacks on Real-World Applications

In this section, we consider an attack scenario where an attacker is able to execute an attack tool on a targeted machine in unprivileged mode. By executing this attack tool, the attacker extracts the cache-activity profiles which are exploited subsequently. Afterwards, the attacker collects the secret information acquired during the exploitation phase.

For this rather realistic and powerful scenario we present various case studies of attacks launched against real applications. We demonstrate the power of automatically launching cache attacks against any binary or library. First, we launch two attacks on Linux user interfaces, including GDK-based user interfaces, and an attack against a Windows user interface. In all attacks we simulate the user input in the profiling phase. Thus, the attack can be automated on the device under attack. To demonstrate the range of possible applications, we also present an automated attack on the T-table-based AES implementation of OpenSSL 1.0.2 [37].

5.1 Attack on Linux User Interfaces

There exists a variety of software-based side-channel attacks on user input data. These attacks either measure differences in the execution time of code in other programs or libraries [48], approximate keypresses through CPU and cache activity [44], or exploit system services leaking user input data [56]. In particular, Zhang et al. [56] use information about other processes from `procfs` on Linux to measure inter-keystroke timings and derive key sequences. Their proposed countermeasures can be implemented with low costs and prevent their attack completely. We, however, employ Cache Template Attacks to find and exploit leaking side-channel information in shared libraries automatically in order to spy on keyboard input.

Given root access to the system, it is trivial to write a keylogger on Linux using `/dev/input/event*` devices. Furthermore, the `xinput` tool can also be used to write a keylogger on Linux, but root access is required to install it. However, using our approach of Cache Template Attacks only requires the unprivileged execution of untrusted code as well as the capability of opening the attacked binaries or shared libraries in a read-only shared memory. In the exploitation phase one round of Flush+Reload on a single address takes less than 100 nanoseconds. If we measure the average latency between keypress and cache hit, we can determine the actual keypress timing up to a few hundred nanoseconds. Compared to the existing attacks mentioned above, our attack is significantly more accurate in terms of both event detection (detection rates near 100%) and timing deviations.

In all attacks presented in this section we compute time-independent cache-hit ratios.

Attack on the GDK Library. Launching the Cache Template profiling phase on different Linux applications revealed thousands of addresses in different libraries, binaries, and data files showing cache activity upon keypresses. Subsequently, we targeted different keypress events in order to find addresses distinguishing the different keys. Figure 3 shows the Cache Template of a memory area in the GDK library `libgdk-3.so.0.1000.8`, a part of the GTK framework which is the default user-interface framework on many Linux distributions.

Figure 3 shows several addresses that yield a cache hit with a high accuracy if and only if a certain key is

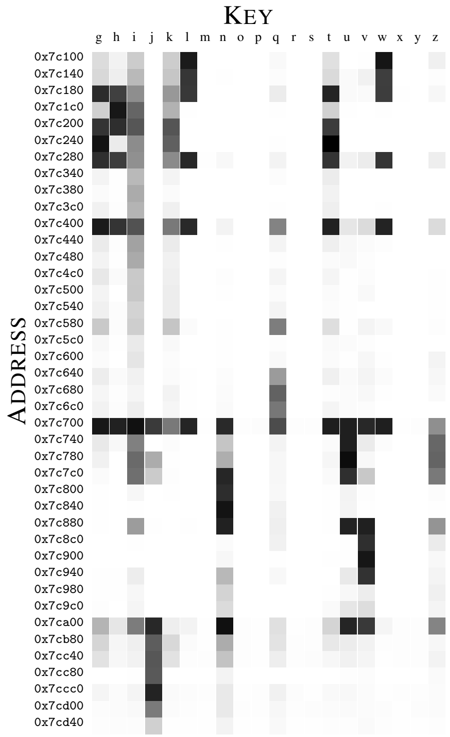

Figure 3: Excerpt of the GDK Cache Template. Dark cells indicate key-address-pairs with high cache-hit ratios.

pressed. For instance, every keypress on key `n` results in cache hit on address `0x7c800`, whereas the same address reacts in only 0.5% of our tests on other keypresses. Furthermore, we found a high cache-hit ratio on some addresses when a key is pressed (i.e., `0x6cd00` in `libgdk`), the mouse is moved (i.e., `0x28760` in `libgdk`) or a modifier key is pressed (i.e., `0x72fc0` in `libgdk`). We also profiled the range of keys a–f but it is omitted from Figure 3 because no high cache-hit ratios have been observed for the shown addresses.

We use the spy tool described in Section 3.2 in order to spy on events based on the Cache Template. We are able to accurately determine the following sets of pressed keys: $\{i\}$,$\{j\}$,$\{n\}$,$\{q\}$,$\{v\}$,$\{l,w\}$,$\{u,z\}$,$\{g,h,k,t\}$. That is, we cannot distinguish between keys in the same set, but keys in one set from keys in other sets. Similarly, we can deduce whether a key is contained in none of these sets.

Not as part of our attack, but in order to understand how keyboard input is processed in the GDK library, we analyzed the binary and the source code. In general, we found out that most of the addresses revealed in the profiling phase point to code executed while processing keyboard input. The address range discussed in this section contains the array `gdk_keysym_to_unicode_tab` which is used to translate key symbols to unicode special characters. The library performs a binary search on this array, which explains why we can identify certain keys accurately, namely the leaf nodes in the binary search.

As the corresponding array is used for keyboard input in all GDK user-interface components, including password fields, our spy tool works for all applications that use the GDK library. This observation allows us to use Cache Template Attacks to build powerful keyloggers for GDK-based user interfaces automatically. Even if we cannot distinguish all keys from each other, Cache Template Attacks allow us to significantly reduce the complexity of cracking a password. In this scenario, we are able to identify 3 keys reliably, as well as the total number of keypresses. Thus, in case of a lowercase password we can reduce the entropy per character from $\log_2(26) = 4.7$ to 4.0 bits. Attacking more than 3 addresses in order to identify more keys adds a significant amount of noise to the results, as it triggers the prefetcher. First experiments demonstrated the feasibility of attacking the lock screen of Linux distributions. However, further evaluation is necessary in order to reliably determine the effectiveness of this approach.

Attack on GDK Key Remapping. If an attacker has additional knowledge about the attacked system or software, more efficient and more powerful attacks are possible. Inspired by Tannous et al. [48] who performed a timing attack on GDK key remapping, we demonstrate a more powerful attack on the GDK library, by examining how the remapping of keys influences the sets of identifiable keypresses. The remapping functionality uses a large key-translation table `gdk_keys_by_keyval` which spreads over more than four pages.

Hence, we repeated the Cache Template Attack on the GDK library with a small modification. Before measuring cache activity for an address during an event, we remapped one key to the key code at that address, retrieved from the `gdk_keys_by_keyval` table. We found significant cache activity for some address and key-remapping combinations.

When profiling each key remapping for $d = 0.8$ seconds, we measured cache activity in 52 cache-line-sized memory regions. In verification scans, we found 0.2-2.5% false positive cache hits in these memory regions. Thus, we have found another highly accurate side channel for specific key remappings. The results are shown in the F-score graph in Figure 4. High values allow accurate detection of keypresses if the key is remapped to this address. Thus, we find more accurate results in terms of timing in our automated attack than Tannous et al. [48].

We can only attack 8 addresses in the profiled memory area simultaneously, since it spreads over 4 pages and we can only monitor 2 or 3 addresses without triggering the prefetcher. Thus, we are able to remap any 8

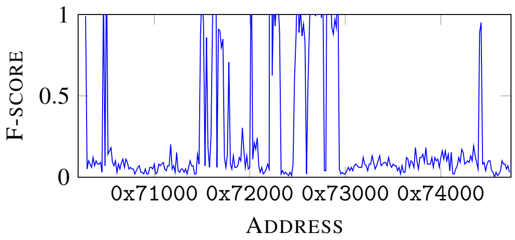

Figure 4: Excerpt of the F-score plot for the address range of the gdk_keys_by_keyval table. High values reveal addresses that can be exploited.

keys to these addresses and reliably distinguish them. In combination with the 3 addresses of our previous results, we are able to distinguish at least 11 keys and observe the timestamp of any keystroke in the system based on cache accesses simultaneously.

It is also possible to remap more than one key to the same key code. Hence, it is possible to distinguish between groups of keys. If we consider a lower-case password again, we can now reduce the entropy per character from $\log_2(26) = 4.7$ to 1.4 bits.

We also profiled keypresses on capslock and shift. Although we were able to log keypresses on both keys, we did not consider upper case or mixed case input. The exploitation phase automatically generates a log file containing the information observed through the cache side channel. However, interpretation of these results, such as deriving a program state from a sequence of events (shift key pressed or capslock active) and the influence of the program state on subsequent events is up to analysis of the results after the attack has been performed.

Tannous et al. [48] also described a login-detection mechanism in order to avoid remapping keys unless the user types in a password field. The spy program simply watches `/proc` to see whether a login program is running. Then the keys are remapped. As soon as the user pauses, the original key mappings are restored. The user will then notice a password mismatch, but the next password entry will work as expected.

Our completely automated password keylogger is a single binary which runs on the attacked system. It maps the GDK library into its own address space and performs the profiling phase. The profiling of each keypress requires the simulation of the keypress into a hidden window. Furthermore, some events require the key remapping we just described. Finally, the keylogger switches into the exploit mode. As soon as a logon screen is detected, for instance, after the screensaver was active or the screen was locked, the keys are remapped and all keypresses are logged into a file accessible by the attacker. Thus, all steps from the deployment of the keylogger to the final log file are fully automated.

5.2 Attacks on other Linux Applications

We also found leakage of accurate keypress timings in other libraries, such as the `ncurses` library (i.e., offset `0xbf90` in `libncurses.so`), and in files used to cache generated data related to user text input, such as `/usr/lib/locale/locale-archive`. The latter one is used to translate keypresses into the current locale. It is a generated file which differs on each system and which changes more frequently than the attacked libraries. In consequence, it is not possible to perform an offline attack, i.e., to use a pre-generated Cache Template in the exploitation phase on another system. Still, our concept of Cache Template Attacks allows us to perform an online attack, as profiling is fully automated by generating keystrokes through `libxdo` or comparable libraries. Thus, keystroke side channels are found within a few seconds of profiling. All keypress-timing side channels we found have a high accuracy and a timing deviation of less than 1 microsecond to the actual keypress.

In order to demonstrate Cache Template Attacks on a low-frequency event which is only indirectly connected to keypresses, we attacked `sshd`, trying to detect when input is sent over an active ssh connection. The received characters are unrelated to the local user input. When profiling for a duration of $d = 0.8$ seconds per address, we found 428 addresses showing cache activity when a character was received. We verified these results for some addresses manually. None of these checked addresses showed false positive hits within a verification period of 60 seconds. Thus, by exploiting the resulting Cache Template matrix, we are able to gain accurate timings for the transmitted characters (significantly less than 1 microsecond deviation to the transmission of the character). These timings can be used to derive the transmitted letters as shown by Zhang et al. [56].

5.3 Attack on Windows User Interfaces

We also performed Cache Template Attacks on Windows applications. The attack works on Windows using MinGW identically to Linux. Even the implementation is the same, except for the keystroke simulation which is now performed using the Windows API instead of the `libxdo` library, and the file under attack is mapped using `LoadLibrary` instead of `mmap`. We performed our attack on Windows 7 and Windows 8.1 systems with the same results on three different platforms, namely Intel Core 2 Duo, Intel i5 Sandy Bridge, and Intel i5 Ivy Bridge. As in the attacks on Linux user interfaces, address space layout randomization has been activated during both profiling and exploitation phase.

In an automated attack, we found cache activity upon keypresses in different libraries with reasonable accuracy. For instance, the Windows 7 common control library `comctl32.dll` can be used to detect keypresses on different addresses. Probing `0xc5c40` results in cache hits on every keypress and mouse click within text fields accurately. Running the generated keypress logger in a verification period of 60 seconds with keyboard input by a real user, we found only a single false positive event detection based on this address. Address `0xc6c00` reacts only on keypresses and not on mouse clicks, but yields more false positive cache hits in general. Again, we can apply the attack proposed by Zhang et al. [56] to recover typed words from inter-keystroke timings.

We did not disassemble the shared library and therefore do not know which function or data accesses cause the cache hit. The addresses were found by starting the Cache Template Attack with the same parameters as on Linux, but on a Windows shared library instead of a Linux shared library. As modern operating systems like Windows 7 and Windows 8.1 employ an immense number of shared libraries, we profiled only a few of these libraries. Hence, further investigations might even reveal addresses for a more accurate identification of keypresses.

5.4 Attack on a T-table-based AES

Cache attacks have been shown to enable powerful attacks against cryptographic implementations. Thus, appropriate countermeasures have already been suggested for the case of AES [15, 25, 30, 43]. Nevertheless, in order to compare the presented approach of Cache Template Attacks to related attacks, we launched an efficient and automated access-driven attack against the AES T-table implementation of OpenSSL 1.0.2, which is known to be insecure and susceptible to cache attacks [2, 4, 5, 16, 21, 22, 39, 53]. Recall that the T-tables are accessed according to the plaintext p and the secret key k, i.e., $T_j[p_i \oplus k_i]$ with $i \equiv j \mod 4$ and $0 \leq i < 16$, during the first round of the AES encryption. For the sake of brevity, we omit the full details of an access-driven cache attack against AES and refer the interested reader to the work of Osvik et al. [39, 49].

Attack of Encryption Events. In a first step, we profiled the two events "no encryption" and "encryption with random key and random plaintext". We profiled each cache-line-aligned address in the OpenSSL library during 100 encryptions. On our test system, one encryption takes around 320 cycles, which is very fast compared to a latency of at least 200 cycles caused by a single cache miss. In order to make the results more deterministically reproducible, we measure whether a cache line was used only after the encryption has finished. Thus, the profiling phase does not run in parallel and only one cache hit or miss is measured per triggered event.

This profiling step takes less than 200 seconds. We detected cache activity on 0.2%-0.3% of the addresses. Only 82 addresses showed a significant difference in cache activity depending on the event. For 18 of these addresses, the cache-hit ratio was 100% for the encryption event. Thus, our generated spy tool is able to accurately detect whenever an encryption is performed.

For the remaining 64 addresses the cache-hit ratio was around 92% for the encryption event. Thus, not each of these addresses is accessed in every encryption, depending on key and plaintext. Since we attack a T-table-based AES implementation, we know that these 64 addresses must be the T-tables, which occupy 4 KB respectively 64 cache lines. Although this information is not used in the first generated spy tool, it encourages performing a second attack to target specific key-byte values.

Attack on Specific Key-Byte Values. Exploiting the knowledge that we attack a T-table implementation, we enhance the attack by profiling over different key-byte values for a fixed plaintext, i.e., the set of events consists of the different key-byte values. Our attack remains fully automated, as we change only the values with which the encryption is performed. The result is again a log file containing the accurate timestamp of each event monitored. The interpretation of the log file, of course, involves manual work and is specific to the targeted events, i.e., key bytes in this case.

For each key byte k_i, we profile only the upper 4 bits of k_i as the lower 4 bits cannot be distinguished because of the cache-line size of 64 bytes. This means that we need to profile only 16 addresses for each key byte k_i. Furthermore, on average 92% of these addresses are already in the cache and the Reload step of the Flush+Reload attack is unlikely to trigger the prefetcher. Thus, we can probe all addresses after a single encryption. Two profiles for different values of k_0 are shown in Figure 5. The two traces were generated using 1 000 encryptions per key byte and address to show the pattern more clearly. According to Osvik et al. [39] and Spreitzer et al. [46] these plots (or patterns) reveal at least the upper 4 bits of a key byte and, hence, attacking the AES T-table implementation works as expected. In our case, experiments showed that 1 to 10 encryptions per key byte are enough to infer these upper 4 bits correctly.

In a T-table-based AES implementation, the index of the T-table is determined by $p_i \oplus k_i$. Therefore, the same profiles can be generated by iterating over the different plaintext byte values while encrypting with a fixed key. Osvik et al. [39] show a similar plot, generated using the Evict+Time attack. However, in our attack the profiles are aggregated into the Cache Template matrix, as de-

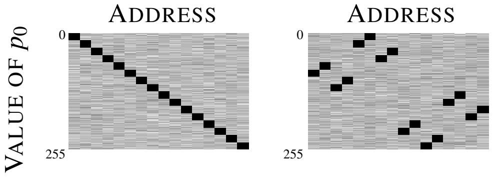

Figure 5: Excerpt of the Cache Template (address range of the first T-table). The plot is transposed to match [39]. In the left trace $k_0 =$ `0x00`, in the right trace $k_0 =$ `0x51`.

scribed in Section 3.1.

In the exploitation phase, the automatically generated spy tool monitors cache hits on the addresses from the Cache Template in order to determine secret key-byte values. We perform encryptions using chosen plaintexts. We attack the 16 key bytes k_i sequentially. In each step $i = 0,\dots,15$, the plaintext is random, except for the upper 4 bits of p_i, which are fixed to the same chosen value as in the profiling phase. Hence, the encryption is performed over a chosen plaintext. The spy tool triggers an encryption, detects when the encryption actually happens and after each encryption, reports the set of possible values for the upper 4 bits of key byte k_i. As soon as only one candidate for the upper 4 bits of key byte k_i remains, we continue with the next key byte.

Using Cache Template Attacks, we are able to infer 64 bits of the secret key with only 16–160 encryptions in a chosen-plaintext attack. Compared to the work of Osvik et al. [39] who require several hundred or thousands encryptions (depending on the measurement approach) targeting the L1 cache, and the work of Spreitzer and Plos [46] who require millions of encryptions targeting the L1 cache on the ARM platform, we clearly observe a significant performance improvement. More recent work shows that full key recovery is possible with less than 30 000 encryptions [17] using Flush+Reload.

The benefit of our approach, compared to existing cache attacks against AES, is that our attack is fully automated. Once the binary is deployed on the target system, it performs both profiling and exploitation phase automatically and finally returns a log file containing the key byte candidates to the attacker. Moreover, we do not need prior knowledge of the attacked system or the attacked executable or library.

AES T-table implementations are already known to be insecure and countermeasures have already been integrated, e.g., in the AES implementation of OpenSSL. Performing our attack on a non-T-table implementation (e.g., by employing AES-NI instructions) did not show key dependent information leakage, but still, we can accurately determine the start and end of the encryption through the cache behavior. However, we leave it as an interesting open issue to employ the presented approach of cache template attacks for further investigations of vulnerabilities in already protected implementations.

Trace-Driven Attack on AES. When attacking an insecure implementation of a cryptographic algorithm, an attacker can often gain significantly more information if it is possible to perform measurements during the encryption [2, 13], i.e., in case the exact trace of cache hits and cache misses can be observed. Even if we cannot increase the frequency of the Flush+Reload attack, we are able to slow down the encryption by constantly flushing the 18 addresses which showed cache activity in every profile. We managed to increase the encryption time from 320 cycles to 16 000–20 000 cycles. Thus, a more fine-grained trace of cache hits and cache misses can be obtained which might even allow the implementation of trace-driven cache attacks purely in software.

6 Countermeasures

We have demonstrated in Section 5 that Cache Template Attacks are applicable to real-world applications without knowledge of the system or the application. Therefore, we emphasize the need for research on effective countermeasures against cache attacks. In Section 6.1, we discuss several countermeasures which have been proposed so far. Subsequently, in Section 6.2, we discuss how Cache Template Attacks can be employed by developers to detect and eliminate cache-based information leakage and also by users to detect and prevent cache attacks running actively on a system. Finally, in Section 6.3, we propose changes to the prefetcher to build a powerful countermeasure against cache attacks.

6.1 Discussion of Countermeasures

Removal of the clflush Instruction is not Effective. The restriction of the `clflush` instruction has been suggested as a possible countermeasure against cache attacks in [54, 55, 58]. However, by adapting our spy tool to evict the cache line without using the `clflush` instruction (Evict+Reload instead of Flush+Reload), we demonstrate that this countermeasure is not effective at all. Thereby, we show that cache attacks can be launched successfully even without the `clflush` instruction.

Instead of using the `clflush` instruction, the eviction is done by accessing physically congruent addresses in a large array which is placed in large pages by the operating system. In order to compute physically congruent addresses we need to determine the lowest 18 bits of the physical address to attack, which can then be used to evict specific cache sets.

The actual mapping of virtual to physical addresses can be retrieved from `/proc/self/pagemap`. Even if such a mapping is not available, methods to find congruent addresses have been developed—simultaneously to this work—by Irazoqui et al. [20] by exploiting large pages, Oren et al. [38] by exploiting timing differences in JavaScript, and Liu et al. [32] by exploiting timing differences in native code.

The removal of the clflush instruction has also been discussed as a countermeasure to protect against DRAM disturbance errors (denoted as rowhammer bug). These disturbance errors have been studied by Kim et al. [27] and, later on, exploited by Seaborn et al. [45] to gain kernel privileges. Several researchers have already claimed to be able to exploit the rowhammer bug without the clflush instruction [14], This can be done by exploiting the Sandy Bridge cache mapping function, which has been reverse engineered by Hund et al. [18], to find congruent addresses.

Our eviction strategy only uses the lowest 18 bits and therefore, we need more than 12 accesses to evict a cache line. With 48 accessed addresses, we measured an eviction rate close to 100%. For performance reasons we use write accesses, as the CPU does not have to wait for data fetches from the physical memory. In contrast to the clflush instruction, which takes only 41 cycles, our eviction function takes 325 cycles. This is still fast enough for most Flush+Reload attacks.

While clflush always evicts the cache line, our eviction rate is only near 100%. Therefore, false positive cache hits occur if the line has not been evicted. Using Flush+Reload, there is a rather low probability for a memory access on the monitored address to happen exactly between the Reload step and the point where the clflush takes effect. This probability is much higher in the case of Evict+Reload, as the eviction step takes 8 times longer than the clflush instruction.

We compare the accuracy of Evict+Reload to Flush+Reload using previously found cache vulnerabilities. For instance, as described in Section 5.1, probing address 0x7c800 of libgdk-3.so.0.1000.8 allows us to detect keypresses on key n. The Flush+Reload spy tool detects on average 98% of the keypresses on key n with a 2% false positive rate (keypresses on other keys). Using Evict+Reload, we still detect 90% of the keypresses on key n with a 5% false positive rate. This clearly shows that the restriction of clflush is not sufficient to prevent this type of cache attack.

Disable Cache-Line Sharing. One prerequisite of Flush+Reload attacks is shared memory. In cloud scenarios, shared memory across virtual machine borders is established through page deduplication. Page deduplication between virtual machines is commonly disabled in order to prevent more coarse-grained attacks like fingerprinting operating systems and files [40, 47] as well as Flush+Reload. Still, as shown by Irazoqui et al. [20], it is possible to use Prime+Probe as a fallback. However, attacking low-frequency events like keypresses becomes infeasible, because Prime+Probe is significantly more susceptible to noise.

Flush+Reload can also be prevented on a system by preventing cache-line sharing, i.e., by disabling shared memory. Unfortunately, operating systems make heavy use of shared memory, and without modifying the operating system it is not possible for a user program to prevent its own memory from being shared with an attacker, even in the case of static linkage as discussed in Section 2.2.

With operating-system modifications, it would be possible to disable shared memory in all cases where a victim program cannot prevent an attack, i.e., shared program binaries, shared libraries, shared generated files (for instance, locale-archive). Furthermore, it would be possible to provide a system call to user programs to mark memory as "do-not-share."

A hardware-based approach is to change cache tags. Virtually tagged caches are either invalidated on context switches or the virtual tag is combined with an address space identifier. Therefore, shared memory is not shared in the cache. Thus, Flush+Reload is not possible on virtually tagged caches.

We emphasize that as long as shared cache lines are available to an attacker, Flush+Reload or Evict+Reload cannot be prevented completely.

Cache Set Associativity. Prime+Probe, Evict+Time and Evict+Reload exploit set-associative caches. In all three cases, it is necessary to fill all ways of a cache set, either for eviction or for the detection of evicted cache sets. Based on which cache set was reloaded (respectively evicted), secret information is deduced. Fully associative caches have better security properties, as such information deduction is not possible and cache eviction can only be enforced by filling the whole cache. However, a timing attack would still be possible, e.g., due to internal cache collisions [5] leading to different execution times. As fully associative caches are impractical for larger caches, new cache architectures have been proposed to provide similar security properties [29, 51, 52]. However, even fully associative caches only prevent attacks which do not exploit cache-line sharing. Thus, a combination of countermeasures is necessary to prevent most types of cache attacks.

6.2 Proactive Prevention of Cache Attacks

Instrumenting cache attacks to detect co-residency [57] with another virtual machine on the same physical machine, or even to detect cache attacks [58] and cache-based side channels in general [11] has already been proposed in the past. Moreover, Brumley and Hakala [7] even suggested that developers should use their attack technique to detect and eliminate cache vulnerabilities in their programs. Inspired by these works, we present defense mechanisms against cache attacks which can be improved by using Cache Template Attacks.

Detect Cache Vulnerabilities as a Developer. Similar to Brumley and Hakala [7], we propose the employment of Cache Template Attacks to find cache-based vulnerabilities automatically. Compared to [7], Cache Template Attacks allow developers to detect potential cache side channels for specifically chosen events automatically, which can subsequently be fixed by the developer. A developer only needs to select the targeted events (e.g., keystrokes, window switches, or encryptions) and to trigger these events automatically during the profiling phase, which significantly eases the evaluation of cache side channels. Ultimately, our approach even allows developers to find such cache vulnerabilities in third party libraries.

Detect and Impede Ongoing Attacks as a User. Zhang et al. [58] stated the possibility to detect cache attacks by performing a cache attack on one of the vulnerable addresses or cache sets. We propose running a Cache Template Attack as a system service to detect code and data under attack. If Flush+Reload prevention is sufficient, we simply disable page sharing for all pages with cache lines under attack. Otherwise, we disable caching for these pages as proposed by Aciiçmez et al. [1] and, thus, prevent all cache attacks. Only the performance for critical code and data parts is reduced, as the cache is only disabled for specific pages in virtual memory.

Furthermore, cache attacks can be impeded by performing additional memory accesses, unrelated to the secret information, or random cache flushes. Such obfuscation methods on the attacker's measurements have already been proposed by Zhang et al. [59]. The idea of the proposed obfuscation technique is to generate random memory accesses, denoted as cache cleansing. However, it does not address the shared last-level cache. In contrast, Cache Template Attacks can be used to identify possible cache-based information leaks and then to specifically add noise to these specific locations by accessing or flushing the corresponding cache lines.

6.3 Enhancing the Prefetcher

During our experiments, we found that the prefetcher influences the cache activity of certain access patterns during cache attacks, especially due to the spatial locality of addresses, as also observed in other work [16, 39, 54]. However, we want to discuss the prefetcher in more detail as it is crucial for the success of a cache attack.

Although the profiling phase of Cache Template Attacks is not restricted by the prefetcher, the spy program performing the exploitation phase might be unable to probe all leaking addresses simultaneously. For instance, we found 255 addresses leaking side-channel information about keypresses in the GDK library but we were only able to probe 8 of them simultaneously in the exploitation phase, because the prefetcher loads multiple cache lines in advance and, thus, generates numerous false positive cache hits.

According to the Intel 64 and IA-32 Architectures Optimization Reference Manual [19], the prefetcher loads multiple memory addresses in advance if "two cache misses occur in the last level cache" and the corresponding memory accesses are within a specific range (the so-called trigger distance). Depending on the CPU model this range is either 256 or 512 bytes, but does not exceed a page boundary of 4 KB. Due to this, we are able to probe at least 2 addresses per page.

We suggest increasing the trigger distance of the prefetcher beyond the 4 KB page boundary if the corresponding page already exists in the translation lookaside buffer. The granularity of the attack will then be too high for many practical targets, especially attacks on executed instructions will then be prevented.

As cache attacks constantly reaccess specific memory locations, another suggestion is to adapt the prefetcher to take temporal spatiality into consideration. If the prefetcher were to prefetch data based on that temporal distance, most existing attacks would be prevented.

Just as we did in Section 4, an attacker might still be able to establish a communication channel targeted to circumvent the prefetcher. However, the presented countermeasures would prevent most cache attacks targeting real-world applications.

7 Conclusion

In this paper, we introduced Cache Template Attacks, a novel technique to find and exploit cache-based side channels easily. Although specific knowledge of the attacked machine and executed programs or libraries helps, it is not required for a successful attack. The attack is performed on closed-source and open-source binaries in exactly the same way.

We studied various applications of Cache Template Attacks. Our results show that an attacker is able to infer highly accurate keystroke timings on Linux as well as Windows. For Linux distributions we even demonstrated a fully automatic keylogger that significantly reduces the entropy of passwords. Hence, we conclude that cache-based side-channel attacks are an even greater threat for today's computer architectures than assumed so far. In fact, even sensitive user input, like passwords, cannot be considered secure on machines employing CPU caches.

We argue that fundamental concepts of computer architectures and operating systems enable the automatic exploitation of cache-based vulnerabilities. We observed that many of the existing countermeasures do not prevent such attacks as expected. Still, the combination of multiple countermeasures can effectively mitigate cache attacks. However, the fact that cache attacks can be launched automatically marks a change of perspective, from a more academic interest towards practical attacks, which can be launched by less sophisticated attackers. This shift emphasizes the need to develop and integrate effective countermeasures immediately. In particular, it is not sufficient to protect only specific cryptographic algorithms like AES. More general countermeasures will be necessary to counter the threat of automated cache attacks.

8 Acknowledgments

We would like to thank the anonymous reviewers and our shepherd, Ben Ransford, for their valuable comments and suggestions. The research leading to these results has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 644052 (HECTOR).

Furthermore, this work has been supported by the Austrian Research Promotion Agency (FFG) and the Styrian Business Promotion Agency (SFG) under grant number 836628 (SeCoS).

Abstract

Public infrastructure-as-a-service clouds, such as Amazon EC2, Google Compute Engine (GCE) and Microsoft Azure allow clients to run virtual machines (VMs) on shared physical infrastructure. This practice of multi-tenancy brings economies of scale, but also introduces the risk of sharing a physical server with an arbitrary and potentially malicious VM. Past works have demonstrated how to place a VM alongside a target victim (co-location) in early-generation clouds and how to extract secret information via side-channels. Although there have been numerous works on side-channel attacks, there have been no studies on placement vulnerabilities in public clouds since the adoption of stronger isolation technologies such as Virtual Private Clouds (VPCs).

We investigate this problem of placement vulnerabilities and quantitatively evaluate three popular public clouds for their susceptibility to co-location attacks. We find that adoption of new technologies (e.g., VPC) makes many prior attacks, such as cloud cartography, ineffective. We find new ways to reliably test for co-location across Amazon EC2, Google GCE, and Microsoft Azure. We also find ways to detect co-location with victim web servers in a multi-tiered cloud application located behind a load balancer.

We use our new co-residence tests and multiple customer accounts to launch VM instances under different strategies that seek to maximize the likelihood of co-residency. We find that it is much easier (10× higher success rate) and cheaper (up to \$114 less) to achieve co-location in these three clouds when compared to a secure reference placement policy.

Keywords: co-location detection, multi-tenancy, cloud security

1 Introduction

Public cloud computing offers easy access to relatively cheap compute and storage resources. Cloud providers are able to sustain this cost-effective solution through *multi-tenancy*, where the infrastructure is shared between computations run by arbitrary customers over the Internet. This increases utilization compared to dedicated infrastructure, allowing lower prices.

However, this practice of multi-tenancy also enables various security attacks in the public cloud. Should an adversary be able to launch a virtual machine on the same physical host as a victim, making the two VMs co-resident (sometimes the term co-located is used), there exist attacks that break the logical isolation provided by virtualization to breach confidentiality [29, 32, 33, 35, 37, 38] or degrade the performance [30, 39] of the victim. Perhaps most notable are the side-channel attacks that steal private keys across the virtual-machine isolation boundary by cleverly monitoring shared resource usage [35, 37, 38].

Less understood is the ability of adversaries to arrange for co-residency in the first place. In general, doing so consists of using a *launch strategy* together with a mechanism for *co-residency detection*. The only prior work on obtaining co-residency [29] showed simple network-topology-based co-residency checks along with low-cost launch strategies that obtain a high probability of achieving co-residency compared to simply launching as many VM instances as possible. When such advantageous strategies exist, we say the cloud suffers from a placement vulnerability. Since then, Amazon has made several changes to their architecture, including removing the ability to do the simplest co-residency check. Whether placement vulnerabilities exist in other public clouds has, to the best of our knowledge, never been explored.

In this work, we provide a framework to systematically evaluate public clouds for placement vulnerabilities and show that three popular public cloud providers may be vulnerable to co-location attacks. More specifically, we set out to answer four questions:

- Can co-residency be effectively detected in modern public clouds?
- Are known launch strategies [29] still effective in modern clouds?

[*] Work primarily done while at the University of Wisconsin-Madison.

- Are there any new exploitable placement vulnerabilities?
- Can we quantify the money and time required of an adversary to achieve a certain probability of success?

We start by exploring the efficacy of prior co-residency tests (§ 4) and develop more reliable tests for our placement study (§ 4.1). We also find a novel test to detect co-residency with VMs uncontrolled by the attacker by just using their public interface even when they are behind a load balancer (§ 4.3).

We use multiple customer accounts across three popular cloud providers, launch VM instances under different scenarios that may affect the placement algorithm, and test for co-residency between all launched instances. We analyze three popular cloud providers, Amazon Elastic Compute Cloud (EC2) [2], Google Compute Engine (GCE) [6] and Microsoft Azure (Azure) [15], for vulnerabilities in their placement algorithm. After exhaustive experimentation with each of these cloud providers and at least 190 runs per cloud provider, we show that an attacker can still successfully arrange for co-location (§ 5). We find new launch strategies in these three clouds that obtain co-location faster (10x higher success rate) and cheaper (up to $114 less) when compared to a secure reference placement policy.

Next, we start by giving some background on public clouds (§ 2) and then define our threat model (§ 3). We conclude the paper with related and future work (§ 6 and § 7, respectively).

2 Background

Public clouds. Infrastructure-as-a-service (IaaS) public clouds, such as Amazon EC2, Google Compute Engine and Microsoft Azure, provide a management interface for customers to launch and terminate VM instances with a user-specified configuration. Typically, users register with the cloud provider for an account and use the cloud interface to specify VM configuration, which includes instance type, disk image, data center or region to host the VMs, and then launch VM instances. In addition, public clouds also provide many higher-level services that monitor load and automatically launch or terminate instances based on the workload [4,8,13]. These services internally use the same mechanisms as users to configure, launch and terminate VMs.

The provider's VM launch service receives from a client a desired set of parameters describing the configuration of the VM. The service then allocates resources for the new VM; this process is called *VM provisioning*. We are most interested in the portion of VM provisioning that selects the physical host to run a VM, which we call the *VM placement algorithms*. The resulting VM-to-host mapping we call the *VM placement*. The placement for a specific virtual machine may depend on many factors: the load on each machine, the number of machines in the data center, the number of concurrent VM launch requests, etc.

Type	Variable
Placement Parameters	# of customers
	# of instances launched per customer
	Instance type
	Data Center (DC) or Region
	Time launched
	Cloud provider
Environment Variable	Time of the day
	Days of the week
	Number of in-use VMs
	Number of machines in DC

Figure 1: **List of placement variables.**

While cloud providers do not generally publish their VM placement algorithms, there are several variables under the control of the user that could affect the VM placement, such as time-of-day, requested data center, and number of instances. A list of some notable parameters are given in Figure 1. By controlling these variables, an adversary can partially influence the placement of VMs on physical machines that may also host a target set of VMs. We call these variables *placement variables* and the set of values for these variables form a *launch strategy*. An example launch strategy is to launch 20 instances 10 minutes after triggering an auto-scale event on a victim application. This is, in fact, a launch strategy suggested by prior work [29].

Placement policies. VM placement algorithms used in public clouds often aim to increase data center efficiency, quality of service, or both by realizing some *placement policy*. For instance, a policy that aims to increase data center utilization may pack launched VMs on a single machine. Similarly policies that optimize the time to provision a VM, which involves fetching an image over the network to the physical machine and booting, may choose the last machine that used the same VM image, as it may already have the VM image cached on local disks. Policies may vary across cloud providers, and even within a provider.

Public cloud placement policies, although undocumented, often exhibit behavior that is externally observable. One example is *parallel placement locality* [29], in which VMs launched from different accounts within a short time window are often placed on the same physical machine. Two instances launched sequentially, where the first instance is terminated before the launch of the second one, are often placed on the same physical machine, a phenomenon called *sequential placement locality* [29].

These placement behaviors are artifacts of the two placement policies described earlier, respectively. Other examples of policies and resulting behaviors exist as well. VMs launched from the same accounts may either be packed on the same physical machine to maximize locality (and hence co-resident with themselves) or striped across different physical machines to maximize redundancy (and hence never co-resident with themselves). In the course of normal usage, such behaviors are unlikely to be noticed, but they can be measured with careful experiments.

Launch strategies. An adversary can exploit placement behaviors to increase the likelihood of co-locating with target victims. As pointed out by Ristenpart et al. [29], parallel placement locality can be exploited by triggering a scale-up event on target victim by increasing their load, which will cause more victim VMs to launch. The adversary can then simultaneously (or after a time lag) launch multiple VMs some of which may be co-located with the newly launched victim VM(s).

In this study, we develop a framework to systematically evaluate public clouds against launch strategies and uncover previously unknown placement behaviors. We approach this study by (i) identifying a set of placement variables that characterize a VM, (ii) enumerating the most interesting values for these variables, and (iii) quantifying the cost of such a strategy, if it in fact exposes a co-residency vulnerability. We repeat this for three major public cloud providers: Amazon EC2, Google Compute Engine, and Microsoft Azure. Note that the goal of this study is not to *reverse engineer* the exact details of the placement policies, but rather to identify launch strategies that can be exploited by an adversary.

Co-residency detection. A key technique for understanding placement vulnerabilities is detecting when VMs are co-resident on the same physical machine (also termed *co-locate*). In 2009, Ristenpart et al. [29] proposed several co-residency detection techniques and used them to identify several placement vulnerabilities in Amazon EC2. As co-resident status is not reported directly by the cloud provider, these detection methods are usually referred to as side-channel based techniques, which can be further classified into two categories: *logical side-channels* or *performance side-channels*.

Logical side-channels: Logical side-channels allow information leakage via logical resources that are observable to a software program, e.g., IP addresses, timestamp counter values. Particularly in Amazon EC2, each VM is assigned two IP addresses, a *public* IP address for communication over the Internet, and a private or *internal* IP address for intra-datacenter communications. The EC2 cloud infrastructure allowed translation of public IP addresses to their internal counterparts. This translation revealed the topology of the internal data center network, which allowed a remote adversary to map the entire public cloud infrastructure and determine, for example, the availability zone and instance type of a victim. Furthermore, co-resident VMs tended to have adjacent internal IP addresses.

Logical side-channels can also be established via shared timestamp counters. In prior work, skew in timestamp counters were used to fingerprint a physical machine [27], although this technique has not yet been explored for co-residency detection. Co-residency detection via shared state like interrupt counts and process statistics reported in `procfs` also come under this category, but are only applicable to container-based platform-as-a-service clouds.

Performance side-channels: Performance side-channels are created when performance variations due to resource contention are observable. Such variations can be used as an indicator of co-residency. For instance, network performance has been used for detecting co-residence [29, 30]. This is because hypervisors often directly relay network traffic between VMs on the same host, providing detectably shorter round-trip times than between VMs on different hosts.

Covert channels, as a special case of side-channels, can be established between two VMs that are cooperating in order to detect co-residency. For purposes of co-residency detection, covert channels based on shared hardware resources, such as last level caches (LLCs) or local storage disks, can be exploited by one VM to detect performance degradation caused by a co-resident VM. Covert channel detection techniques require control over both VMs, and are usually used in experimentation rather than in practical attacks. We later refer to such approaches as *cooperative co-residency detection*.

Placement study in PaaS. While we mainly studied placement vulnerabilities in the context of IaaS, we also experimented with Platform-as-a-Service (PaaS) clouds. PaaS clouds offer elastic application hosting services. Unlike IaaS where users are granted full control of a VM, PaaS provides managed compute tasks (or instances) for the execution of hosted web applications, and allow multiple such instances to share the same operating system. These clouds use either process-level isolation via file system access controls, or increasingly Linux-style containers (see [38] for a more detailed description). As such, logical side-channels alone are usually sufficient for co-residency detection purposes. For instance, in PaaS clouds, co-resident instances often share the same public IP address as the host machine. This is because the host-to-instance network is often configured using Network Address Translation (NAT) and each instance is assigned a unique port under the host IP address for incoming connections.

We found that many such logical side-channel-based co-residency detection approaches worked on PaaS clouds, even on those using containers. Specifically, we used both system-level interrupt statistics via `/proc/interrupts` and shared public IP addresses of the instances to detect co-location in Heroku [10].

Our brief investigation of co-location attacks in Heroku showed that naïve strategies like scaling two PaaS web applications to 30 instances with a time interval of 5 minutes between them, resulted in co-location in 6 out of 10 attempts. Moreover, since the co-location detection was simple and quick including the time taken for application scaling, we were able to do these experiments free of cost.

This result reinforces prior findings on PaaS co-location attacks [38] and confirms the existence of cheap launch strategies to achieve co-location and easy detection mechanisms to verify it. We do not investigate PaaS clouds further in the rest of this paper.

3 Threat Model

Co-residency attacks in public clouds, as mentioned earlier, involve two steps: a launch strategy and co-residency detection. We assume that the adversary has access to tools to identify a set of target victims, and either knows victim VMs' launch characteristics or can directly trigger their launches. The latter is possible by increasing load in order to cause the victim to scale up by launching more instances. The focus of this study is to identify if there exists any launch strategy that an adversary can devise to increase the chance of co-residency with a set of targeted victim VMs.

In our threat model, we assume that the cloud provider is trusted and the attacker has no affiliation of any form with the cloud provider. This also means that the adversary has no internal knowledge of the placement policies that are responsible for the VM placements in the public cloud. An adversary also has the same interface for launching and terminated VMs as regular customers, and no other special interfaces. Even though there may be per-account limits on the number of VMs that a cloud provider imposes, an adversary has access to an unlimited number of accounts and hence has no limit on the number of VMs he could launch at any given time.

No resource-limited cloud provider is a match to an adversary with limitless resources and hence realistically we assume that the adversary is resource-limited. For the same reason, a cloud provider is vulnerable to a launch strategy only when it is trivial or cost-effective for an adversary. As such, we aim to (i) quantify the cost of executing a launch strategy by an adversary, (ii) define a reference placement policy with which the placement policies of real clouds can be compared, and (iii) define metrics to quantify placement vulnerability.

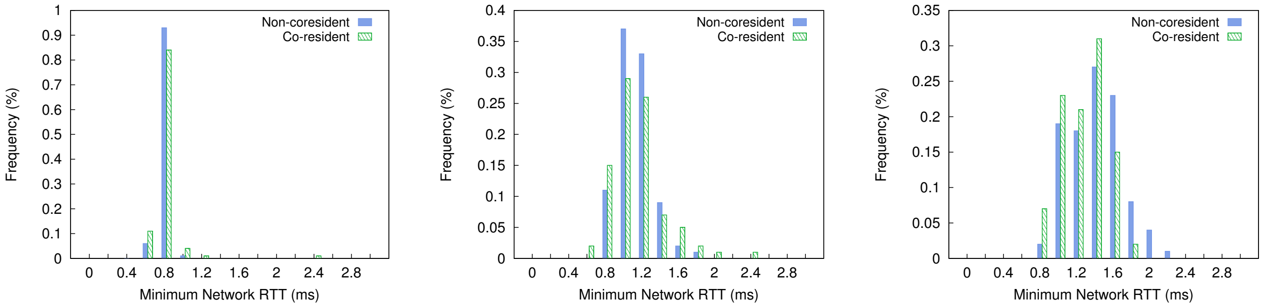
Cost of a launch strategy. Quantifying the cost of a launch strategy is straightforward: it is the cost of launching a number of VMs and running tests to detect co-residency with one or more target victim VMs. To be precise, the cost of a launch strategy S is given by $C_S = a * P(a_{type}) * T_d(v,a)$, where a is the number of attacker VMs of type a_{type} launched to get co-located with one of the v victim VMs. $P(a_{type})$ is the price of running one VM of type a_{type} for a unit time. $T_d(a,v)$ is the time to detect (in billing units) co-residency between all pairs of a attackers and v victim VMs, excluding pairs within each group. For simplicity, we assume that the attacker is running all instances till the last co-residency check is completed.

Reference placement policy. In order to define placement vulnerability, we need a yardstick to compare various placement policies and the launch strategies that they may be vulnerable to. To aid this purpose, we define a simple reference placement policy that has good security properties against co-residency attacks and use it to gauge the placement policies used in public clouds. Let there be N machines in a data center and let each machine have unlimited capacity. Given a set of unordered VM launch requests, the mapping of each VM to a machine follows a uniform random distribution. Let there be v victim VMs assigned to v unique machines among N, where $v \ll N$. The probability of *at least one* collision (i.e. co-residency) under the random placement policy and the above attack scenario when attacker launches a instances is given by $1 - \left(1 - v/N\right)^a$. We call this probability the reference probability[1]. Recall that for calculating cost of a launch strategy under this reference policy, we also need to define the price function, $P(vm_{type})$. For simplicity, we use the minimum price offered by any cloud provider as the price for the compute resource under the reference policy. For example, at the time of this study, Amazon EC2 offered t2.small instances at $0.026 per hour of instance activity, which was the cheapest price across all three clouds considered in this study.

Note that the reference placement policy makes several simplifying assumptions, but these only benefit the attacker. This is conservative as we will compare our experimental results to the best possible launch strategy under the reference policy. For instance, the assumption on unlimited capacity of the servers only benefits the attacker as it never limits the number of victim VMs an attacker could potentially co-locate with. We use a conservative value of 1000 for N, which is at least an order-of-magnitude less than the number of servers (50,000) in the smallest reported Amazon EC2 data centers [5]. Similarly, the price function of this placement policy also favors an attacker as it provides the cheapest price possible in the market even though in reality a secure placement policy may demand a higher price. Hence, it would be troubling if the state-of-the-art placement policies used in public clouds does not measure well even against such a conservative reference placement policy.

Placement Vulnerability. Putting it all together, we define two metrics to gauge any launch strategy against a placement policy: (i) *normalized success rate*, and (ii) *cost-benefit*. The normalized success rate is the success rate of the launch strategy in the cloud under test normalized to the success rate of the same strategy under the reference placement policy. The cost-benefit of a strategy is the additional cost that is incurred by the adversary in the reference placement policy to achieve the same success rate as the strategy in the placement policy under test. We define that a placement policy has a *placement vulnerability* if and only if there exists a launch strategy with a normalized success rate that is greater than 1.

[1] This probability event follows a hypergeometric distribution.



(a) GCE (b) EC2 (c) Azure

Figure 2: **Histogram of minimum network round trip times between pairs of VMs.** The frequency is represented as a fraction of total number of pairs in each category. The figure does not show the tail of the histogram.

Note that the normalized success rate quantifies how easy it is to get co-location. On the other hand, the cost benefit metric helps to quantify how cheap it is to get co-location compared to a more secure placement policy. These metrics can be used to compare launch strategies under different placement policies, where a higher value for any of these metrics indicate that the placement policy is relatively more vulnerable to that launch strategy. An ideal placement policy should aim to reduce both the success rate and the cost benefit of any strategy.

4 Detecting Co-Residence

An essential prerequisite for the placement vulnerability study is access to a co-residency detection technique that identifies whether two VMs are resident on the same physical machine in a third-party public cloud.

Challenges in modern clouds. Applying the detection techniques mentioned in Section 2 is no longer feasible in modern clouds. In part due to the vulnerability disclosure by Ristenpart et al. [29], modern public clouds have adopted new technologies that enhance the isolation between cloud tenants and thwart known co-residence detection techniques. In the network layer, virtual private clouds (VPCs) have been broadly employed for data center management [17, 20]. With VPCs, internal IP addresses are private to a cloud tenant, and can no longer be used for cloud cartography. Although EC2 allowed this in older generation instances (called EC2-classic), this is no longer possible under Amazon VPC setting. In addition, VPCs require communication between tenants to use public IP addresses for communication. As shown in Figure 2, the network timing test is also defeated, as using public IP addresses seems to involve routing in the data center network rather than short-circuiting through the hypervisor. Here, the ground-truth of co-residency is detected using memory-based covert-channel (described later in this section). Notice that there is *no* clear distinction between the frequency distribution of the network round trip times of co-resident and non-coresident pairs on all three clouds.

In the system layer, persistent storage using local disks is no longer the default. For instance, many Amazon EC2 instance types do not support local storage [1]; GCE and Azure provide only local Solid State Drives (SSD) [7, 14], which are less susceptible to detectable delays from long seeks. In addition, covert channels based on last-level caches [29, 30, 33, 36] are less reliable in modern clouds that use multiple CPU packages. Two VMs sharing the same machine may not share LLCs to establish the covert channel. Hence, these LLC-based covert-channels can only capture a subset of co-resident instances.

As a result of these technology changes, none of the prior techniques for detecting co-residency reliably work in modern clouds, compelling us to develop new approaches for our study.

4.1 Co-residency Tests

We describe in this subsection a pair of tools for co-residency tests, with the following design goals:

- Applicable to a variety of *heterogeneous* software and hardware stacks used in public clouds.
- Detect co-residency with *high confidence*: the false detection rate should be low even in the presence of background noise from other neighboring VMs.
- Detect co-residency *fast* enough to facilitate experimentation among large sets of VMs.

We chose a performance covert-channel based detection technique that exploits shared hardware resources, as this type of covert-channels are often hard to remove and most clouds are very likely to be vulnerable to it.

A covert-channel consists of a *sender* and a *receiver*. The sender creates contention for a shared resource and uses it to signal another tenant that potentially share the same resource. The receiver, on the other hand, senses this contention by periodically measuring the performance of that shared resource. A significant performance degradation measured at the receiver results in a successful detection of a sender's signal. Here the reliability of the covert-channel is highly dependent on the choice of the shared resource and the level of contention created by the sender. The sender is the key component of the co-residency detection techniques we developed as part of this study.

```
// allocate memory multiples of 64 bits
char_ptr = allocate_memory((N+1)*8)
//move half word up
unaligned_addr = char_ptr + 2
loop forever:
   loop i from (1..N):
     atomic_op(unaligned_addr + i, some_value)
   end loop
```

Figure 3: **Memory-locking – Sender.**

Memory-locking sender. Modern x86 processors support atomic memory operations, such as `XADD` for atomic addition, and maintain their atomicity using cache coherence protocols. However, when a locked operation extends across a cache-line boundary, the processor may lock the memory bus temporarily [32]. This locking of the bus can be detected as it slows down other uses of the bus, such as fetching data from DRAM. Hence, when used properly, it provides a timing covert channel to send a signal to another VM. Unlike cache-based covert channels, this technique works regardless of whether VMs share a CPU core or package.

We developed a sender exploiting this shared memory-bus covert-channel. The psuedocode for the sender is shown in Figure 3. The sender creates a memory buffer and uses pointer arithmetic to force atomic operations on unaligned memory addresses. This indirectly locks the memory bus even on all modern processor architectures [32].

```
size = LLC_size * (LLC_ways +1)
stride = LLC_sets * cacheline_sz)
buffer = alloc_ptr_chasing_buff(size, stride)
loop sample from (1..10): //number of samples
     start_rdtsc = rdtsc()
     loop probes from (1..10000):
         probe(buffer); //always hits memory
     end loop
     time_taken[sample] = (rdtsc() - start_rdtsc)
end loop
```

Figure 4: **Memory-probing – Receiver.**

Receivers. With the aforementioned memory-locking sender, there are several ways to sense the memory-locking contention induced by the sender in another co-resident tenant instance. All the receivers measure the memory bandwidth of the shared system. We present two types of receivers that we used in this study that works on heterogeneous hardware configurations.

Memory-probing receiver uses carefully crafted memory requests that always miss in the cache hierarchy and always hit memory. Constricting the data accesses of the receiver into a *single LLC set* ensures this. In order to evade hardware prefetching, we use a pointer-chasing buffer to randomly access a list of memory addresses (pseudocode shown in Figure 4). The time needed to complete a fixed number of probes (e.g., 10,000) provides a signal of co-residence: when the sender is performing locked operations, loads from memory proceed slowly.

Memory-locking receiver is similar to the sender but measures the number of unaligned atomic operations that could be completed per unit time. Although it also measures the memory bandwidth, unlike the memory-probing receiver, it works even when the cache architecture of the machine is unknown.

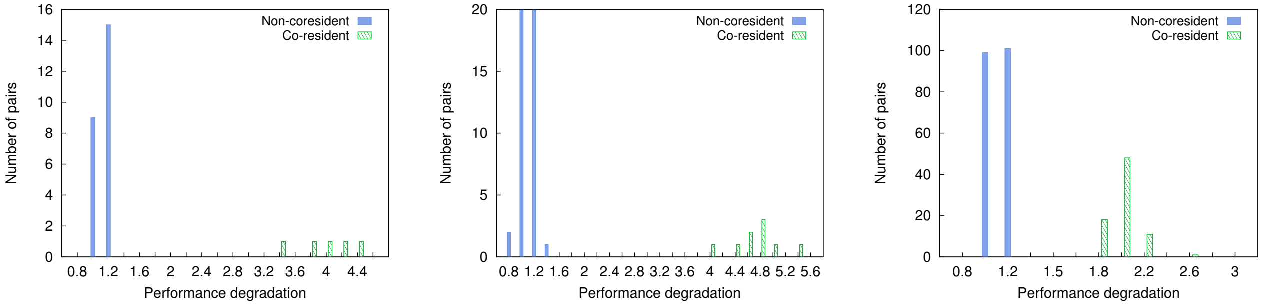
The sender along with these two receivers form our two novel co-residency detection methods that we use in this study: *memory-probing test* and *memory-locking test* (named after their respective receivers). These comprise our co-residency test suite. Each test in the suite starts by running the receiver on one VM while keeping the other idle. The performance measured by this run is the baseline performance without contention. Then the receiver and the sender are run together. If the receiver detects decreased performance, the tests conclude that the two VMs are co-resident. We use a slowdown threshold to detect when the change in receiver performance indicates co-residence (discussed later in the section).

Machine	Cores	Memory	Memory	Socket
Architecture		Probing	Locking	
Xeon E5645	6	3.51	1.79	Same
Xeon X5650	12	3.61	1.77	Same
Xeon X5650	12	3.46	1.55	Diff.

Figure 5: **Memory-probing and -locking on testbed machines.** Slowdown relative to the baseline performance observed by the receiver averaged across 10 samples. Same – sender and receiver on different cores on the same socket, Diff. – sender and receiver on different cores on different sockets. Xeon E5645 machine had a single socket.

Evaluation on local testbed. In order to measure the efficacy of this covert-channel we ran tests in our local testbed. Results of running memory-probing and -locking tests under various configurations are shown in Figure 5. The hardware architectures of these machines are similar to what is observed in the cloud [21]. Across these hardware configurations, we observed a performance degradation of at least 3.4× compared to not running memory-locking sender on a non-coresident instance (i.e. a baseline run with idle sender), indicating reliability. Note that this works even when the co-resident instances are running on cores on different sockets, which does not share the same LLC (works on *heterogeneous* hardware). Further, a single run takes one tenth of a second to complete and hence is also *quick*.

Note that for this test suite to work in the real world, an attacker requires control over both the VMs under test, which includes the victim. We call this scenario as co-residency detection under cooperative victims (in short, *co-operative co-residency detection*). Such a mechanism is sufficient to observe placement behavior in public clouds (Section 4.2). We further investigated approaches to detect co-residency under a realistic setting with an uncooperative victim. In Section 4.3 we show how to adapt the memory-probing test to detect co-location with one of the many web-servers behind a load balancer.



(a) GCE (b) EC2 (c) Azure – Intel machines

Figure 6: **Distribution of performance degradation of memory-probing test.** For varying number of pairs on each cloud (GCE:29, EC2:300, Azure:278). Note the x-axis plots performance degradation. Also for EC2 x-axis range is cut short at 20 pairs for clarity.

4.2 Cooperative Co-residency Detection

In this section, we describe the methodology we used to detect co-residency in public clouds. For the purposes of studying placement policies, we had the flexibility to control both VMs that we test for co-residence. We did this by launching VMs from two separate accounts and test them for pairwise co-residence. We encountered several challenges when running the co-residency test suite on three different public clouds - Google Computer Engine, Amazon EC2 and Microsoft Azure.

First, we had to handle noise from neighboring VMs sharing the same host. Second, hardware and software heterogeneity in the three different public clouds required special tuning process for the co-residency detection tests. Finally, testing co-residency for a large set of VMs demanded a scalable implementation. We elaborate on our solution to these challenges below.

Handling noise. Any noise from neighboring VMs could affect the performance of the receiver with and without the signal (or baseline) and result in misdetection. To handle such noise, we alternate between measuring the performance with and without the sender's signal, such that any noise equally affects both the measurements. Secondly, we take ten samples of each measurement and only detect co-residence if the ratios of *both* the mean and median of these samples exceed the threshold. As each run takes a fraction of a second to complete, repeating 10 times is still fast enough.

Cloud	**Machine**	**Clock**	**LLC**
Provider	**Architecture**	(GHz)	(Ways × Set)
EC2	Intel Xeon E5-2670	2.50	20 × 20480
GCE	Generic Xeon*	2.60*	20 × 16384
Azure	Intel E5-2660	2.20	20 × 16384
Azure	AMD Opteron 4171 HE	2.10	48 × 1706

Figure 7: **Machine configuration in public clouds.** The machine configurations observed over all runs with small instance types. GCE did not reveal the exact microarchitecture of the physical host (*). Ways × Sets × Word Size gives the LLC size. The word size is 64 bytes on all these x86-64 machines.

Tuning thresholds. As expected, we encountered different machine configurations on the three different public clouds (shown in Figure 7) with heterogeneous cache dimensions, organizations and replacement policies [11, 26]. This affects the performance degradation observed by the receivers with respect to the baseline and the ideal threshold for detecting co-residency. This is important because the thresholds we use to detect co-residence yield false positives, if set too low, and false negatives if set too high. Hence, we tuned the threshold to each hardware we found on all three clouds.

We started with a conservative threshold of 1.5x and tuned to a final threshold of 2x for GCE and EC2 and 1.5x for Azure for both the memory-probing and -locking tests. Figure 6 shows the distribution of performance degradation under the memory-probing tests across Intel machines in EC2, GCE, and Azure. For GCE and EC2, a performance degradation threshold of 2 clearly separates co-resident from non-coresident instances. For all Intel machines we encountered, although we ran both memory-locking and -probing tests, memory-probing was sufficient to detect co-residency. For Azure, overall we observe lower performance degradation and the initial threshold of 1.5 was sufficient to detect co-location on Intel machines.

The picture for AMD machines in Azure differs significantly as shown in Figure 8. The distribution of perfor-

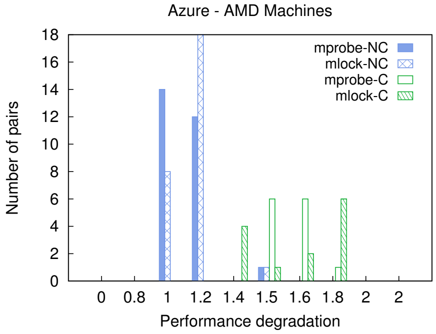


Figure 8: **Distribution of performance degradation of memory-probing and -locking tests.** On AMD machines in Azure with 40 pairs of nodes. Here NC stands for non-coresident and C, co-resident pairs. Note that the x-axis plots performance degradation.

mance degradation for both memory-locking and memory-probing shows that, unlike for other architectures, co-residency detection is highly sensitive to the choice of the threshold for AMD machines. This may be due to the more associative cache (48 ways vs. 20 for Intel), or different handling of locked instructions. For these machines, a threshold of 1.5 was high enough to have no false positives, which we verified by hand checking the instances using the two covert-channels and observed consistent performance degradation of at least 50%. We determine a pair of VMs as co-resident if the degradation in *either* of the tests is above this threshold. We did not detect any cross-architecture (false) co-residency detection in any of the runs.

Scaling co-residency detection tests. Testing co-residency at scale is time-consuming and increases quadratically with the number of instances: checking 40 VM instances, involves 780 pair-wise tests. Even if each run of the entire co-residency test suite takes only 10 seconds, a naïve sequential execution of the tests on all the pairs will take 2 hours. Parallel co-residency checks can speed checking, but concurrent tests may interfere with each other.

To parallelize the test, we partition the set of all VM pairs ($\binom{v+a}{2}$) into sets of pairs with no VMs twice; we run one of these sets at a time and record which pairs detected possible co-residence. After running all sets, we have a set of candidate co-resident pairs, which we test sequentially. Parallelizing co-residency tests significantly decreased the time taken to test all co-residency pairs. For instance, the parallel version of the test on one of the cloud providers took 2.4 seconds per pair whereas the serial version took almost 46.3 seconds per pair (a speedup of 20x). While there are faster ways to parallelize co-residency detection, we chose this approach for simplicity.

Veracity of our tests. Notice that a performance degradation of 1.5x, 2x and 4x corresponds to 50%, 100% and 300% performance degradation. Such high performance degradation (even 50%) is clear enough signal to declare co-residency due to resource sharing. Furthermore, we hand checked by running the two tests in isolation on the detected instance-pairs for a significant fraction of the runs for all clouds and observed a consistent covert-channel signal. Thus our methodology did not detect any false positives, which are more detrimental to our study than false negatives. Although *co-residency* here implies sharing of memory channel, which may not always mean sharing of cores or other per-core hardware resources.

4.3 Co-residency Detection on Uncooperative Victims

Until now, we described a method to detect co-residency with a cooperative victim. In this section, we look at a more realistic setting where an adversary wishes to detect co-residency with a victim VM with accesses limited to only public interfaces like HTTP or a key-value (KV) store's put-get interface. We show that the basic cooperative co-residency detection can also be employed to detect co-residency with an uncooperative victim in the wild.

Attack setting. Unlike previous attack scenarios, we assume the attacker has no access to the victim VMs or its application other than what is permitted to any user on the Internet. That is, the victim application exposes a well-known public interface (e.g., HTTP, FTP, KV-store protocol) that allows incoming requests, which is also the only access point for the attacker to the victim. The front end of this victim application can range from caching or data storage services (e.g., memcached, cassandra) to generic webservers. We also assume that there may be multiple instances of this front-end service running behind a load balancer. Under this scenario, the attacker wishes to detect co-location with one or more of the front-facing victim VMs.

Co-residency test. We adapt the memory tests used in previous section by running the memory-locking sender in the attacker instance. For a receiver, we use the public interface exposed by the victim by generating a set of requests that potentially makes the victim VMs hit the memory bus. This can be achieved by looping through a large number of requests of sizes approximately equal or greater than the size of the LLC. This creates a performance side-channel that leaks co-residency information. This receiver runs in an independent VM under the adversary's control, which we call the co-residency detector.

Experiment setup. To evaluate the efficacy of this method, we used the Olio multi-tier web application [12] that is designed to mimic a social-networking application. We used an instance of this workload from CloudSuite [22]. Although Olio supports several tiers (e.g., memcached to cache results of database queries), we configured it with two tiers, with each webserver and the database server running in a separate VM of type t2.small on Amazon EC2. Multiple of these webserver VMs are configured behind a HAProxy-based load balancer [9] running in an m3.medium instance (for better networking performance). The load balancer follows the standard configuration of using round-robin load balancing algorithm with sticky client sessions using cookies. We believe such a victim web application and its configuration is a reasonable generalization of real world applications running in the cloud.

For the attacker, we use an off-the-shelf HTTP performance measurement utility called `HTTPerf` [28] as the receiver in the co-residency detection test. This receiver is run inside a t2.micro instance (for free of charge). We used a set of 212 requests that included web pages and web objects (images, PDF files). We gathered these requests using the access log of manual navigation around the web application from a web browser.

Evaluation methodology. We start with a known co-resident VM pair using the cooperative co-residency detection method. We configure one of the VMs as a victim webserver VM and launch four more VMs: two webservers, one database server and a load balancer, all of which are not co-resident with the attacker VM.

Co-residency detection starts by measuring the average request latency at the receiver inside the co-residency detector for the baseline (with idle attacker) and contended case with the attacker running the memory-locking sender. A significant performance degradation between the baseline and the contended case across multiple samples reveal co-residency of one of the victim VMs with the attacker VM. On Amazon EC2, with the above setup we observed an average request latency of 4.66ms in the baseline case and a 10.6ms in the memory-locked case, i.e., a performance degradation of $\approx 2.3\times$.

Background noise. The above test was performed when the victim web application was idle. In reality, any victim in the cloud might experience constant or varying background load on the system. False positives or negatives may occur when there is spike in load on the victim servers. In such case, we use the same solution as in Section 4.2 — alternating between measuring the idle and the contended case.

In order to gauge the efficacy of the test under constant background load, we repeated the above experiment with varying load on the victim. The result of this experiment is summarized in Figure 9. Counterintuitively, we found that a constant load on the background server exacerbates the performance degradation gap, hence resulting in a clearer signal of co-residency. This is because running memory-locking on the co-resident attacker increases the service time of all requests as majority of the requests rely on memory bandwidth. This increases the queuing delay in the system and in turn increasing the overall request latency. Interestingly, this aforementioned performance gap stops widening at higher loads of 750 to 1000 concurrent users as the system hits a bottleneck (in our case a network bottleneck at the load balancer) even without running the memory-locking sender. Thus, detecting co-residency with a victim VM that is part of a highly loaded and bottlenecked application would be hard using this test.

We also experimented with increasing the number of victim webservers behind the load balancer beyond 3 (Figure 10). As expected, the co-residency signal grew weaker with increasing victims, and at 9 webservers, the performance degradation was too low to be useful for detecting co-residency.

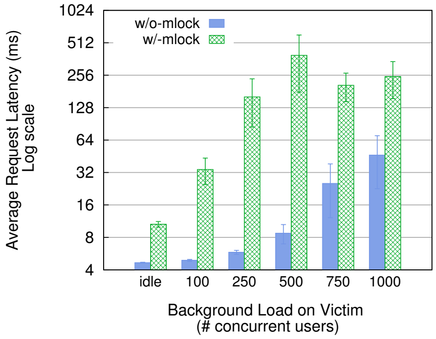

Figure 9: **Co-residency detection on an uncooperative victim.** The graph shows the average request latency at the co-residency detector without and with memory-locking sender running on the co-resident attacker VM under varying background load on the victim. Note that the y-axis is in log scale. The load is in the number of concurrent users, where each user on average generates 20 HTTP requests per second to the webserver.

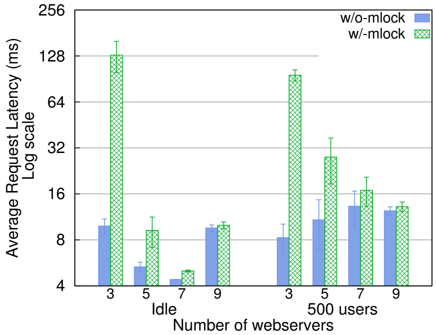

Figure 10: **Varying number of webservers behind the load balancer.** The graph shows the average request latency at the co-residency detector without and with memory-locking sender running on the co-residency attacker VM under varying background load on the victim. Note that the y-axis is in log scale. The error bars show the standard deviation over 5 samples.

5 Placement Vulnerability Study

In this section, we evaluate three public clouds, Amazon EC2, Google Compute Engine and Microsoft Azure, for placement vulnerabilities and answer the following questions: (i) what are all the strategies that an adversary can employ to increase the chance of co-location with one or more victim VMs? (ii) what are the chances of success and cost of each strategy? and (iii) how do these strategies compare against the reference placement policy introduced in Section 3?

5.1 Experimental Methodology

Before presenting the results, we first describe the experiment setting and methodology that we employed for this placement vulnerability study.

Experiment settings. Recall VM placement depends on several placement variables (shown in Figure 1). We assigned reasonable values to these placement variables and enumerated through several launch strategies. A *run* corresponds to one launch strategy and involves launching multiple VMs from two distinct accounts (i.e., subscriptions in Azure and projects in GCE) and checking for co-residency between all pairs of VMs launched. One account was designated as a proxy for the victim and the other for the adversary. We denote a *run configuration* by $v \times a$, where v is the number of victim instances and a is the number of attacker instances launched in that run. We varied v and a for all v, $a \in \{10, 20, 30\}$ and restricted them to the inequality, $v \leq a$, as it increases the likelihood of achieving co-residency.

Other placement variables that are part of the run configuration include: victim launch time (including time of the day, day of the week), delay between victim and attacker VM launches, victim and attacker instance types and data center location or region where the VMs are launched. We repeat each run multiple times across all three cloud providers. The repetition of experiments is especially required to control the effect of certain environment variables like time of day. We repeat experiments for each run configuration over various times of the day and days of the week. We fix the instance type of VMs to small instances (t2.small on EC2, g1.small on GCE and small or Standard-A1 on Azure) and data center regions to us-east for EC2, us-central1-a for GCE and east-us for Azure, unless otherwise noted. All experiments were conducted over 3 months between December 2014 to February 2015.

We used a single, local Intel Core i7-2600 machine with 8 SMT cores to launch VM instances, log instance information and run the co-residency detection test suite.

Implementation and the Cloud APIs. In order to automate our experiments, we used Python and the libcloud[2] library [3] to interface with EC2 and GCE. Unfortunately, libcloud did not support Azure. The only Azure cloud API on Linux platform was a node.js library and a cross-platform command-line interface (CLI). We built a wrapper around the CLI. There were no significant differences across different cloud APIs except that Azure did not have any explicit interface to launch multiple VMs simultaneously.

As mentioned in the experiment settings, we experimented with various delays between the victim and attacker VM launches (0, 1, 2, 4 ... hours). To save money, we reused the same set of victim instances for each of the longer runs. That is, for the run configuration of 10x10 with 0, 1, 2, and 4 hours of delay between victim and attacker VM launches, we launched the victim VMs only once at the start of the experiment. After running co-residency tests on the first set of VM pairs, we terminated all the attacker instances and relaunched attacker VM instances after appropriate delays (say 1 hour) and rerun the tests with *the same set* of victim VMs. We repeat this until we experiment with all delays for this configuration. We call this methodology the *leap-frog method*. It is also important to note that zero delay here means parallel launch of VMs from our test machine (and not sequential launch of VMs from one account after another), unless otherwise noted.

In the sections below, we take a closer look at the effect of varying one placement variable while keeping other variables fixed across all the cloud providers. In each case, we use three metrics to measure the degree of co-residency: chances of getting at least one co-resident instance across a number of runs (or success rate), average number of co-resident instances over multiple runs and average coverage (i.e., fraction of victim VMs with which attacker VMs were co-resident). Although these experiments were done with victim VMs under our control, the results can be extrapolated to guide an attacker's launch strategy for an uncooperative victim. We also discuss a set of such strategic questions that the results help answer. At the end of this section, we summarize and calculate the cost of several interesting launch strategies and evaluate the public clouds against our reference placement policy.

Delay (hr.)	**Config.**	**Mean**	**S.D.**	**Min**	**Median**	**Max**
0	10x10	0.11	0.33	0	0	1
0	10x20	0.2	0.42	0	0	1

1	30x30	3.89	2.09	2	3	9

Figure 12: **Distribution of number of co-resident pairs on EC2.** Region: us-east.

5.2 Effect of Number of Instances

In this section, we observe the placement behavior while varying the number of victim and attacker instances. Intuitively, we expect the chances of co-residency to increase with the number of attacker and victim instances.

Varying number of attacker instances. Keeping all the placement variables constant including the number of victim instances, we measure the chance of co-residency over multiple runs. The result of this experiment helps to answer the question: How many VMs should an adversary launch to increase the chance of co-residency?

As is shown in Figure 14, the placement behavior

[2] We used libcloud version 0.15.1 for EC2, and a modified version of 0.16.0 for GCE to support the use of multiple accounts in GCE.

Delay (hr.)	**Config.**	**Mean**	**S.D.**	**Min**	**Median**	**Max**
0	10x10	15.22	19.51	0	14	64
0	10x20	3.78	4.71	0	3	14
0	10x30	4.25	6.41	0	2.5	19
0	20x20	9.67	8.43	0	8	27
0	20x30	2.38	1.51	1	2	5
0	30x30	24.57	36.54	1	6	99
1	10x10	2.78	3.87	0	1	12
1	10x20	0.78	1.2	0	0	3
1	10x30	0.75	1.39	0	0	3
1	20x20	0.67	1.66	0	0	5
1	20x30	0.86	0.9	0	1	2
1	30x30	4.71	9.89	0	1	27

Figure 13: **Distribution of number of co-resident pairs on Azure.** Region: East US 1.

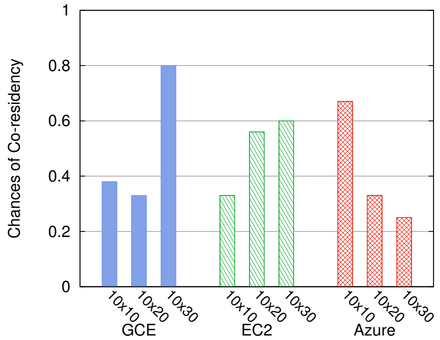

Figure 14: **Chances of co-residency of 10 victim instances with varying number of attacker instances.** All results are from one data center region (EC2: us-east, GCE: us-central1-a, Azure: East US) and the delays between victim and attacker instance launch were 1 hour. Results are over at least 9 runs per run configuration with at least 3 runs per time of day.

changes across different cloud providers. For GCE and EC2, we observe that higher the number of attacker instances relative to the victim instances, the higher the chance of co-residency is. Figure 11 and 12 show the distribution of number of co-resident VM pairs on GCE and EC2, respectively. The number of co-resident VM pairs also increases with the number of attacker instances, implying that the coverage of an attack could be increased with larger fraction of attacker instances than the target VM instances if the launch times are coordinated.

Contrary to our expectations, the placement behavior observed on Azure is the inverse. The chances of co-residency with 10 attacker instances are almost twice as high as with 30 attacker instances. This is also reflected in the distribution of number of co-residency VM pairs (shown in Figure 13). Further investigation revealed a correlation between the number of victim and attacker instances launched and the chance of co-residency. That is, for the run configuration of 10x10, 20x20 and 30x30, where number of victim and attacker instances are the same, and with 0 delay, the chance of co-residency were equally high for all these configurations (between 0.9 to 1). This suggests a possible placement policy that collates VM launch requests together based on their request size and places them on the same group of machines.

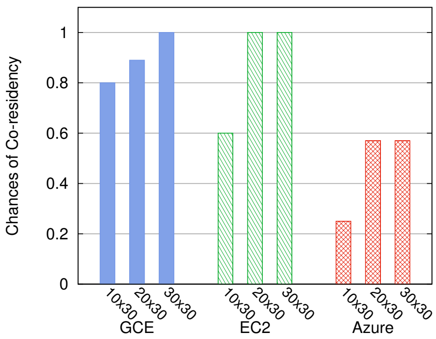

Figure 15: **Chances of co-residency of 30 attacker instances with varying number of victim instances.** All results are from one data center region (EC2: us-east, GCE: us-central1-a, Azure: East US) and the delays between victim and attacker instance launch were 1 hour. Results are over at least 9 runs per configuration with at least 3 runs per time of day.

Varying number of victim instances. Similarly, we also varied the number of victim instances by keeping the number of attacker instances and other placement variables constant (results shown in Figure 15). We expect the chance of co-residency to increase with the number of victims targeted. Hence, the results presented here help an adversary answer the question: What are the chances of co-residency with varying sizes of target victims?

As expected, we see an increase in the chances of co-residency with increasing number of victim VMs across all cloud providers. We see that the absolute value of the chance of co-residency is lower for Azure than other clouds. This may be the result of significant additional delay between victim and attacker launch times in Azure as a result of our methodology (more on this later).

5.3 Effect of Instance Launch Time

In this section, we answer two questions that aid an adversary to design better launch strategies: How quickly should an attacker launch VMs after the victim VMs are launched? Is there any increase in chance associated with the time of day of the launch?

Varying delay between attacker and victim launches. The result of varying the delay between 0 (i.e., parallel launch) and 1 hour delay is shown in Figure 16. We can make two immediate observations from this result.

The first observation reveals a significant artifact of EC2's placement policy: VMs launched within a short time window are never co-resident on the same machine. This observation helps an adversary to avoid such a strategy. We further investigated placement behaviors on EC2 with

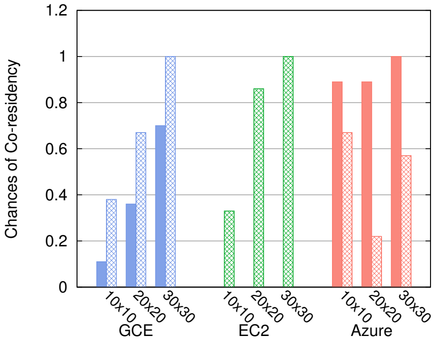

Figure 16: **Chances of co-residency with varying delays between victim and attacker launches.** *Solid* boxes correspond to zero delay (simultaneous launches) and *gauze*-like boxes correspond to 1 hour delay between victim and attacker launches. We did not observe any co-resident instances for runs with zero delay on EC2. All results are from one data center region (EC2: us-east, GCE: us-central1-a, Azure: East US). Results are over at least 9 runs per run configuration with at least 3 runs per time of day.

Delay	Mean	S.D.	Min	Median	Max	Success rate
0+	0.6	1.07	0	0	3	0.30
5 min	1.38	0.92	0	1	3	0.88
1 hr	3.57	2.59	0	3.5	9	0.86

Figure 17: **Distribution of number of co-resident pairs and success rate or chances of co-residency for shorter delays under 20x20 run configuration in EC2.** A delay with 0+ means victim and attacker instances were launched sequentially, i.e. attacker instances were not launched until all victim instances were running. The results averaged are over 9 runs with 3 runs per time of day.

shorter non-zero delays in order to find the duration of this time window in which there are zero co-residency (results shown in Figure 17). We found that this time window is very short and that even a sequential launch of instances (denoted by 0+) could result in co-residency.

The second observation shows that non-zero delay on GCE and zero delay on Azure increases the chance of co-residency and hence directly benefits an attacker. It should be noted that on Azure, the launch delays between victim and attacker instances were longer than 1 hour due to our leap-frog experimental methodology; the actual delays between the VM launches were, on average, 3 hours (with a maximum delay of 10 hours for few runs). This higher delay was more common in runs with larger number of instances as there were significantly more false positives, which required a separate sequential phase to resolve (see Section 4.2).

We also experimented with longer delays on EC2 and GCE to understand whether and how quickly the chance of co-residency drops with increasing delay (results shown in Figure 18). Contrary to our expectation, we did not find the chance of co-residency to drop to zero even for delays as high as 16 and 32 hours. We speculate that the reason for this observation could be that the system was under constant churn where some neighboring VMs on the victim's machine were terminated. Note that our leap-frog methodology may, in theory, interfere with the VM placement. But it is noteworthy that we observed increased number of unique co-resident pairs with increasing delays, suggesting fresh co-residency with victim VMs over longer delays.

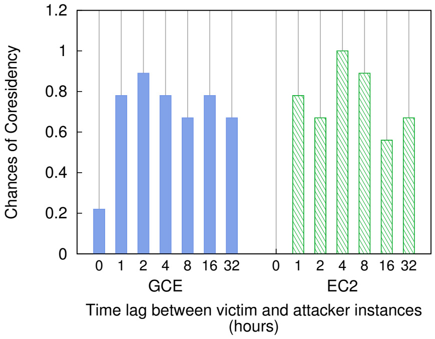

Figure 18: **Chances of co-residency over long periods.** Results include 9 runs over two weeks with 3 runs per time of day under the 20x20 run configuration. Note that we only conducted 3 runs for 32 hour delay as opposed to 9 runs for all other delays.

Chances of Co-residency			
Cloud	**Morning**	**Afternoon**	**Night**
	02:00 - 10:00	10:00 - 18:00	18:00 - 02:00
GCE	0.68	0.61	0.78
EC2	0.89	0.73	0.6

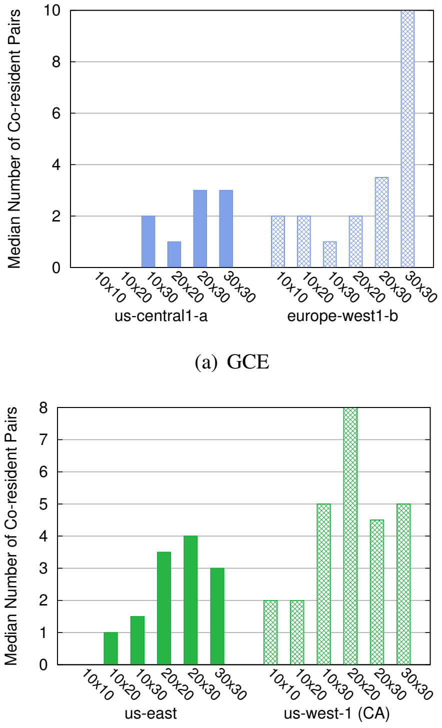
Figure 19: **Effect of time of day.** Chances of co-residency when an attacker changes the launch time of his instances. The results were aggregated across all run configurations with 1 hour delay between victim and attacker launch times. All times are in PT.

Effect of time of day. Prior works have shown that churn or load is often correlated with the time of day [31]. Our simple reference placement policy does not have a notion of load and hence have no effect on time of day. In reality, with limited number of servers in datacenters and limited number of capacity per host, load on the system has direct effect on the placement behavior of any placement policy.

As expected, we observe small effect on VM placement based on the time of day when attacker instances are launched (results shown in Figure 19). Specifically, there is a slightly higher chance of co-residency if the attacker instances are launched in the early morning for EC2 and at night for GCE.

5.4 Effect of Data Center Location

All the above experiments were conducted on relatively popular regions in each cloud (especially true for EC2 [31]). In this section, we report the results on other smaller and less popular regions. As the regions are less popular and have relatively fewer machines, we expect higher co-residency rates and more co-resident instances. Figure 20 shows the median number of co-resident VM



(a) GCE

(b) EC2

Figure 20: **Median number of co-resident pairs across two regions.** The box plot shows the median number of co-resident pairs excluding co-residency within the same account. Results are over at least 3 run per run configuration (x-axis).

pairs placed in these regions alongside the results for popular regions. The distribution of number of co-resident instances is not shown here in the interest of space.

The main observation from these experiments is that there is a higher chance of co-residency in these smaller regions than the larger, more popular regions. Note that we placed at least one co-resident pair in all the runs in these regions. Also the higher number of co-resident pairs also suggests a larger coverage over victim VMs in these smaller regions.

One anomaly that we found during two 20x20 runs on EC2 between 30^{th} and 31^{st} of January 2015, when we observed an unusually large number of co-resident instances (including three VMs from the same account). We believe this anomaly may be a result of an internal management incident in the Amazon EC2 us-west-1 region.

5.5 Other Observations

We report several other interesting observations in this section. First, we found more than two VMs can be co-resident on the same host on both Azure and GCE, but not on EC2. Figure 21 shows the distribution of number of co-resident instances per host. Particularly, in one of the runs, we placed 16 VMs on a single host.

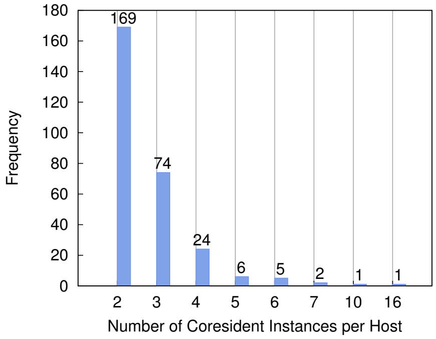


Figure 21: **Distribution of number of co-resident instances per host on Azure.** The results shown are across all the runs. We saw at most 2 instances per host in EC2 and at most 3 instances per host in GCE.

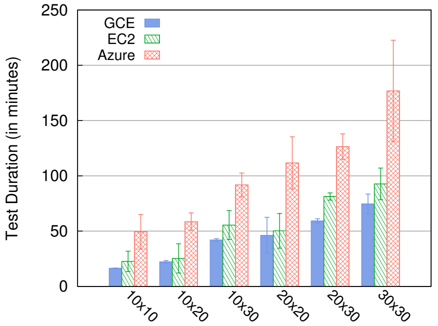

Figure 22: **Launch strategy and co-residency detection execution times.** The run configurations $v \times a$ indicates the number of victims vs. number of attackers launched. The error bars show the standard deviation across at least 7 runs.

Another interesting observation is related to co-resident instances from the same account. We term them as *self-co-resident instances*. We observed many self-co-resident pairs on GCE and Azure (not shown). On the other hand, we never noticed any self co-resident pair on EC2 except for the anomaly in us-west-1. Although we did not notice any effect on the actual chance of co-residence, we believe such placement behaviors (or the lack of) may affect VM placement.

We also experimented with medium instances and successfully placed few co-located VMs on both EC2 and GCE by employing similar successful strategies learned with small instances.

5.6 Cost of Launch Strategies

Recall that the cost of a launch strategy from Section 3, $C_S = a * P(a_{type}) * T_d(v,a)$. In order to calculate this cost, we need $T_d(v,a)$ which is the time taken to detect co-location with a attackers and v victims. Figure 22 shows the average time taken to complete launching attacker instances and complete co-residency detection for each run configuration. Here the measured co-residency detection is the parallelized version discussed in Section 4.2 and also includes time taken to detect co-residency within each tenant account. Hence, for these reasons the time to detect

Run	**Average Cost ($)**			**Maximum Cost ($)**		
config.	GCE	EC2	Azure	GCE	EC2	Azure
10x10	**0.137**	0.260	0.494	0.140	0.260	0.819
10x20	0.370	0.520	1.171	0.412	0.520	1.358
10x30	1.049	0.780	2.754	1.088	1.560	3.257
20x20	0.770	0.520	2.235	1.595	1.040	3.255
20x30	1.482	1.560	3.792	1.581	1.560	4.420
30x30	1.866	1.560	5.304	2.433	1.560	**7.965**

Figure 23: **Cost of running a launch strategy** (in dollars). Maximum cost column refers to the maximum cost we incurred out of all the runs for that particular configuration and cloud provider. The cost per hour of small instances at the time of this study were: 0.05, 0.026 and 0.06 dollars for GCE, EC2 and Azure, respectively. The minimum and maximum costs are in **bold**.

Run Config.	10x10	10x20	10x30	20x20	20x30	30x30
$\Pr[\mathbf{E}_a^v > 0]$	0.10	0.18	0.26	0.33	0.45	0.60

Figure 24: **Probability of co-residency under the reference placement policy.**

co-location is an upper bound for a realistic and highly optimized co-residency detection mechanism.

We calculate the cost of executing each launch strategy under the three public clouds. The result is summarized in Figure 23. Note that we only consider the cost incurred by the compute instances because the cost for other resources such as network and storage, was insignificant. Also note that EC2 bills every hour even if an instance runs less than an hour [16], whereas GCE and Azure charge per minute of instance activity. This difference is considered in our cost calculation. Overall, the maximum cost we incurred was about $8 for running 30 VMs for 4 hours 25 minutes on Azure and a minimum of 14 cents on GCE for running 10 VMs for 17 minutes. We incurred the highest cost for all the launch strategies in Azure because of overall higher cost per hour and partly due to longer tests due to our co-residency detection methodology.

5.7 Summary of Placement Vulnerabilities

In this section, we return to the secure reference placement policy introduced in Section 3 and use it to identify placement vulnerabilities across all the three clouds. Recall that the probability of at least one pair of co-residency under this random placement policy is given by $\Pr[\mathbf{E}_a^v > 0] = 1 - (1 - v/N)^a$, where $\mathbf{E}_a^v$ is the random variable denoting the number of co-location observed when placing a attacker VMs among $N = 1000$ total machines where v machines are already picked for the v victim VMs. First, we evaluate this probability for various run configurations that we experimented with in the public clouds. The probabilities are shown in Figure 24.

Strategy	v & a	a'	**Cost benefit ($)**	**Normalized Success**
S1 & S2	10	688	113.87	10
S3	30	227	32.75	1.67
S4(i)	20	105	4.36	2.67
S4(ii)	20	342	53.76	3.03
S5	20	110	4.83	1.48

Figure 25: **Cost benefit analysis.** $N = 1000$, $P(a_{type}) = 0.026$, which is the cost per instance-hour on EC2 (the cheapest). For simplicity $T_d(v,a) = (v * a) * 3.85$, where 3.85 is fastest average time to detect co-residency per instance-pair. Here, $v \times a$ is the run configuration of the strategy under test. Note that the cost benefit is the additional cost incurred under the reference policy, hence is equal to cost incurred by $a' - a$ additional VMs.

Recall that a launch strategy in a cloud implies a placement vulnerability in that cloud's placement policy if its normalized success rate is greater than 1. The normalized success rate of the strategy is the ratio of the chance of co-location under that launch strategy to the probability of co-location in the reference policy ($\Pr[\mathbf{E}_a^v > 0]$). Below is a list of selected launch strategies that escalate to placement vulnerabilities using our reference policy with their normalized success rate in parenthesis.

(S1) In Azure, launch ten attacker VMs closely after the victim VMs are launched (1.0/0.10).

(S2) In EC2 and GCE, if there are known victims in any of the smaller datacenters, launch at least ten attacker VMs with a non-zero delay (1.0/0.10).

(S3) In all three clouds, launch 30 attacker instances, either with no delay (Azure) or one hour delay (EC2, GCE) from victim launch, to get co-located with one of the 30 victim instances (1.00/0.60).

(S4) (i) In Amazon EC2, launch 20 attacker VMs with a delay of 5 minutes or more after the victims are launched (0.88/0.33). (ii) The optimal delay between victim and attacker VM launches is around 4 hours for a 20x20 run (1.00/0.33).

(S5) In Amazon EC2, launch the attacker VMs with 1 hour after the victim VMs are launched where the time of day falls in the early morning, i.e., 02:00 to 10:00hrs PST (0.89/0.60).

Cost benefit. Next, we quantify the cost benefit of each of these strategies over the reference policy. As the success rate of any launch strategy on a vulnerable placement policy is greater than what is possible in the reference policy, we need more attacker instances in the reference policy to achieve the same success rate. We calculate this number of attacker instances a' using: $a' = \ln(1 - S_a^v)/\ln(1 - v/N)$, where, S_a^v is the success rate of a strategy with run configuration of $v \times a$. The result of this calculation is presented in Figure 25. The result shows that the best strategy, S1 and S2, on all three cloud providers is $114 cheaper than what is possible in the reference policy.

It is also evident that these metrics enable evaluating and comparing various launch strategies and their efficacy on various placement policies both on robust placements and attack cost. For example, note that although the normalized success rate of *S3* is lower than *S4*, it has a higher cost benefit for the attacker.

5.8 Limitations

Although we exhaustively experimented with a variety of placement variables, the results have limitations. One major limitation of this study is the number of placement variables and the set of values for the variables that we used to experiment. For example, we limited our experiments with only one instance type, one availability zone per region and used only one account for the victim VMs. Although different instance types may exhibit different placement behavior, the presented results hold strong for the chosen instance type. The only caveat that may affect the results is if the placement policy uses account ID for VM placement decisions. Since, we experimented with only one victim account (separate from the designated attacker account) across all providers, these results, in the worst case, may have captured the placement behavior of an unlucky victim account that was subject to similar placement decisions (and hence co-resident) as that of the VMs from the designated attacker account.

Even though we ran at least 190 runs per cloud provider over a period of 3 months to increase statistical significant of our results, we were still limited to at most 9 runs per run configuration (with 3 runs per time of day). These limitations have only minor bearing on the results presented, if any, and the reported results are significant and impactful for cloud computing security research.

6 Related Work

VM placement vulnerability studies. Ristenpart et al. [29] first studied the placement vulnerability in public clouds, which showed that a malicious cloud tenant could place one of his VMs on the same machine as a target VM with high probability. Placement vulnerabilities exploited in their study include publicly available mapping of VM's public/internal IP addresses, disclosure of Dom0 IP addresses, and a shortcut communication path between co-resident VMs. Their study was followed by Xu et al. [33] and further extended by Herzberg et al. [25]. However, the results of these studies have been outdated by the recent development of cloud technologies, which is the main motivation of our work.

Concurrent with our work, Xu et al. [34] conducted a systematic measurement study of co-resident threats in Amazon EC2. Their focus, however, is in-depth evaluation of co-residency detection using network route traces and quantification of co-residence threats on older generation instances with EC2's classic networking (prior to Amazon VPC). In contrast, we study placement vulnerabilities in the context of VPC on EC2, as well as on Azure and GCE. The two studies are mostly complementary and strengthen the arguments made by each other.

New VM placement policies to defend against placement attacks have been studied by Han et al. [23, 24] and Azar et al. [18]. It is unclear, however, whether their proposed policies work against the performance and reliability goals of public cloud providers.

Co-residency detection techniques. Techniques for co-residency detection have been studied in various contexts. We categorize these techniques into one of the two classes: side-channel approaches to detecting co-residency with *uncooperative* VMs and covert-channel approaches to detecting co-residency with *cooperative* VMs.

Side-channels allow one party to exfiltrate secret information from another; therefore these approaches may be adapted in practical placement attack scenarios with targets not controlled by the attackers. Network round-trip timing side-channel was used by Ristenpart et al. [29] to detect co-residency. Zhang et al. [36] developed a system called *HomeAlone* to enable VMs to detect third-party VMs using timing side-channels in the last level caches. Bates et al. [19] proposed a side-channel for co-residency detection by causing network traffic congestion in the host NICs from attacker-controlled VMs; the interference of target VM's performance, if the two VMs are co-resident, should be detectable by remote clients. Kohno et al. [27] explored techniques to fingerprint remote machines using timestamps in TCP or ICMP based network probes, although their approach was not designed for co-residency detection. However, none of these approaches works effectively in modern cloud infrastructures.

Covert-channels on shared hardware components can be used for co-residency detection when both VMs under test are cooperative. Coarse-grained covert-channels in CPU caches and hard disk drives were used in Ristenpart et al. [29] for co-residency confirmation. Xu et al. [33] established covert-channels in shared last level caches between two colluding VMs in the public clouds. Wu el al. [32] exploited memory bus as a covert-channel on modern x86 processors, in which the sender issues atomic operations on memory blocks spanning multiple cache lines to cause memory bus locking or similar effects on recent processors. However, covert-channels proposed in the latter two studies were not designed for co-residency detection, while those developed in our work are tuned for this purpose.

7 Conclusion and Future Work

Multi-tenancy in public clouds enable co-residency attacks. In this paper, we revisited the problem of placement — can an attacker achieve co-location? — in modern public clouds. We find that while past techniques for verifying co-location no longer work, insufficient performance isolation in hardware still allows detection of co-location. Furthermore, we show that in the three popular cloud providers (EC2, GCE and Azure), achieving co-location is surprisingly simple and cheap. It is even simpler and costs nothing to achieve co-location in some PaaS clouds. Our results demonstrate that even though cloud providers have massive datacenters with numerous physical servers, the chances of co-location are far higher than expected. More work is needed to achieve a better balance of efficiency and security using smarter co-location-aware placement policies.

Abstract

As the most basic cloud service model, Infrastructure as a Service (IaaS) has been widely used for serving the ever-growing computing demand due to the prevalence of the cloud. Using pools of hypervisors within the cloud, IaaS can support a large number of Virtual Machines (VMs) and scale services in a highly dynamic manner. However, it is well-known that the VMs in IaaS are vulnerable to co-residence threat, which can be easily exploited to launch different malicious attacks. In this measurement study, we investigate how IaaS evolves in VM placement, network management, and Virtual Private Cloud (VPC), as well as the impact upon co-residence. Specifically, through intensive measurement probing, we first profile the dynamic environment of cloud instances inside the cloud. Then using real experiments, we quantify the impacts of VM placement and network management upon co-residence. Moreover, we explore VPC, which is a defensive network-based service of Amazon EC2 for security enhancement, from the routing perspective. On one hand, our measurement shows that VPC is widely used and can indeed suppress co-residence threat. On the other hand, we demonstrate a new approach to achieving co-residence in VPC, indicating that co-residence threat still exists in the cloud.

1 Introduction

Entering the era of cloud computing, Infrastructure as a Service(IaaS) has become prevalent in providing Information Technology (IT) support. IT giants such as Amazon [1], Microsoft [4], and Google [2] have deployed large-scale IaaS services for public usage. Employing IaaS, individual IT service providers can achieve high reliability with low operation cost and no longer need to maintain their own computing infrastructures. However, IaaS groups multiple third-party services together into one physical pool, and sharing physical resources with other customers could lead to unexpected security breaches such as side-channel [25] and covert channel [19] attacks. It is well-known that IaaS is vulnerable to the co-residence threat, in which two cloud instances (i.e., VMs) from different organizations share the same physical machine. Co-residence with the victim is the prerequisite for mounting a side-channel or covert-channel attack.

The security issues induced by co-residence threat have been studied in previous research. However, most previous works focus on "what an attacker can do" [14, 19, 25], "what a victim user should do" [24], and "what a cloud vendor would do" [12, 15, 26]. In contrast, to the best of our knowledge, this measurement work initiates one of the first attempts to understand how cloud service vendors have potentially reacted to co-residence threat in the past few years and explore potential new vulnerabilities of co-residence inside the cloud. While Amazon Elastic Compute Cloud (EC2) is the pioneer of IaaS, it has the largest business scale among mainstream IaaS vendors [11, 18]. Therefore, we focus our study on Amazon EC2. More specifically, our measurement is mainly conducted in the largest data center hosting EC2 services: the northern Virginia data center, widely known as US-East region.

In our measurement study, we first perform a 15-day continuous measurement on the data center using ZMap [10] to investigate the data center's business scale and some basic management policies. With the basic knowledge of the cloud, we explore how EC2 has adjusted VM placement along with its impact on security. We further evaluate how much effort an attacker needs to expend to achieve co-residence in different circumstances. Comparing our evaluation results with those from 2008 [14], we demonstrate that the VM placement adjustment made by EC2 during the past few years has mitigated the co-residence threat.

As network management plays a critical role in cloud performance and security, we also investigate how the networking management in EC2 has been calibrated to suppress co-residence threat. We conduct large scale trace-routing from multiple sources. Based on our measurements, we highlight how the current networking configuration of EC2 is different from what it was and demonstrate how such evolution impacts co-residence inside the cloud. In particular, we measure the change of routing configuration made by EC2 to increase the difficulty of cloud cartography. We also propose a new algorithm to identify whether a rack is connected with Top of Rack switch or End of Row switch. With this algorithm, we are able to derive the network topology of EC2, which is useful for achieving co-residence inside the cloud.

To provide tenants an isolated networking environment, EC2 has introduced the service of Virtual Private Cloud (VPC). While VPC can isolate the instances from the large networking pool of EC2, it does not physically isolate the instances. After profiling the VPC usage and the routing configurations in VPC, we propose a novel approach to speculating the physical location of an instance in VPC based on trace-routing information. Our experiments show that even if a cloud instance is hidden behind VPC, an adversary can still gain co-residence with the victim with some extra effort.

The remainder of the paper is organized as follows. Section 2 introduces background and related work on cloud measurement and security. Section 3 presents our measurement results on understanding the overview of Amazon EC2 and its basic management policies. Section 4 details our measurement on VM placement in EC2, including co-residence quantification. Section 5 quantifies the impact of EC2-improved network management upon co-residence. Section 6 describes VPC, the most effective defense against co-residence threat, and reveals the haunted co-residence threat in VPC. Section 7 proposes potential solutions to make the cloud environment more secure. Finally, Section 8 concludes our work.

2 Background and Related Work

To leverage physical resources efficiently and provide high flexibility, IaaS vendors place multiple VMs owned by different tenants on the same physical machine. Generally, a scenario where VMs from different tenants are located on the same physical machine is called co-residence. In this work, the definition of co-residence is further relaxed. We define two VMs located in the same physical rack as co-residence. Thus, two VMs located in the same physical machine is considered as machine-level co-residence, while two VMs located in the same rack is defined as rack-level co-residence.

2.1 Co-residence threat

The threat of co-residence in the cloud was first identified by Ristenpart et al. [14] in 2009. Their work demonstrates that an attacker can place a malicious VM co-resident with a target and then launch certain attacks such as side channel and covert channel attacks. Following Ristenpart's work, Xu et al. [20] studied the bit rate of cache-based covert channel in EC2. Wu et al. [19] constructed a new covert channel on a memory bus with a much higher bit rate, resulting in more serious threats in an IaaS cloud. Zhang et al. [25] proposed a new framework to launch side channel attacks as well as approaches to detect and mitigate co-residence threat in the cloud [24, 26]. Bates et al. [7] proposed a co-resident watermarking scheme to detect co-residence by leveraging active traffic analysis.

The reason we define different levels of co-residence is that some attacks do not require VMs to be located on the same physical machine, but rather in the same rack or in a higher level network topology. For instance, Xu et al. [23] proposed a new threat called power attack in the cloud, in which an attacker can rent many VMs under the same rack in a data center and cause a power outage. There are also some side channel and covert channel attacks that only require the co-residence in the same sub-network [5].

In parallel with our work, Varadarajan et al. [16] performed a systematical study on placement vulnerability in different clouds. While their work mainly stands at the attacker side to explore more effective launch strategies for achieving co-residence in three different clouds, our work performs an in-depth study to understand the evolution of cloud management and the impact on co-residence threat in Amazon EC2. The two complementary works both support the point that public clouds are still vulnerable to co-residence threat.

2.2 Measurement in the cloud

In contrast to the measurement on private clouds from an internal point of view[9], the measurement works on public data centers are mostly conducted from the perspective of cloud customers. Wang et al. [17] demonstrated that in a public cloud, the virtualization technique induces a negative impact on network performance of different instance types. The work of Xu et al. [21] measures network performance in Amazon EC2 and demonstrates a long tail distribution of the latency. Their work also analyzes the reason behind the long tails and proposes a new VM deployment solution to address this issue. Bermudez et al. [8] performed a large-scale measurement on Amazon AWS traffic. Their study shows that most web service traffic towards Amazon AWS goes to the data center in Virginia, U.S. Some recent studies [11, 18] measure how web services are deployed in public clouds. They found that although many top-ranked domains deploy their subdomains into the cloud, most subdomains are located in the same region or zone,

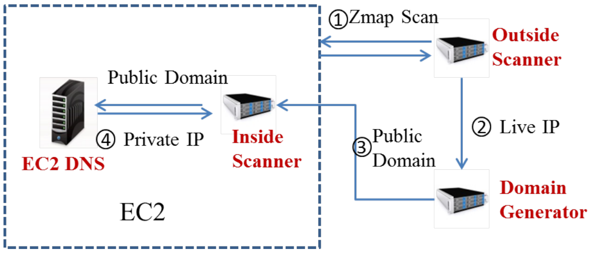

Figure 1: The system used to scan EC2.

resulting in a relatively poor fault tolerance.

In contrast to those measurement efforts, our study provides a measurement analysis from the perspective of security to reveal the management policies of a public cloud and their impact upon co-residence threat.

3 An Overview of EC2 Management

As the pioneer of IaaS, Amazon EC2 deploys its data centers all around the world, hosting the largest scale of IaaS business. In this section, we introduce some terminology in EC2 and provide an overview of the EC2 environment.

3.1 Instance type

An instance represents a virtual machine (VM) in the cloud, so we use the term "instance" and "VM" interchangeably throughout the rest of the paper. EC2 provides a list of instance types for clients to select while launching a new instance. The type of an instance indicates the configuration of the VM, determining the amount of resources the VM can use. The instance type is defined in the format *XX.XXX* such as *m1.small*. The first part of the instance type reveals the model of the physical server that will host this type of instance. The second part indicates the "size" of the VM, i.e., the amount of resources allocated to the instance. The detailed configuration of different instance types can be found at [3].

3.2 Regions and zones

Amazon EC2 has the concept of "region," which represents the physical area where the booted instance will be placed. Amazon has 9 locations around the world hosting EC2 services. Therefore, the instances in EC2 can be located in 9 regions: US east (northern Virginia), US west (Oregon), US west (northern California), South America (Sao Paulo), Asia Pacific southeast (Singapore), Asia Pacific southeast (Sydney), Asia Pacific northeast (Tokyo), EU west (Ireland), and EU central (Frankfurt). As pointed out in previous work [11], the majority of IaaS business is hosted in the US east region, e.g., in the data center located in northern Virginia. Most existing research on cloud measurement was conducted on this region [8, 13, 14]. Therefore, we also focus our study on the US east region. For the rest of the paper, we use the term "cloud" to mean the EC2 US east region and the term "data center" to mean the Amazon EC2 data center in northern Virginia, US.

In addition to regions, Amazon EC2 also allows clients to assign an instance to a certain "zone." A zone is a logical partition of the space within a region. Previous work shows that the instances in the same zone share common characters in private IP addresses, and likely instances within the same zone are physically close to each other [14, 19]. There are four availability zones in the US east region: us-east-1a, us-east-1b, us-east-1c, and us-east-1d.

3.3 Naming

The naming service is essential to cloud management. On one hand, the naming service can help customers to easily access their instances and simplify resource management. On the other hand, the naming service should help the cloud vendor to manage the cloud efficiently with high network performance.

In EC2, an instance is automatically assigned two domain names: one public and one private. The public domain name is constructed based on the public IP address of the instance, while the private domain name is constructed based on either the private IP address or the MAC address. Performing a DNS lookup outside EC2 returns the public IP of the instance, while performing a DNS lookup inside EC2 returns the private IP of the instance.

3.4 Scanning EC2 inside and outside

To better understand the environment and business scale of EC2, we performed a 15-day continuous measurement on the EC2 US east region.

Figure 1 illustrates our system to scan EC2. First we deployed a scanner outside EC2 to scan the cloud through a public IP address. Since EC2 publishes the IP range for its IaaS instances, our scanner uses ZMap [10] to scan the specified ranges of IP addresses. The ports we scanned include: ports 20 and 21 used for FTP, port 22 used for SSH, port 23 for telnet, ports 25 and 587 for SMTP, port 43 for WHOIS, port 53 for DNS, port 68 for DHCP, port 79 for Finger protocol, port 80 for HTTP, port 118 for SQL, port 443 for HTTPS, and port 3306 for MySQL. We also performed an ICMP echo scan. After scanning, our outside scanner obtained a list of live hosts in EC2 with the corresponding public IP addresses. In the next step, we performed automatic domain name generation. As mentioned above, the public domain name of an instance in EC2 can be derived using its public IP. This step produces a list of public domain names of live hosts. The generated public domain names were then sent to our inside scanner deployed inside EC2. Our inside scanner then performed DNS lookups for these domain names.

Due to the DNS lookup mechanism of EC2, the DNS server in EC2 answered the queries with the private IP addresses of the hosts. Reaching this point, our measurement system can detect live hosts in EC2 with their domain names, IP addresses, as well as the mapping between the public IP address and private IP address.

The scan interval is set to 20 minutes, which is a tradeoff between cost and accuracy. Scanning the entire EC2 US east region per port takes about 40 seconds, and we have 14 ports to scan. This means that scanning all the ports will take around 10 minutes. Note that our measurement also includes DNS lookups for all the detected live hosts. Performing these DNS lookups takes around 20 minutes, which is approximately the time for two rounds of scanning.

Our scanning measurement provides us an overview of the large business scale of EC2, the diversity of services, and the dynamic running environment. This scanning measurement also gives us the knowledge base to understand co-residence threat. The detailed results and analysis of our scanning measurement can be found in the Appendix A and B.

4 The Impact of VM Placement upon Co-residence

The VM placement policy of the cloud determines how easy or hard it is for an attacker to achieve co-residence. In this section, we present our measurement on VM placement and quantification of achieving co-residence. By comparing our measurement results with previous work, we demonstrate how the VM placement policy has been evolving in EC2 and its impact on mitigating co-residence threats.

4.1 Basic understanding of VM placement

We first launched a sufficiently large number of instances with different types in EC2. Then, we had two tasks to fulfill: (1) collecting networking (i.e., location) information of launched instances and (2) quantifying co-residence threat, i.e., given the current VM placement policy of EC2, how much effort an attacker needs to make to achieve co-residence. Since the process of achieving co-residence requires the knowledge of instance location, we can complete the two tasks together. For every instance we launched while seeking co-residence, we recorded its private IP address and public IP address. We also performed an automatic traceroute from the instance to its "neighbors" that share the /24 prefix with it. This information can provide us the basic knowledge of where the instances are placed.

During our measurement, we recorded the detailed information of 2,200 instances of type t1.micro, 1,800 instances of type m1.small, 1,000 instances of type m1.medium, 1,000 instances of type m3.medium, 80 instances of m3.large, and 40 instances of m3.xlarge. We selected some random samples from the instances we recorded to study the internal IP distribution. We investigated how private IP addresses are associated by the instance type and availability zones, i.e., whether the VM placement has type and zone locality. Our results demonstrate that currently EC2 still exhibits certain type and zone locality, i.e., instances with the same type in the same zone are more likely to be placed close to one another. However, compared with corresponding results in 2008 [14], such locality has been significantly weakened. More details of locality comparison can be found in Appendix C.

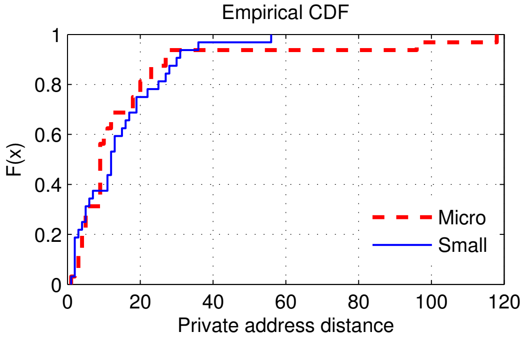

Figure 2: CDF of IP address distances between co-resident VMs.

After understanding the current VM placement in EC2, we further investigate co-residence threats in EC2.

4.2 Quantifying machine level co-residence

To understand how VM placement will affect co-residence, we assess the effort one needs to make to achieve machine level co-residence in two scenarios. The first scenario is to have a random pair of instances located on the same physical machine, and the second scenario is to have an instance co-reside with a targeted victim.

4.2.1 Random co-residence

To make our random co-residence quantification more comprehensive, we perform our measurement with different instance types and in different availability zones. Since zone us-east-1c is no longer hosting t1, m1, c1, and m3 instances, our measurement is performed in zone us-east-1a, us-east-1b, and us-east-1d. We achieve co-residence pairs with t1.micro, m1.small, m1.medium, and m3.medium. We did not achieve co-residence with large, xlarge or 2xlarge instances, because there are only 1 to 4 such large instances on one physical machine and it will be very difficult and costly to achieve co-residence with these types. Overall, we conduct 12 sets of experiments, with each set targeting a specific type of instances in a specific availability zone.

In each set of experiments, we perform rounds of co-residence probing until we find a co-residence pair.

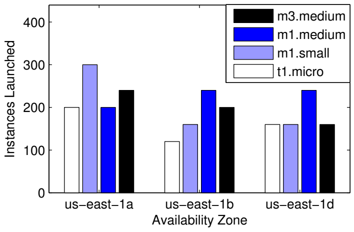

Figure 3: The service hour spent, i.e., the number of instances booted to achieve co-residence.

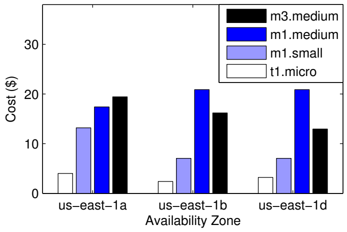

Figure 4: The financial cost (in US dollar) to achieve co-residence.

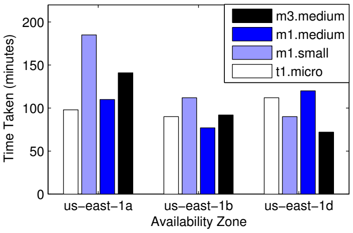

Figure 5: The time spent to achieve co-residence.

For the sake of robustness, EC2 has never placed instances from the same user on the same physical machine [14]. Therefore, we set up two accounts to launch instances simultaneously. Within one round, each account launches 20 instances, which will produce 400 pairs of co-residence candidates. Once a co-residence pair is verified, this set of experiments are terminated and the corresponding cost is recorded. If there is no co-residence pair found in this round, we move on to the next round by terminating all running instances and launching another 20 instances in each account, and then repeat the same procedure.

Given a pair of instances, verifying whether they are located on the same physical machine involves two steps: (1) pre-filtering unlikely pairs and (2) using a covert channel to justify co-residence.

For the first step, we need to screen out those pairs that are not likely to be co-resident to reduce probing space. Since the private IP address of an instance can indicate its physical location to some extent, and if the private IP addresses of two instances are not close enough, the two instances will have little chance to be co-resident. Based on this heuristic, we use the share of /24 prefix as the prerequisite of co-residence, i.e., if two instances do not share the /24 prefix, we consider them as not being co-resident and bypass the highly costly step 2. The rationale of setting the /24 prefix sharing as pre-filter is twofold:

1. First, the prerequisite of the /24 prefix sharing will not likely rule out any co-residence instance pairs. The number of instances that are hosted on the same physical machine is limited. Even for micro instances, there are no more than 32 instances running on a physical machine. For the instance type with larger size, there are even fewer instances running on a physical machine. In contrast, a /24 address space can contain 256 instances. Therefore, two co-resident instances are unlikely to be in different /24 subnets. Moreover, we obtained some co-residence pairs without any pre-filtering and recorded the private IP address distance between a pair of co-residence instances. Figure 2 illustrates the CDF of IP address distance between two co-residence instances. The distance is calculated as the difference between the two 32-bit integers of the two IP addresses. From the results we can figure out that most of these co-residence instances share the /27 prefix, which further confirms that the /24 prefix filtering will introduce very few, if any, false negatives.

2. Second, the prerequisite of sharing the /24 prefix can effectively narrow down the candidate space. Each time we use one account to launch 20 instances and use another account to launch another 20 instances, we will have 400 candidate pairs. During our measurement, we generated more than 40 rounds of such 400-pair batches. The average number of instance pairs that share the /24 prefix among 400 candidates is only 4. This means the /24 prefix sharing prerequisite can help us to screen out 99% of the candidates, which significantly accelerates the process of co-residence verification. During the 40 rounds of measurement, five co-residence pairs are observed.

The second step is to use a covert channel to verify whether two instances are actually located on the same physical machine. We use the technique introduced by Wu et al. [19] to construct a memory-bus-based covert channel between two instances. If the two instances can communicate with each other via the covert channel, then they are located on the same physical machine. This covert-channel-based verification can guarantee zero false positives.

The cost of achieving co-residence includes financial cost and time. According to the pay-as-you-go billing system, the financial cost is mainly determined by the service hours consumed during the co-residence probing. Every time an instance is launched, one billing hour is charged. Thus, the more probing instances an attacker needs to launch, the higher financial cost it will cause. In our experiments, we use only two accounts. In a real world attack, an attacker could use more accounts to launch the attack in parallel, which will result in less time required to achieve co-residence. However, under the same condition, regardless of attack process op-

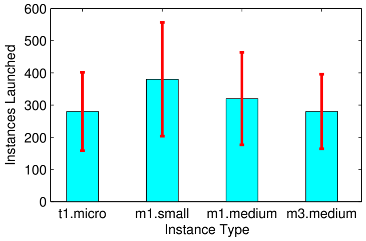

Figure 6: The service hour spent, i.e. the number of instances booted to achieve co-residence with a target.

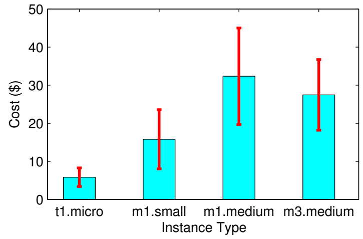

Figure 7: The financial cost (in US dollar) to achieve co-residence with a target.

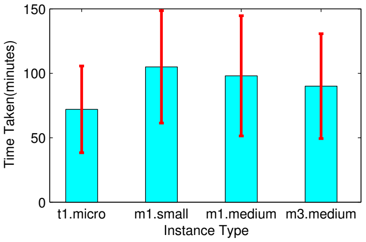

Figure 8: The time spent to achieve co-residence with a target.

timization, the time spent to achieve co-residence should have a positive correlation with the number of instances to launch, i.e., the more instances need to launch, the more time spent for detecting co-residence.

Figure 3 illustrates how many instances are required to achieve co-residence, while Figure 4 illustrates the actual financial cost. Figure 5 illustrates how much time it takes to achieve co-residence, i.e., the time cost. For each type of instance, the measurement repeats for five times and the mean value is shown in the figures. From the figures, it is evident that the cost for achieving co-residence of different types in different availability zones is quite different. Intuitively, as a larger instance has higher resource charge, it costs more money to achieve co-residence with those instances at a larger size. However, there is no such rule that the smaller size an instance is, the lower time cost we need to pay for co-residence.

4.2.2 Target co-residence

In the quantification of achieving co-residence with a particular target, we first randomly launched one instance with specific type from one account as the target. Then, from the other account, we also performed many rounds of co-residence probing until we found the instance that is co-resident with the target. The process of verifying co-residence remains the same. As demonstrated by the verification results of random co-residence above, different availability zones do not greatly impact the difficulty of achieving co-residence. Here we only show the results when our target instances are placed in zone us-east-1a.

Figures 6, 7 and 8 illustrate the number of instances to launch, the financial cost, and the time taken to achieve co-residence with a particular target, respectively. For each type of instance, the measurement is repeated for 15 times and the mean value is illustrated. The error bar with standard deviation is also shown in the figures. As is intuitive, achieving co-residence with a particular target requires launching more instances than achieving random co-residence. Getting a random co-residence pair requires launching 200 to 300 instances with two accounts (i.e., 100 to 150 instances per account), which can be done in 5 to 8 rounds. In contrast, achieving co-residence with a particular target requires launching 300 to 400 instances, which will take 15 to 20 rounds with each round launching 20 instances from one account. However, achieving co-residence with a particular target does not cost more time than achieving a random co-residence pair. The reason for this is simple: To get a random pair, we need to check 400 candidate pairs in each round, but to get a co-residence pair with a target, we only need to check 20 candidates in one round.

It is also possible that an attacker is unable to achieve co-residence with a certain target due to various reasons, e.g., the target physical machine reaches full capacity. During our study, we failed to achieve co-residence with two targets, one is m1.medium type and the other is m3.medium type. By failing to achieve co-residence we mean that after trying with more than 1,000 probing instances in two different days, we still cannot achieve co-residence with these two targets.

Overall, it is still very feasible to achieve co-residence in EC2 nowadays. However, an attacker needs to launch hundreds of instances to reach that goal, which may introduce considerable cost. In Section 4.4, we will compare our results to previous studies, demonstrating that achieving machine-level co-residence has become much more difficult than before, due to the change in cloud environments and VM placement policies.

4.3 Quantifying rack level co-residence

While covert channel and side channel attacks require an attacker to obtain an instance located exactly on the same physical machine with the victim, some malicious activities only need coarse-grained co-residence. Xu et al. [23] proposed a new attack called power attack. In their threat model, the attacker attempts to significantly increase power consumption of multiple machines connected by the same power facility simultaneously to trip the circuit breaker (CB). Since these machines located in the same rack are likely to be connected by the same CB, in a power attack the attack instances are not required to be placed on a same physical machine. Instead the attacker should place many instances within the same rack as the victim, i.e., achieving as much rack-level co-residence as possible. We performed measurement on how much effort is required to place a certain number of

Table 1: The number of co-residence pairs achieved by one round of probing in 2008 [14].

	Account A	Account B	Co-residence
Zone 1	1	20	1
	10	20	5
	20	20	7
Zone 2	1	20	0
	10	20	3
	20	20	8
Zone 3	1	20	1
	10	20	2
	20	20	8

instances under the same rack.

We first use one account to launch 20 instances, and then we check whether there are any instances in this batch that are located within the same rack. If there are no instances located in the same rack, we just randomly pick an instance and set its hosting rack as the target rack. Thanks to the Top of Rack(ToR) switch topology, verifying whether two instances are in the same rack is simple. Through a simple trace-routing, we can verify whether an instance has the same ToR switch with our target rack. This rack level co-residence can be further verified by performing trace-route from the candidate instance to the target instance. If the two instances are in the same rack, there should be only one hop in the trace, i.e., they are one hop away.

Figure 9 shows our measurement results. It is clear that an attacker can easily have multiple instances located within the same rack. The information of ToR switch helps the attacker quickly verify the rack-level co-residence. Since the malicious attack based on the rack-level co-residence is newly proposed [23], EC2 is unlikely to take any action to suppress rack-level co-residence.

4.4 Battle in VM placement

Table 1 lists the data from the original work on co-residence [14]. We can see that it was extremely easy to achieve co-residence in 2008. With two accounts each launching 20 instances, there were 7 or 8 co-residence pairs observed. In the 2012 work [19], the cost of achieving a co-residence instance pair is also briefly reported: A co-residence pair (micro) is achieved with 160 instances booted.

As we can see, nowadays it is much more difficult to achieve co-residence than in 2008 and 2012. EC2 could have adjusted its VM placement policies to suppress co-residence.

4.4.1 A larger pool

The business of EC2 is scaling fast, and thus it is intuitive that Amazon keeps deploying more servers into EC2. The measurement in 2008 [14] shows that there were three availability zones in the US east region. At present, the availability zones are expanded to four. Such expansion in availability zones also indicates that the business scale of EC2 is growing rapidly.

The measurement in 2008 [14] also shows 78 unique Domain0 IP addresses with 1785 m1.small instances, which means it only observed 78 physical machines that host m1.small service. Due to the evolution in EC2 management, we are no longer able to identify Dom0. However, we have identified at least 59 racks of servers that host m1.small instances. This suggests that the number of physical machines hosting m1.small instances is significantly larger than that in 2008. The enlarged pool provides EC2 with more flexibility to place incoming VMs, which is one of the reasons that it is now much more difficult to achieve co-residence than before.

4.4.2 Time locality

Time locality can help to achieve co-residence. Time locality means if two accounts launch instances simultaneously, it is more likely that some of these instances with time locality will be assigned to the same physical machine.

To verify whether such time locality exists in the current EC2, we performed another measurement. We set up four groups of experiments. In the first group, the two accounts always launch 20 VMs simultaneously. In the second group, the second account launches 20 VMs 10 minutes after the first account launches 20 VMs. In the third group, the launching time of the second account is one hour apart from that of the first account. In the fourth group, the second account launches VMs four hours after the first account. All instances are t1.micro type. In each group, the measurement terminates whenever a co-residence pair is observed and the number of instances required to achieve co-residence is recorded. All the experiments are repeated 5 times and the average is noted.

Figure 10 illustrates the number of instances required to achieve co-residence in each case. We can see that the efforts required to achieve co-residence do not vary significantly with the change of instance launching intervals. This implies that time locality seems to be very weak in the current EC2, which increases co-residence cost.

4.4.3 Dynamic assignment

In 2008, the IP addresses and instances in EC2 were assigned in a relatively static manner [14]. However, as we have demonstrated before, there are considerable mapping changes in our measurement, which indicates that the IP assignment has introduced a certain dynamism.

Meanwhile, in 2008, the instances were placed strictly based on the instance type, i.e., one physical machine can only host one type of instance [14]. In contrast, our measurement results show that such an assumption may not hold anymore. First, some small instances use internal IP addresses that were used by micro instances

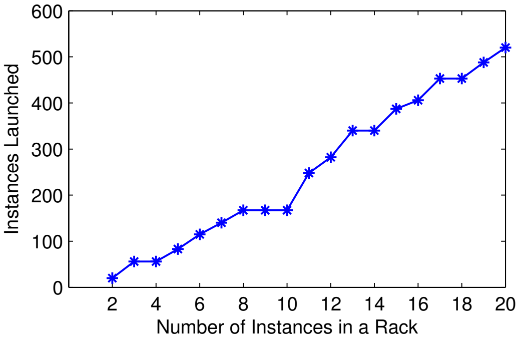

Figure 9: Instances launched to place certain number of instances within the same rack.

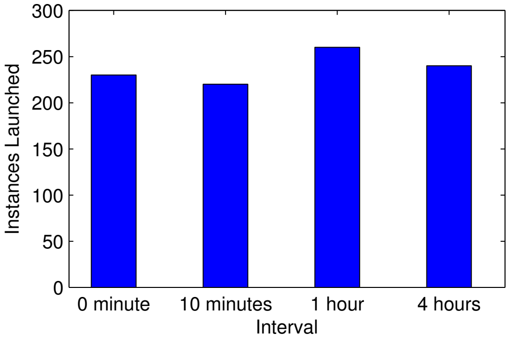

Figure 10: Effort to achieve co-residence with different time locality.

before. Second, during our measurement, by accident we observed that one live small instance has very close IP to a medium instance. We then attempted to build a covert channel between them. It turned out that the covert channel did work, which verifies that these two instances with different types are indeed located on a same physical machine. Following such an observation, in the rest of our rest measurement we also kept checking co-residence between different types of instances. Overall, five pairs of different-type co-residence instances are observed throughout our study. Our results indicate that in certain cases current VM placement policies in EC2 can mix different types of instances on one physical machine, potentially to reduce fragmentation. Such a policy also increases the difficulty of achieving co-residence.

5 The Impact of Network Management upon Co-residence

As network management plays a critical role in data center management, it has a significant impact on co-residence. On one hand, an attacker attempts to obtain as much networking information inside the cloud as possible to ease the gaining process of co-residence. On the other hand, the cloud vendors try to protect sensitive information while not degrading regular networking management and performance. In this section, we introduce the adjustments made by EC2 in network management during recent years to mitigate co-residence threat and the effectiveness of these approaches.

5.1 Methodology

To study the adjustment made by EC2 in network management, we performed large scale trace-routing. First, for the instances we booted, we performed "neighborhood trace-routing" from our instances to their "neighbors." Here we define neighbors as all those instances that share the /23 prefix of their private IP addresses with our source instances. Such trace-routing can inform us of the routing paths between an instance and other instances in the same rack and neighboring racks.

We next performed trace-routing from several of our instances (i.e., the instances we booted) to all the instances in a target list. We use the live host list from our scanning measurement (see Section 3.5 and Appendix A) as the target list. Trace-routing from our instances to over 650,000 target instances takes more than 8 days, but it can help us to understand network management in EC2 in a more comprehensive manner.

5.2 The evolution in routing configuration

The routing information has been leveraged to perform cloud cartography [14], which can further be used to launch co-residence-based attacks. However, our trace-routing results demonstrate that, as a response to cloud cartography, EC2 has adjusted its routing configurations to enhance security in the past few years. The adjustments we found are listed as follows.

5.2.1 Hidden Domain0

EC2 uses XEN as the virtualization technique in the cloud. According to the networking I/O mechanism of XEN [6], all the network traffic of guest VMs (instances) should travel through the privileged instance: Domain-0 (i.e, Dom0). Thus, Dom0 acts as the gateway of all instances on the physical machine, and all instances on this physical machine should have the same first-hop in their routing paths. Such Dom0 information provides an attacker with a very efficient probing technique: by simply checking the Dom0's IP addresses of two instances, one can know whether they are co-resident. Therefore, to prevent this Dom0 information divulgation, EC2 has hidden Dom0 in any and all routing paths, i.e. at present the Dom0 does not appear in any trace-routing results.

5.2.2 Hidden hops

To suppress cloud cartography enabled by trace-routing, EC2 has hidden certain hops in the routing paths. According to the work in May 2013 [13], traffic only needs to traverse one hop between two instances on the same physical machine and two hops between instances in

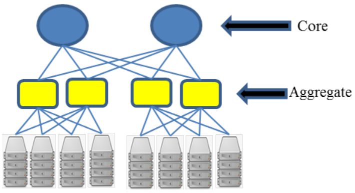

Figure 11: A common tree topology of a data center.

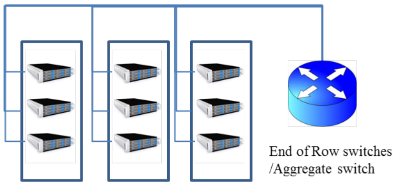

Figure 12: The topology with End of Row switch.

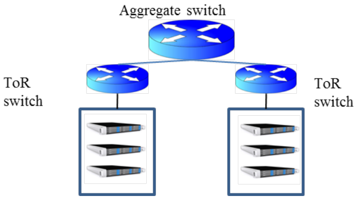

Figure 13: The topology with Top of Rack switch.

a same rack but not on the same physical machine. The paths between instances in different racks typically have 4 or 6 hops. However, our neighborhood trace-routing results show that the routing management has been changed in EC2.

First, a path of one hop does not necessarily indicate co-residence anymore. Our neighborhood trace-routing results show that an instance can have a very large number of 1-hop neighbors. For instance, one m1.small instance can have more than 60 1-hop neighbors. It is technically impractical to host so many instances on an m1 machine. To verify our hypothesis, we selected several pairs of instances with a 1-hop path and checked co-residence using covert channel construction. Our co-residence verification fails for most of these pairs, confirming that two instances with a 1-hop path do not necessarily co-locate on the same physical machine. This observation indicates that EC2 even hides the ToR switches in the routing path in some cases, leaving only one hop in the path between two instances in the same rack.

Second, we observed many odd-hop paths, accounting for 34.26% of all paths. In contrast, almost all the paths in the measurement conducted in May 2013 are even-hop [13]. This indicates that the network configuration of EC2 has changed since May 2013.

Third, the ToR switch of a source instance is shown as the first hop in the path, which indicates that the ToR switch should be an L3 router. However, we cannot observe the ToR switch of a target instance in the traces, implying that EC2 has configured the ToR switch to hide itself in the incoming traffic to the rack. Moreover, among our traces, we observed that 76.11% of paths have at least one hop filled with stars. The hops filled with stars can be a result of the configuration of certain devices such as L2 switches; it is also possible that EC2 has deliberately obscured those hops for security reasons. These paths with invisible or obscured hops significantly increase the difficulty of conducting cloud cartography.

5.3 Introducing VPC

To suppress the threat from internal networks, EC2 proposes a service called Virtual Private Cloud (VPC). VPC is a logically isolated networking environment that has a separate private IP space and routing configuration. After creating a VPC, a customer can launch instances into its VPC, instead of the large EC2 network pool. The customer can also divide a VPC into multiple subnets, where each subnet can have a preferred availability zone to place instances.

Moreover, EC2 provides instance types that are dedicated for VPC instances. These instance types include t2.micro, t2.small, and t2.medium. According to the instance type naming policy, instances with t2 type should be placed on those physical servers with the t2 model.

An instance in a VPC can only be detected through its public IP address, and its private address can never be known by any entity except the owner. Therefore, within a VPC, an attacker can no longer speculate the physical location of a target using its private IP address, which significantly reduces the threat of co-residence.

5.4 Speculating network topology

Besides routing configuration, the knowledge of network topology also helps to achieve co-residence, especially for high level co-residence such as rack-level. Figure 11 depicts the typical network topology in a data center. The core and aggregation switches construct a tree topology. Before connecting to the aggregate switches, there are two mainstream ways to connect servers in a rack/racks: End of Row (EoR) switches and Top of Rack (ToR) switches.

For EoR switches, as illustrated in Figure 12, servers of several racks are connected to the same EoR switch. To be more precise, an EoR switch can be a switch array including a group of interconnected switches. These switches can function as aggregate switches themselves. For ToR switches, as illustrated in Figure 13, all servers in a rack are first connected to a separate ToR switch, and then the ToR switch is connected to aggregate switches. Such a topology has currently become the mainstream network topology in a data center.

There are several variants of EoR topology, such as Middle of Rack (MoR) and ToR switch with EoR management. Meanwhile, there are other potential topologies such as OpenStack cluster in a data center. Therefore, we classify the network topology of a rack/racks into two classes: ToR connected and non-ToR connected. To identify whether a rack uses a ToR switch or a non-ToR switch, we analyze the neighborhood trace-routing results of multiple instances. Based on our analysis, we proposed a method to identify the network topology of a rack, ToR-connected or non-ToR-connected.

ToR-connected: a rack that deploys ToR switches must satisfy all of the following conditions:

1. For an instance A in the rack, there should be at least one instance B that is only one hop away from A.
2. For an instance A in the rack, there should be at least 8 instances that are two hops away from A.
3. For any two instances A and B, if (i) conditions 1 and 2 hold for both A and B, (ii) the trace-routing path between A and B has no more than two hops, and (iii) for any instance C, the first hop in the trace-routing path from A to C is the same as the first hop in the path from B to C, then A and B are considered as being in the same ToR rack.
4. For an instance A in the rack, for any trace-routing path with A as source and length larger than 2, the first hop in the path should share the /16 prefix with the private IP address of A.

The IP address of the first hop (i.e., ToR switch's IP address) is used to differentiate two ToR racks.

Non-ToR-connected: a rack that deploys non-ToR switches must satisfy all of the following conditions:

1. For an instance A in the rack, there should be no instance B such that the path between A and B has two hops.
2. For an instance A in the rack, for any instance B in EC2, either (i) A and B are machine-level co-resident and the path between A and B has only one hop or (ii) the path between A and B has more than two hops.
3. For two instances A and B, if (i) conditions 1 and 2 hold for both A and B, (ii) A and B share the /24 prefix of their private IP, (iii) the trace-routing path between A and B has 4 or 6 hops, and (iv) for any instance C, the first hop in the path between A and C is the same as the first hop in the path between B and C, then A and B are considered as being in the same non-ToR rack.
4. For an instance A in the rack, for any trace-routing path with A as source and length larger than 2, the first hop in the path should not share the /20 prefix with the private IP address of A.

Again, the IP address of the first hop is used to differentiate two non-ToR racks.

In EC2, there are two "generations" of instances. The old generation carries all the instances with m1 type, and the new generation covers all the instances with other types. We applied our method on m1.small, m1.medium, m3.medium, and m3.large type, which cover both old-generation instances and new-generation instances.

Overall, we identified 59 distinct racks that host m1.small instances, 18 racks that host m1.medium instances, 22 racks that host m3.medium instances, and 10 racks that host m3.large instances. Among the 109 racks, there are only 14 racks identified as non-ToR-connected while the rest are ToR-connected. Among the 14 non-ToR racks, we observed 12 old-generation racks, in which 7 racks host m1.small instances and 5 racks host m1.medium instances, and only 2 new-generation racks host m3.medium instances.

Our results demonstrate that while both ToR racks and non-ToR racks exist in EC2, ToR-connected is the dominating topology in EC2. Moreover, it is evident that new-generation machines are more likely to be located in the ToR-connected topology, indicating that the ToR-connected topology has become the main trend. While the ToR-connected topology is easy to manage, the routing information is very straightforward since the first hop reveals which rack the instance is in. Such information can be leveraged by an attacker to achieve rack-level co-residence.

6 A New Battle in VPC

Using VPC, customers can protect their instances in an isolated network environment. However, VPC only logically isolates the networks. The instances from different VPCs may still share the same physical machine, leaving the opportunity to achieve co-residence. In this section, we first take an overview on the usage of VPC in EC2, and then we introduce a new method to attack instances that are hidden behind VPCs.

6.1 The overview of VPC usage

For those instances in the default networks of EC2, our inside scanner can obtain their private addresses via DNS lookups. However, the DNS query for an instance in a VPC will only return its public IP address. Therefore, the instances in a VPC can be easily identified by checking the DNS query results of our inside scanner, i.e., any instance whose private IP address cannot be detected by our inside scanner is an instance in a VPC. Figure 14 shows the VPC usage in EC2. As we can see, all instances in VPC are assigned public IP addresses in five different ranges: 107.20.0.0/14, 184.72.64.0/18, 54.208.0.0/15, 54.236.0.0/15, and 54.80.0.0/13. This implies that all instances in a VPC are managed in a uniform manner. On average, in each round of our probing we can observe 115,801 instances in a VPC, which are around 17% of all live instances observed, demonstrating that VPC is widely used in EC2 to protect instances.

6.2 Routing paths of VPC instances

Since a VPC should be treated as a private network, the routing policies for instances inside a VPC must be different from those in the default EC2 network. This routing difference can help us further understand the management of a VPC. To connect a VPC to the public Internet, a

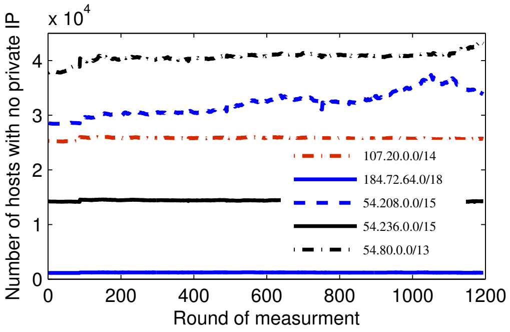

Figure 14: The live instances in VPCs.

customer must create a gateway and attach it to the VPC. The gateway must be included into the route table of the VPC. All traffic from or to the Internet must go through the gateway, but the traffic inside EC2 does not require the gateway to be involved.

Besides the basic understanding of the routing configuration of a VPC, we also need to know how a VPC is connected with the default EC2 network and other VPCs. We created several VPCs with two different accounts. The instances with different types are launched into these VPCs. Trace-routing is performed in four different ways: (1) trace-routing from an instance in a VPC to another instance in the same VPC, (2) trace-routing from an instance in a VPC to an instance in another VPC, (3) trace-routing from an instance in a VPC to an instance in the default EC2 network, and (4) trace-routing from an instance in the default EC2 network to an instance in a VPC.

6.2.1 Routing within VPC

Routing inside the same VPC is expected to be simple. We performed trace-routing between two instances in the same VPC, using both private and public IP addresses. The results show that trace-routing with private IP or public IP addresses will yield different routing paths. If trace-routing is performed with the private IP of the target instance, the result path has only one-hop, i.e., the direct connection to the destination, which is reasonable. However, if trace-routing is performed with the public IP of the target, trace-routing will return two hops with the first hop obscured with stars. Apparently, EC2 intentionally hides some routing information. The routing information between the two instances within the same VPC is made transparent to customers. Such obscuration disables a customer from speculating the physical location of the instances.

As discussed in Section V, even within the same VPC, two instances can be located in different "subnets." We also performed trace-routing between two instances in the same VPC but in different subnets. The resulting paths do not differ from the paths between two instances within the same subnet.

6.2.2 Routing between VPCs

The traffic between instances in different VPCs should traverse multiple switches and routers. Surprisingly, we found that any routing path between any two instances in any two different VPCs only has two hops: the first hop is obscured and the second hop is the destination. EC2 once again obscures the routing path between VPCs to prevent an adversary from revealing sensitive information of a VPC, e.g., the IP address of a gateway.

6.2.3 Routing from VPC to default EC2 network

Although instances in a VPC no longer share a private network with the default pool of EC2, the switches/routers that connect VPCs might still be physically connected to the other switches/routers in the data center. How EC2 routes the traffic between instances in a VPC and instances in the default EC2 network can reveal its network topology to some extent. Figure 15 shows a sample trace-routing result from an instance in a VPC to an instance in the default EC2 network. We can see that the first two hops of the path are obscured. This prevents us from knowing the switch/router that connects the VPC, thereby hiding the physical location of VPC instances. However, we can still see parts of the path and can infer the end-to-end latency based on the trace-routing result.

6.2.4 Routing from default EC2 network to VPC

Figure 16 shows a sample trace-routing result from an instance in the default EC2 network to an instance in a VPC. The path is almost symmetric to the path from a VPC to the default EC2 network. Again, the last two hops before reaching the destination are obscured to hide the information of the router/switch.

Overall, EC2 manages a VPC in a transparent fashion, i.e., to a customer it should look like all instances in a VPC are connected by a dedicated switch, just like a real private network. However, instances in the same VPC are not physically located together. These instances are still located in different racks and are connected to different ToR or EoR switches. Thus, the traffic inside a VPC might still traverse multiple switches/routers. Similarly, the traffic between an instance in a VPC and an instance in the default EC2 network can have a similar path to the traffic between two instances in the default EC2 network. However, EC2 hides or obscures certain hops in the path to provide the image of "private network."

6.3 Co-residence in VPC

The traditional way of achieving co-residence relies on the knowledge of private IP address to seek potential candidates. With VPC, this approach no longer works as VPC hides the private IP address of an instance. An alternative is to infer the physical location of a target based on

Figure 16: A sample trace-routing result from an instance in EC2 to an instance in VPC.

the routing paths to the target. Unfortunately, our trace-routing results show that sensitive information of a routing path is obscured by EC2, and therefore it also does not work well.

However, in our trace-routing results we found that the end-to-end latency to and from an instance in a VPC varies with different instance types and the location of the instance. This latency variation can be leveraged to help an attacker speculate the type and location of a target instance. Moreover, while performing trace-routing between an instance in a VPC and an instance in the default EC2 network, the number of hops required is not obscured. Therefore, the number of hops in a path can also be leveraged to derive useful information for achieving co-residence.

Based on our measurement analysis, we propose a new method to achieve co-residence with instances in a VPC. It has two steps: (1) speculate the type and availability zone of a target and (2) launch probing instances with the same type in the same availability zone and perform co-residence verification.

6.3.1 Type and zone speculation

We collected statistical data of the end-to-end latency between a pair of instances with different types and in different zones. Table 2 shows part of the end-to-end latency statistics. Each row represents an instance in a VPC with a certain type and availability zone preference. Each column stands for an instance in the default EC2 network with a certain type and availability zone preference. Each value in the table is calculated as the average of 50 samples. Each sample is obtained with a distinct instance pair and is averaged over five rounds of latency measurement. With this latency table, we are able to construct a latency vector for each target instance in a VPC and use the latency vectors to speculate the type and availability zone of a target.

There are three availability zones and each zone has six types: t1.micro, m1.small, m1.medium, m1.large, m3.medium, and m3.large. Thus, the complete version of Table 2 has 18 rows and 18 columns, which can be found in our technical report [22]. Note that each row in the table can represent a latency vector, and such a latency vector derived from our controlled sampling is called a *baseline vector*.

In each different availability zone, we randomly select an instance for each different type, resulting in 18 (3×6) sample instances in total for testing type and zone speculation. For each target in a VPC, we perform trace-routing from each of our sample instances to the target for 5 times and record the average end-to-end latency of each pair. Such measurement can provide us 18 end-to-end latency values, which constitute an input vector of length 18. We then calculate the cosine similarity between the input vector and these 18 baseline vectors. The baseline latency vector that has the highest similarity with the target input vector is selected, and we can speculate that the target instance has the same {instance type, availability zone} as the instance in the selected baseline vector.

6.3.2 Verifying co-residence

To achieve co-residence with an instance in a VPC, our probing instances are also launched in a VPC. There are two reasons that we do not use the instances in the default EC2 network as probing instances. First, it is possible that EC2 uses a separate algorithm to place instances in a VPC. In other words, compared to an instance in the default EC2 network, an instance in a VPC may have a better chance to achieve co-residence with an instance in another VPC. Second, as we have observed, the end-to-end latency between two instances in two different VPCs is more stable than the latency between an instance in the default EC2 network and an instance in a VPC, which allows us to leverage latency for pre-filtering.

Similar to verifying co-residence in the default EC2 network, verifying co-residence in a VPC also includes two steps: pre-filtering and covert channel construction. While the way of using covert channel construction to confirm co-residence remains the same, the pre-filtering process in a VPC is different.

To verify whether an attack instance is co-resident with a target, we rely on two rounds of pre-filtering to screen out irrelevant candidates. First, we perform trace-routing from our 18 sample instances to our attack instance and the target instance. If any path from the sample instance to the attack instance is not equivalent to the corresponding path from the sample instance to the target in terms of number of hops, this attack instance is abandoned.

Second, if all the paths match in the number of hops, we measure end-to-end latency between our attack instance and the target instance. Figure 17 shows a sample latency distribution between an instance in a VPC

Table 2: End to end latency between different instances.

	1a-t1.micro	1a-m1.small	1a-m1.medium	1b-t1.micro	1b-m1.small	1b-m1.medium
1a-t1.micro	1.224ms	1.123ms	1.025ms	2.237ms	2.221ms	2.304ms
1a-m1.small	1.361ms	1.059ms	1.100ms	2.208ms	2.055ms	2.198ms
1a-m1.medium	1.165ms	1.102ms	0.986ms	2.211ms	2.060ms	1.988ms
1b-t1.micro	2.101ms	2.235ms	2.188ms	1.108ms	1.243ms	1.202ms
1b-m1.small	2.202ms	2.003ms	2.190ms	1.131ms	0.968ms	1.048ms
1b-m1.medium	2.087ms	2.113ms	1.965ms	1.088ms	1.023ms	0.855ms

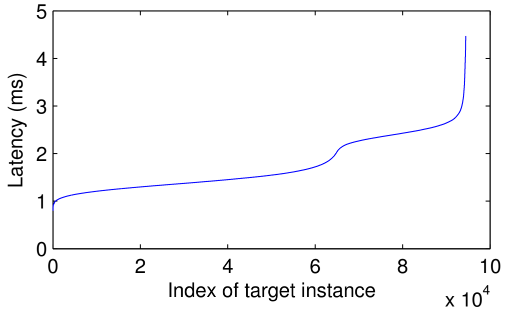

Figure 17: End-to-end latency between an instance in VPC and all other instances in other VPCs in EC2.

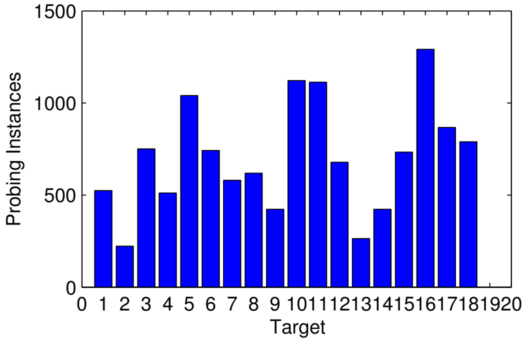

Figure 18: The effort for co-residence with instances in VPC.

with the micro type in availability zone 1a to all live VPC instances in EC2. As we can see, most end-to-end latency values (over 99%) are above 1ms, and in very rare cases (below 0.1%) the latency is below 0.850ms. We perform such latency measurement from 18 sample VPC instances with different types in different availability zones, and similar distribution is repeatedly observed. Based on such observations and the heuristics that instances located on the same physical machine should have lower latency than instances located in a different physical location, we set a latency threshold for each type of instance in each availability zone. The threshold is selected so that for an instance in a VPC with certain type and availability zone, the end-to-end latency between the instance and 99.9% of all other VPC instances should be above the threshold. For example, based on our measurement introduced above, if we speculate that the target VPC instance is located in availability zone 1a with micro type, the latency threshold is set to 0.850ms. Only if the end-to-end latency between a probing instance and a target instance is below the threshold, will the probing instance be considered as a co-residence candidate.

If the probing instance passes the two rounds of filtering, we will perform covert-channel construction to confirm co-residence.

6.4 VPC co-residence evaluation

To verify the feasibility of our VPC co-residence approach, we conducted a series of experiments in EC2. We first tested whether our approach can speculate the type and availability zone of a target instance correctly. We launched VPC instances in three availability zones with six different types. For each combination, 20 instances were launched. We applied our approach to speculate the type and availability zone of the target. If both the type and availability zone are correctly inferred, we consider that the target instance is correctly identified. Table 3 lists our evaluation results. Each number in the table indicates the number of the successfully identified instances among the 20 launched instances for a zone-type combination (e.g., 1a-t1.micro means t1.micro instances launched in the us-east-1a zone). The results show that our type/zone speculation can achieve an accuracy of 77.8%.

We then evaluated the overall effectiveness of our approach for achieving co-residence. We launched 40 instances in one VPC, with different types and availability zones. We performed the full process of achieving co-residence with VPC instances.

First, we measured the effectiveness of our two-stage filtering technique. Among all the probing instances we launched, 63.2% of them did not pass the first step filtering. For the second stage, our technique filtered out 97.9% of the instances that passed the first stage filtering. For all the instances passed the two-stages filtering, 17.6% of them passed the covert-channel verification, which are the instances actually co-resident with the target.

Eventually, among 40 instances, we successfully achieved co-residence with 18 of them. Figure 18 illustrates the effort we paid to achieve co-residence, showing that to achieve co-residence in VPC is not an easy task. An attacker may need to launch more than 1,000 probing instances and such a process can take many hours.

Overall, we are the first to demonstrate that an attacker can achieve co-resident with a target inside a VPC with high cost, and hence VPC only mitigates co-residence threat rather than eliminating the threat all together.

Table 3: The number of successfully identified targets.

	1a-t1.micro	1a-m1.small	1a-m1.medium	1a-m1.large	1a-m3.medium	1a-m3.large
Success	16	13	18	14	16	17

Success	12	18	15	13	14	18

7 A More Secure Cloud

Based on our measurement analysis, we have proposed some guidelines towards more secure IaaS cloud management.

First, the cloud should manage the naming system properly. In general, a domain name is not sensitive information. However, EC2's automatic naming system reveals its internal space. In contrast, Azure and Rackspace employ flexible naming systems that can prevent automatic location probing. However, automatic domain name generation is more user-friendly since it allows a user to launch instances in batch, while a customer can only launch instances one by one in Azure and Rackspace. Moreover, automatic domain name generation can help an IaaS vendor manage the cloud more efficiently. To balance management efficiency and security, we suggest that IaaS clouds integrate automatic domain name generation with a certain randomness. For example, a random number that is derived from the customer's account information can be embedded into the EC2 default domain name. This improved naming approach can prevent location probing while not degrading management efficiency.

Second, it is controversial to publish all IP ranges of a cloud. With the introduction of ZMap [10], it is not difficult to scan all public IPs in the cloud. We have demonstrated that such scanning can cause serious security concerns.

Third, the routing information should be well-protected. While trace-routing is a tool for a customer to diagnose a networking anomaly, it can also be exploited by an attacker to infer the internal networking information of the cloud. However, the approach taken by Azure and Rackspace is too strict. The prohibition of networking probing deprives a customer from self-diagnosis and self-management. A good trade-off is to show only part of the paths, but always obscure the first hop (ToR) and the last second hop.

Fourth, VM placement should be more dynamic and have more constraints. Locality reduction will make it more difficult for an attacker to locate a target. IaaS vendors can also leverage some historical information of a user's account to prevent the abuse of launching instances. While EC2 has significantly increased the difficulty of achieving machine-level co-residence, it is also necessary to suppress rack-level co-residence in the future.

8 Conclusion

We have presented a systematic measurement study on the co-residence threat in Amazon EC2, from the perspectives of VM placement, network management, and VPC. In terms of VM placement, we have demonstrated that time locality in VM placement is significantly reduced and VM placement in EC2 becomes more dynamic, indicating that EC2 has adjusted its VM placement policy to mitigate co-residence. Regarding network management, by conducting a large-scale trace-routing measurement, we have shown that EC2 has refined networking configurations and introduced VPC to reduce the threat of co-residence. We have also proposed a novel method to identify a ToR-connected or non-ToR-connected topology, which can help an attacker to achieve rack-level co-residence. As the first to investigate the co-residence threat in VPC, on one hand, we have confirmed the effectiveness of VPC in mitigating the co-residence threat. On the other hand, we have shown that an attacker can still achieve co-residence by exploiting a latency-based probing method, indicating that VPC only mitigates co-residence threat rather than eliminating the threat.

A Business scale of EC2

Figure 19 illustrates the number of all the detected live instances in EC2 US east region during the measurement period. We can see that the business scale in EC2 US east region is very impressive. Our scanning can always detect more than 650,000 live instances in the cloud. During the peak time, we can detect almost 700,000 live instances. It is noteworthy that our system only scans some common ports. Besides the instances we detected, there are some instances with no common ports opened or within the VPC that do not have public IP addresses. Thus, the real number of live instances in the cloud could be even larger.

Table 4 lists the break-down statistics, showing the number of instances hosting a certain service on average. It is obvious that web service still dominates the usage in IaaS. Most customers rent the instances to host their web services. Among these web services (i.e., HTTP), more than half of them deploy HTTPS at the same time. Since the default way of accessing an instance in EC2 is through SSH, the number of instances listening on port 22 is the second largest. There are also considerable instances hosting FTP service, DNS service, and database service (MYSQL+SQL). For the rest of services, the number of instances hosting them are less significant.

Table 4: Number of instances hosting a certain service

	FTP	SSH	Telnet	SMTP	WHOIS	DNS	DHCP	Finger	HTTP	SQL	HTTPS	MYSQL
Live instances	24,962	327,294	350	18,376	305	3,392	15	68	441,499	48	261,446	25,872

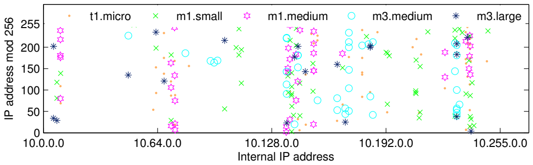

Figure 22: The distribution of internal IP addresses of instances with different types in availability zone us-east-1a.

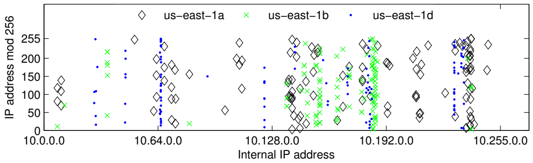

Figure 23: The distribution of internal IP addresses of instances in different availability zones.

B Dynamic environment of EC2

Our measurement can also reflect the dynamic environment of EC2 to some extent. First, as shown in Figure 19, the number of live instances varies over time within a day. We observed a similar pattern each day: the peak time is around 5 p.m. (EST) while the service reaches a valley around 4 a.m. (EST). Despite this diurnal pattern, the difference in the number of live instances between peak and valley is not as significant as we expected. There are only 1,000 more live instances at peak than valley, which is relatively small considering the overall 650,000 live instances. The diurnal pattern is reasonable, as 4 a.m. EST is very early morning for the US east coast and it is also midnight for the US west coast. It is intuitive that at this time period fewer users are using EC2. The small difference between peak and valley can be explained from two aspects. First, most instances run stable services such as web and database services. These instances remain active all the time. Second, although the data center is located in the US, the customers are distributed all around the world. For instance, Bermudez et al. [8] demonstrated that the Virginia data center is responsible for more than 85% of EC2 traffic in Italy. The time of 4 a.m. on the US east coast is 10 a.m. in Italy when customers are very active there.

We are also interested in how dynamic the cloud environment is. Figure 20 illustrates how many instances are shutdown, newly booted, or re-located between each round of measurement. We can see there are more than 15,000 hosts that are changed every 20 minutes, indicating that EC2 is a very dynamic environment with tens of VMs booted and shut down every second.

Besides the dynamics of live instances, we are also interested in the networking dynamics. During our measurement, we observed overall 975,032 distinct private IP addresses and 1,024,589 distinct public IP addresses. We recorded all the mappings from public IP to private IP and the mappings from private IP to public IP during our measurement. We also recorded the mappings that are changed during the measurement period. Over the course of our 15-day measurement, 103,242 mappings changed. This implies that EC2 has likely recruited dynamic NAT for address translation.

Figure 21 shows the private IP addresses that are included in the changed mappings. It is clear that the IP address pool in the cloud is dynamic as well. The density of the IPs in a certain range is significantly higher than other areas. This range of private IPs are mostly assigned to micro and small instances. Since micro and small instances are usually used for temporary purposes, ON/OFF operations on them are more frequent, leading to more frequent changes in private-public IP mappings.

C VM placement locality in EC2

To investigate the VM placement locality in EC2, we launched numerous instances with different types and in different availability zones to study whether the type or zone will impact the physical location of an instance.

Figure 22 illustrates the private IP distribution of some sample instances with different types in zone us-east-1a. The IP distribution exhibits a certain type locality. We can see from the figure that the instances of the same type tend to have closer internal IPs, i.e., they are more likely to be placed physically close to one another. However, compared with corresponding results in 2008 [14], we can see that such type locality has been significantly weakened.

We also study how availability zone could affect VM placement. Figure 23 illustrates the internal IP distribution of instances in different availability zones. As we can see, VM placement still has availability zone locality, i.e., instances in the same zone are more likely to have their internal IP addresses located within a certain range. However, such locality is also much weaker than in 2008 [14].

Towards Discovering and Understanding Task Hijacking in Android

Abstract

Android multitasking provides rich features to enhance user experience and offers great flexibility for app developers to promote app personalization. However, the security implication of Android multitasking remains under-investigated. With a systematic study of the complex tasks dynamics, we find design flaws of Android multitasking which make all recent versions of Android vulnerable to *task hijacking* attacks. We demonstrate proof-of-concept examples utilizing the task hijacking attack surface to implement UI spoofing, denial-of-service and user monitoring attacks. Attackers may steal login credentials, implement ransomware and spy on user's activities. We have collected and analyzed over 6.8 million apps from various Android markets. Our analysis shows that the task hijacking risk is prevalent. Since many apps depend on the current multitasking design, defeating task hijacking is not easy. We have notified the Android team about these issues and we discuss possible mitigation techniques in this paper.

1 Introduction

In the PC world, computer multitasking means multiple processes are running at the same period of time. In Android systems, however, multitasking is a unique and very different concept, as defined in Android documentation: "A *task* is a collection of activities that users interact with when performing a certain job" [1]. In other words, a task contains activities [4] (UI components) that may belong to multiple apps, and each app can run in one or multiple processes. The unique design of Android multitasking helps users to organize the user sessions through tasks and provides rich features such as the handy application switching, background app state maintenance, smooth task history navigation using the "back" button, etc. By further exposing task control to app developers, Android tasks have substantially enhanced user experience of the system and promoted personalized features for app design.

Despite the merits, we find that the Android task management mechanism is plagued by severe security risks. When abused, these convenient multitasking features can backfire and trigger a wide spectrum of *task hijacking attacks*. For instance, whenever the user launches an app, the attacker can condition the system to display to the user a spoofed UI under attacker's control instead of the real UI from the original app, without user's awareness. All apps on the user's device are vulnerable, including the privileged system apps. In another attack, the malware can be crafted as one type of ransomware, which can effectively "lock" the tasks that any apps belong to on the device (including system apps or packages like "Settings" or "Package Installer"), i.e. restricting user access to the app UIs and thus disabling the functionality of the target apps; and there is no easy way for a normal user to remove the ransomware from the system. Moreover, Android multitasking features can also be abused to create a number of other attacks, such as phishing and spyware. These attacks can lead to real harms, such as sensitive information stolen, denial-of-service of the device, and user privacy infringement, etc.

The Android multitasking mechanism and the underlying feature provider, the Activity Manager Service (AMS), haven't been thoroughly studied before. In this paper, we take the first step to systematically investigate the security implications behind Android multitasking design and the AMS. At the heart of the problem, although the Android security model renders different apps sandboxed and isolated from one another, Android allows the UI components (i.e., activities) from different apps to co-reside in the same task. Given the complexity of task dynamics, as well as the vagaries of additional task controls available to developers, the attacker can play tricky maneuvers to let malware reside side by side with the victim apps in the same task and hijack the user sessions of the victim apps. We call this *task hijack-*

Attacks Types	Consequences	Vulnerable system & apps
Spoofing	Sensitive info stolen	all; all
Denial-of-service	Restriction of use access to apps on device	all; all
Monitoring	User privacy infringement	Android 5.0.x; all

Table 1: Types of task hijacking attacks presented in this paper (system versions considered - Android 3.x, 4.x, 5.0.x).

ing.

Given the security threats, it becomes important to fully study Android multitasking behaviors in a systematic way. We approach this topic by projecting the task behaviors into a state transition model and systematically study the security hazards originated from the discrepancies between the design assumptions and implementations of Android tasks. We find that there is a plethora of opportunities of task hijacking exploitable to create a wide spectrum of attacks. To showcase a subset of the attack scenarios and their consequences, we implement and present a set of proof-of-concept attacks as shown in Table 1.

We do vulnerability assessment to the task hijacking threats and discover that all recent Android versions, including Android 5, can be affected by these threats, and all apps (including all privileged system apps) are vulnerable to most of our proof-of-concept attacks on a vulnerable system. By investigating the employment of task control features by app developers based on 6.8 million apps in various Android markets, we find that despite the serious security risks, the “security-sensitive” task control features are popular with developers and users. We have reported our findings to the Android security team, who responded to take a serious look into the issue. We summarize our contributions below:

- To the best of our knowledge, we are the first to systematically study the security implications of Android multitasking and the Activity Manager Service design in depth.
- We discover a wide open attack surface in Android multitasking design that poses severe threats to the security of Android system and applications.
- Base on our vulnerability analysis over 6.8 million apps, we find that this problem is prevalent and can lead to a variety of serious security consequences.
- We provide mitigation suggestions towards a more secure Android multitasking sub-system.

2 Background

Android Application Sandbox: The Android security model treats third-party apps as untrusted and isolates them from one another. The underlying Linux kernel enforces the Linux-user based protection and process isolation, building a sandbox for each app. By default, the components of one app run in the same Linux process with an unique UID. Components from different apps run in separate processes. One exception is that different apps can run in one process only if they are from the same developer (same public key certificate), and the developer explicitly specifies the same process in the manifest file. The Linux sandbox provides the foundation for app security in Android. In addition, Android provides a permission model [12, 19] to extend app privileges based on user agreement, and offers an inter-component communication scheme guarded by permissions for inter-app communication.

Activity: *Activity* is a type of app component. An activity instance provides a graphic UI on screen. An app typically has more than one activities for different user interactions such as dialing phone numbers and reading a contact list. All activities must be defined in an app’s *manifest file*.

Intent: To cross the process boundaries and enable communication between app components, Android provides an inter-component communication (ICC) scheme supported by an efficient underlying IPC mechanism called *binder*. To perform ICC with other components, an component use *intent*, an abstract description of the operations to be performed. An intent object is the message carrier object used to request an action from another component, e.g., starting an activity instance by calling `startActivity()` function. Intent comes in two flavors. *Explicit intent* specifies the component to start explicitly by name. *Implicit intent* instead encapsulates a general type of action, category or data for a component to take. The system will launch a component “capable” of handling this intent. If more than one target activities exist in the system, the user is prompted to choose a preferred one.

Activity Manager Service (AMS): AMS is an Android system service that supervises all the activity instances running in the system and controls their life cycles (creation, pause, resume, and destroy). The interaction and communication protocols between activities and the AMS are implemented by the Android framework code, which is transparent to app developers, leaving developers focusing on the app functionality. While Window Manager Service (WMS) manages all windows in the system and dispatches user inputs from the windows, AMS organizes all the activities in the system into tasks, and is responsible for managing the tasks and supporting the multitasking features as will be described in Section 3.

In addition, AMS is in charge of supervising service components, intent routing, broadcasting, content providers accesses, app process management, etc., making itself one of the most critical system services in the Android system.

3 Android Tasks State Transition Model

3.1 Task and Back Stack

In Android, a *task* [1] is a collection of activities that users have visited in a particular job. The activities in a task are kept in a stack, namely *back stack*, ordered by the time the activities are visited, such that clicking the "back" button would navigate the user back to the most recent activity in the current task. The activities in the back stack may be from the same or different apps.

The activity displayed on the screen is a *foreground activity* (on the top of the back stack) and the task associated with it is a *foreground task*. Therefore, there is only one foreground task at a time and all other tasks are *background tasks*. When switched to the background, all activities in a task stop, and remain intact in the back stack of the task, such that when the users return they can pick up from where they left off. This is the fundamental feature that Android multitasking offers to users.

3.2 A Tasks State Transition Model

The status of tasks in a system keeps changing as a result of user interaction or app program behaviors. To understand the complex task dynamics and its behind security implications, we view the task transitions through time as a state transition model. The model is described by $(S, E, \Lambda, \rightarrow)$, where S denotes a set of task states; E and Λ are sets of events and conditions respectively; and $\rightarrow$ indicates a set of feasible transactions allowed by the system under proper events and conditions.

1. **Task state** (**$s \in S$**): represents the state of all tasks (specifically, the back stacks) in the system and their foreground/background statuses. In other words, the tasks in the system remain in one state iff the activity entries and their orders in the back stacks stay the same, and the foreground task remains to be the same task.
2. **Event** (**$e \in E$**): denotes the event(s) it takes to trigger the state transition, for example, pressing the "back" button or calling `startActivity()` function.
3. **Condition** (**$\lambda \in \Lambda$**): the prerequisites or configurations (usually default) that enable a state transition under certain events. We denote $\lambda^{default}$ as the system default conditions in this paper.

4. **Transition** (**$\rightarrow$**): stands for a feasible state transition. Not all task transitions are feasible, e.g., the order of activities in back stack cannot be changed arbitrarily (only push and pop are viable operations over the stack). A viable transaction is also represented as $s_1 \rightarrow s_2$, or (s_1, s_2, e, λ), where $s_1, s_2 \in S$.

3.3 A Task State Transition Example

Given the state transition model, we depict a simple task state transition example in Figure 1. The figure shows three task states, and the state transitions reflect the process in which the user first launches an app from the home screen ($s_0 \rightarrow s_1$), visits an additional activity UI in the app ($s_1 \rightarrow s_2$) and returns to the home screen by pressing the "back" button twice ($s_2 \rightarrow s_1 \rightarrow s_0$).

In each task state, we show all existing tasks and their back stacks. For example, s_0 is a task state in which no task, except the launcher task, is running in the system. The launcher task has only one activity in its back stack - the home screen from which users can launch other apps.

In $(s_0, s_1, e^{start}, \lambda^{newtask})$, a new app task is created and brought to the foreground in the resulting state s_1. e^{start} represents the event that `startActivity()` is called by the home activity in the launcher task. This event could happen when the user clicks the app's icon on the home screen. $\lambda^{newtask}$ specifies a special condition, i.e., the FLAG_ACTIVITY_NEW_TASK flag is set to the input intent object to `startActivity()` function. This flag notifies the AMS the intention of creating a new task to host the new activity. Note that in this example most state transitions are under default conditions, indicated by $\lambda^{default}$, while here $s_0 \rightarrow s_1$ is an exception because the launcher app customizes the condition ($\lambda^{newtask}$) for a valid design purpose: start the app in a brand new task when the user launches an new app. This is an example where app developers can customize certain configurable conditions to implement helpful app features. However, condition like $\lambda^{newtask}$ can be abused in a task hijacking attack, as discussed in Section 4.

Next, $(s_1, s_2, e^{start}, \lambda^{default})$ is triggered by event e^{start} again (this time called by activity A instead), yet under the default condition. By default, AMS pushes the new activity instance B on top of the current back stack

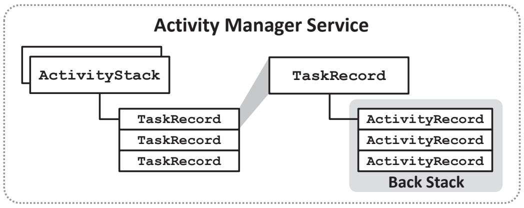

Figure 2: Data structures of tasks, activities and back stacks in the Activity Manager Service.

as shown in s_2. The previous activity A is stopped and its state is retained. In $(s_2, s_1, e^{back}, \lambda^{default})$, e^{back} represents the event of user pressing the "back" button. As expected by the user, the next activity A on stack is brought back to the screen, and its original state is resumed. Activity B is popped from the back stack and destroyed by the system. The initial state s_0 is finally restored through $(s_1, s_0, e^{back}, \lambda^{default})$ when the user presses "back" button again. The app's task is destroyed because when the popped activity is the last activity in the back stack, the activity is destroyed together with the "empty" task.

Note that activities from different apps can co-reside in the same task (e.g. activity A and B in this example). In other words, although activities from different apps are isolated and protected within their own process sandboxes, Android allows different apps to co-exist in a common task. This creates opportunities for malicious activities to interfere with other activities once they are placed in the same task, and the system passes the program control to the malicious activities.

In reality, the amount of possible task states in a system is big, and the state transitions can be complex, e.g., each state may again have numerous incoming and outgoing transitions connecting with other states. In Section 4, we discuss what may go wrong during the complex task state transitions.

3.4 Android Implementation

AMS maintains Android tasks and activities in a hierarchy shown in Figure 2. AMS uses `TaskRecord` and `ActivityRecord` objects to represent tasks and activities in the system respectively. A `TaskRecord` maintains a stack of `ActivityRecord` instances, which is the back stack of that task. Similar to the activities in a back stack, tasks are organized in a stack as well, maintained by a `ActivityStack` object, such that when a task is destroyed, the next task on stack is resumed and brought to the foreground. There are usually two `ActivityStack` containers in the system - one containing only the launcher's tasks and the other holding all remaining app tasks.

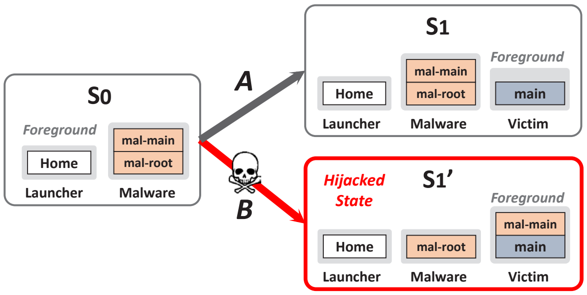

Figure 3: Task state transition of spoofing attack (A: task state transition by system-default. B: Hijacking state transition).

4 Task Hijacking in Android

In this section, we first discuss an example showing how an attacker could manipulate the task state transitions to his advantage, causing task hijacking attacks. We then explore the extent of different task hijacking methods and how they can be used for other various attack goals.

4.1 Motivating Example

Suppose attacker's goal is to launch an UI spoofing attack. Specifically, when the user launches a victim app from the home screen, a spoofing activity with an UI masquerading the victim app's main activity (e.g. the login screen of a bank app) shows up instead of the original activity.

Figure 3 shows the task state transitions of the UI spoofing attack. Initially in s_0, the home screen is displayed to the user while a malware task waits in the background. Like the task state transition example just shown in Section 3.3, when the user launches the victim app from the launcher, state transition A is supposed to occur by default, i.e. a new task is created and the app's main activity is displayed on screen. However, as shown in state transition B, the malware can manipulate the task state transition conditions such that the system instead displays the spoofing UI of activity "mal-main" by relocating "mal-main" from the background task to the top of victim app's back stack. The user has no way to detect the spoofing UI since the original activity UI is not shown on screen at all, and the "mal-main" activity appears to be part of the victim app's task (perceivable in recent task list). By this means, the victim task is smoothly hijacked by the malware activity from launch time, and all user behaviors within this task are now under malware's control.

In this example, the attacker successfully misleads the system and launches the spoofing UI by abusing some task state transition conditions, i.e. `taskAffinity` and `allowTaskReparenting`. We will introduce them together with other exploitable conditions/events in

Conditions	
Intent Flags (FLAG_ACTIVITY_*)	*Activity Attribute*

	startActivities()
	TaskStackBuilder class

Table 2: Task control knobs - configurable task state transition conditions and events provided by Android.

Section 4.5 and 4.6.

4.2 Adversary Model

We assume the user's Android device already has a malware installed (similar assumptions are made in [8, 25, 34, 38]). The malware pretends to seem harmless, requiring only a minimum set of widely-requested permissions such as INTERNET permission. The attacker's goal is clear: blend the malicious activities with the target app's activities in one task, and intercept the normal user operations to achieve malicious purposes.

4.3 Hijacking State Transition

A *hijacked task state* is a desirable state to attackers, in which at least one task in the system contains both malicious activities (from malware) and benign activities (from the victim app). The task state $s_1^{'}$ in the spoofing attack is an example of hijacked task state. A *hijacking state transition* (HST) is a state transition which turns the tasks in the system to a dangerous hijacked task state, e.g., the task state transition B in the previous example. Conceptually, there are two types of HSTs:

1. The malicious activity gets pushed onto the victim task's back stack (malware⇒victim);
2. The victim app activity is "tricked" by malware and pushed on the malware's back stack (victim⇒malware).

4.4 The Causes of HSTs

Android provides a rich set of task control features, i.e., task state transition conditions and events. We call these features as *task control knobs*. The task control knobs provide app developers with broad flexibility in controlling the launch of new activities, the relocation of existing activity to another task, "back" button behaviors, even the visibility of a task in the recent task list (a.k.a overview screen), etc. Table 2 lists such conditions and events in four categories: activity attribute, intent flags, call-back functions, and framework APIs. All these control flexibility further complicates task state transitions.

Due to HST's potential threats to app and system security, understanding the extent of HSTs in the complex task state transitions becomes important. To achieve this, we simulate the task state transitions in a Android system and try to capture all possible HSTs and hijacked task states that occur during the state transitions.

In theory, there are a huge number of possible task states (each app may have a number of activities, and an activity can be instantiated for multiple times). We confine the number of task states to more interesting cases by adding two constraints: (1) each app only has two activities - the main activity and another public exported activity (can be invoked by other apps), and (2) each activity can only be instantiated once. In the simulation, we specify three apps in the system - namely, Alice, Bob and Mallory (the malware) - as it covers most HST cases.

Given the task states, we generate the task state transition graph by connecting pairs of states with directed edges. For instance, state s_1 and s_2 are connected only if $\exists e \in E, \lambda \in \Lambda$, such that (s_1, s_2, e, λ) or (s_2, s_1, e, λ) are valid transitions, where E denotes all feasible events and Λ represents all possible conditions in Table 2. After constructing the task state transition graph, all hijacked states and HSTs are highlighted. We show a sub-graph of the resulting task state transition graph in Figure 4(a) and visualize the task states in Figure 4(b). For clarity of the presentation, we only show the interesting branches of the over-sized graph and have skipped many duplicated HST cases. Moreover, we zoom in each of the HSTs and show their detailed information in Table 3, including the conditions and events that trigger the HSTs. We manually verify all presented HSTs on real systems and these HSTs are proven to be exploitable to launch real attacks (indicated in the last column in Table 3).

We make two important observations from our result. First, once exploited, the hijacked states shown in Figure 4(a) could result in serious security hazards. For example, HST#3 is the task state transition of our example attack discussed earlier. As a result of this HST, the screen is under attacker's control in state s_{14}. As another example, in HST#2, the benign activity B2 is tricked to be placed in Mallory's task instead of Alice's task during start-up. This can also lead to spoofing attack or GUI confidentiality breaches.

Second, compared with the HST triggered by the system-default conditions and events (e.g., HST#1), more HST scenarios are produced under the configurable conditions and events (HST#2-6) . It means that, by abusing the flexible task control "knobs" readily offered

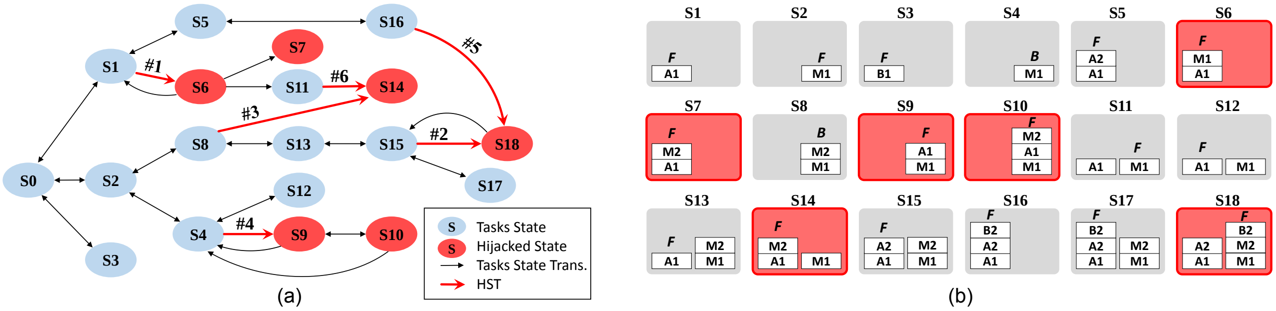

Figure 4: (a) A sub-graph of the over-sized task state transition graph for a simulated system with three apps. The sub-graph shows the typical cases of HSTs (red edges with HST indexes) and the resulting hijacked task states (red nodes). s_0 represents the initial state, i.e., no tasks except the launcher task exists in the system. (b) Visualization of task states of all nodes in figure (a). A, B and M represent the activities from Alice, Bob and Mallory (the malware) respectively. We skip showing the launcher task in the task states. Hijacked states are highlighted as red boxes. F and B denote foreground and background tasks respectively.

HST #	HST Type	Conditions	Events	Attacks in Section 5
1	malware⇒victim	Default	A1: startActivity(M1)	phishing I
2	victim⇒malware	M1:taskAffinity=B2 NEW_TASK intent flag set or B2:launchMode=”singleTask”	A2: startActivity(B2)	phishing II
3	malware⇒victim	M2:taskAffinity=A1; M2:allowTaskReparenting=”true” NEW TASK intent flag set	launcher: startActivity(A1)	spoofing

4	victim⇒malware	M1:taskAffinity=A1; NEW_TASK intent flag set	launcher: startActivity(A1)	denial-of-use;
				ransomware;
				spyware

5	victim⇒malware	M1:taskAffinity=B2; B2:allowTaskReparenting=”true”	startActivities([M1, M2]) or use TaskStackBuilder	phishing III
6	malware⇒victim	M2:taskAffinity=A1 NEW_TASK intent flag set or M2:launchMode=”singleTask”	M1: startActivity(M2)	-

Table 3: Detailed information of the HSTs (red edges with HST indexes in Figure 4). E.g., condition “M1:taskAffinity=B2” indicates that the taskAffinity attribute of activity M1 is set to that of B2; Event “launcher:startActivity(A1)” means that activity A1 is started by the launcher.

by the Android system, the attacker can actively create a plethora of HSTs that harm other apps. In Figure 4(a), we only show several typical HST cases, yet there are much more HST instances of these types in the complete state transition graph.

The HST cases and their conditions/events summarized in Table 3 may now look mysterious. We will demystify these conditions and events in the rest of this section.

4.5 Exploiting Conditions

In Table 3, HSTs #2, #4, #6 are similar with respect to their state transition conditions, i.e. all three HSTs occur by virtue of customized activity launch mode (by setting `launchMode` attribute or NEW_TASK intent flag). HSTs #3, #5 are similar as they both use `allowTaskReparenting` attribute to enable activity re-parenting.

4.5.1 Activity Attributes

One can define the attributes [2] of an activity in the `<activity>` element in manifest file. The attributes not explicitly defined are set to default values.

Task Affinity: Task affinity declares what task an activity prefers to join. It is a hard-coded string defined as `<android:taskAffinity="affinity">`, where `affinity` is the task affinity string that can be defined arbitrarily. By explicitly declaring a task affinity, an activity is able to actively “choose” a preferable task to join within its life cycle. If not explicitely specified in the manifest, the task affinity of an activity is the app package name, such that all activities in an app prefer to reside in the same task by default. The affinity of a task is determined by the task affinity of the task’s *root activity* (the activity on the bottom of back stack).

Task affinity is a crucial condition used in most of the HSTs in Table 3. There are two occasions in which an activity can “choose” its preferred host task: (1) when an activity attempts to be started as a new task (i.e., “`singleTask`” launch mode or NEW_TASK intent flag as in HST#2, #4, #6), and (2) if the `allowTaskReparenting` activity attribute is set to true, and another task with the same task affinity is brought to the foreground (as in HST#3, #5). We explain the above two cases in detail in the following paragraphs.

Launch Mode: Activity launch mode defines how an activity should be started by the system. Based on the launch mode, the system determines: (1) if a new activity instance needs to be created, and (2) if yes, what task should the new instance be associated with. The launch mode can be either statically declared by specifying `<android:launchMode="value">` in the manifest file or dynamically defined using intent flags discussed in Section 4.5.2.

By default, `launchMode="standard"`. In this mode, the AMS would create a new activity instance and put it on top of the back stack on which it is started. It's possible to create multiple instances of the same activity and those instances may or may not belong to the same task. With `launchMode="singleTask"`, the decision-making of activity start-up is more complex. An investigation into Android source code reveals three major steps the AMS takes towards starting an activity. First, if the activity instance already exists, Android resumes the existing instance instead of creating a new one. It means that there is at most one activity instance in the system under this mode. Second, if creating a new activity instance is necessary, the AMS selects a task to host the newly created instance by finding a "matching" one in all existing tasks. An activity "matches" a task if they have the same *task affinity*. After finding such a "matching" task, the AMS puts the new instance into the "matching" task. This explains why in HST #2 and #6, the newly-started and foreground activities (B2 and M2) are put on other "matching" tasks (with the same task affinity) instead of the tasks who start them. Third, without finding a "matching" task, the AMS creates a new task and makes the new activity instance the root activity of the newly created task.

Task Re-parenting: By default, once an activity starts and gets associated with a task, such association persists for the activity's entire life cycle. However, setting `allowTaskReparenting` to true breaks this restriction, allowing an existing activity (residing on an "alien" task) to be re-parented to a newly created "native" task, i.e., a task having the same task affinity as the activity.

For example, in HST#3 resembles the spoofing attack example discussed in Section 4.1. M2 is supposed to stay on Mallory's task at all time. However, M2 has its `allowTaskReparenting` set to true, and `taskAffinity` set to Alice's package name, such that when Alice's task is started (A1 as the root activity) by the launcher, M2 is re-parented to Alice's new task and the user sees M2 on screen instead of A1. In this process, A1 is never brought to the screen at all. Likewise, HST #5 occurs due to similar reason, except that this time the benign activity B2 (with its `allowTaskReparenting` set to true) is re-parented to the malware task.

The above activity attributes offer attackers with great flexibility. The attackers can put their malicious activities to a preferred hosting tasks under certain events, e.g., `singleTask` launch mode during an activity start-up and `allowTaskReparenting` during a new task creation. Furthermore, an activity is free to choose any app as their preferred task owner (including the privileged system apps) by specifying the target app's package name as their task affinity. These conditions lead to a bulk of HSTs in the simulation, and these HSTs can be employed to launch powerful task hijacking attacks as we will see in Section 5.

4.5.2 Intent Flags

Before sending an intent to start an activity, one could set intent flags to control how the activity should be started and maintained in the system by calling `intent.setFlags(flags)`. `intent` is the intent object to be sent, and `flags` is an `int` value (each bit indicates a configuration flag to the AMS).

Noticeably, the `FLAG_ACTIVITY_NEW_TASK` intent flag, if set, lets an activity be started as if its `launchMode="singleTask"`, i.e. the system goes through the same procedures as explained in launch mode to find a "matching" task or create a new task for the new activity instance. This is the dynamic way of setting activity's launch mode. Launcher app always uses this flag to start an app in a new task as in HST#4.

4.6 Exploiting Events

4.6.1 Callback Function

Android framework provides a variety of callback functions for activities to customize their behaviors under particular events, e.g., activity life cycle events (start, pause, resume or stop), key pressing events, system events, etc.

`onBackPressed()` is a callback function defined in `Activity` class, and is invoked upon user pressing the "back" button. The default implementation in framework code simply stops and destroys the current activity, and it then resumes the next activity on top of the current back stack, as we have seen in Section 3.3. However, an attacker can override this callback function for its malicious activity and arbitrarily define a new behavior upon "back" button pressing, or simply disable the "back" button by providing an empty function. As a result, once the malicious activity is brought to the foreground, pressing the "back" button triggers the code of attacker's control.

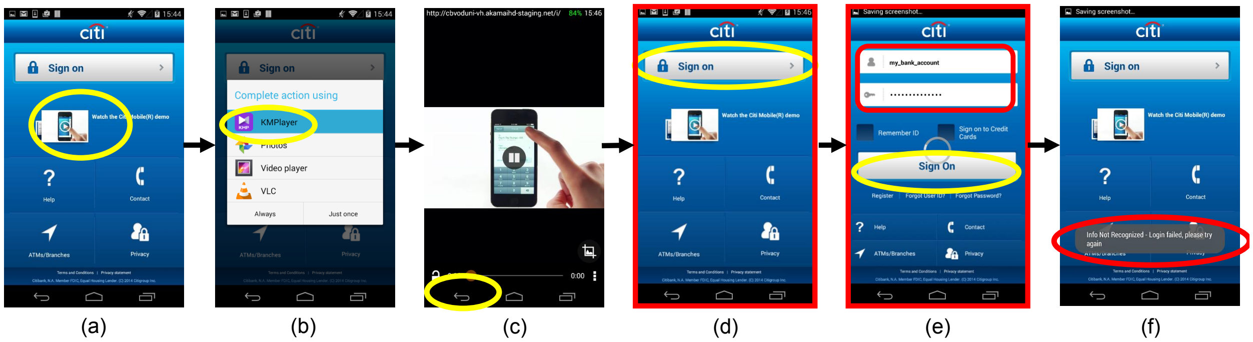

Figure 5: The process of "back hijacking" phishing attack to a well-known bank app. (a) shows the main activity of the bank app. A new user taps on the tutorial video link in the bank app; In (b), a system dialog prompts the user to choose a video player available in the system; In (c), the video player activity is started, and the user later clicks "back" button, intending to "goes back" to the original main activity; In (d) and (e), the back button directs the user to the phishing UIs, which spoof the user and steal bank account credentials. The phishing activity then quits after user clicks "Sign On"; In (f), the original main activity is resumed, with a log-in failure toast message displayed by the quitting malware.

4.6.2 Framework API

Android framework provides APIs to create new tasks with established back stacks. For example, `TaskStackBuilder` is a utility class that allows an app developer to construct a back stack with specified activities, and to start the back stack as a brand new task in the system at a later time (e.g. using a PendingIntent). Similarly, `startActivities()` in `Activity` class achieves the same thing except that it builds and starts the tasks in one API function call. These framework APIs are helpful for attackers to build and launch new tasks containing designated back stacks without explicitly displaying all activities in the back stacks on screen.

5 Task Hijacking Attack Examples

In this section, we demonstrate more attack examples utilizing exploitable HSTs in Table 3. These attacks can breach the integrity, availability and confidentiality of victim apps' UIs respectively. We have tested these attacks on Android 3.x, 4.x and 5.0.x.

5.1 Breaching UI Integrity

The UI integrity here means the "origin/source integrity" of the victim app's activities, instead of the "data integrity". That is, instead of modifying the original activities of the victim app, attackers deceive the user by spoofing UIs, which can prevent the original UIs from being displayed on screen.

5.1.1 Spoofing Attack

As we have already seen in Section 4.1 and 4.5, by manipulating `allowTaskReparenting` and `taskAffinity`, an attacker can successfully hijack a new task with a spoofing activity. This attack affects all apps on device including the most privileged system apps (e.g., Settings). The attacker can even target multiple apps on user device at the same time, as long as the background malware tasks (targeting different task affinity) are started in advance.

Stealthiness: In order to make the spoofing attack more stealthy, the attacker could take advantage of other task transition conditions and events to achieve this. For example, the attacker can make its background malware tasks absent from the recent task list by setting the activity attribute `excludeFromRecents` to true. As another example, the user may accidentally resume the app's original activity (the root activity of victim app's task) by clicking the "back" button from the on-screen spoofing activity. To prevent users from observing this abnormal app behavior, the attacker can override `onBackPressed()` of the spoofing activity, bringing the home screen back to the foreground, such that it gives the user an illusion that it is in coherence with the system's default "back" behavior.

5.1.2 Phishing Attack - "Back Hijacking"

The back button is popular with users because it allows users to navigate back through the history of activities. However, attackers may abuse the back button to mislead the user into a phishing activity.

We devise three phishing attack methods that target the same banking app, and demonstrate two of them in this paper. Figure 5 shows the screen shots of the phishing attack process. The phishing UIs show up when the user returns from a third-party app activity, and the user unwittingly believes that he/she has returned to the original bank activity.

Figure 6 shows the state transition diagrams of two attack methods. The two attack methods differ in that,

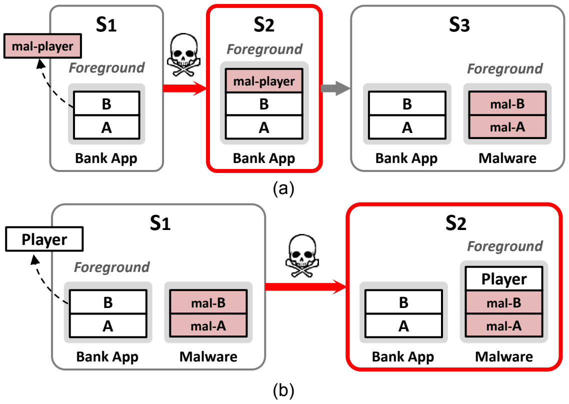

Figure 6: Tasks state transition diagrams of "back hijacking" attacks. Figure (a) and (b) shows method I and II respectively.

user chooses a malicious video player in the first attack, while in the second attack, even though the user chooses a benign player, the bank task can still be hijacked when the user launches the video player.

Method I: Figure 6(a) shows the state transition diagram of the first attack method. We skip the unrelated task(s) (e.g. launcher) in the system and only show tasks of interest. In s_1, the bank app task contains activities A and B, in which B is the login activity. The HST occurs in $s_1 \rightarrow s_2$, triggered by the event that the user clicks the tutorial video from the login UI, sending out a implicit intent to look for an exported activity in the system capable of playing the tutorial video. Unfortunately, the user selects the malicious video player activity "mal-player" from the system pop-up and this results in the hijacked state s_2. After user finishes watching the video, $s_2 \rightarrow s_3$ is triggered by user pressing the "back" button. However, the "back"-pressing event is modified by overriding `onBackPressed()` in the "mal-player" activity. As a result, instead of resuming activity B, a new malicious task is created (by using `TaskStackBuilder`) and brought to the front. As can be seen, the HST takes place under default conditions as in HST#1 (in Table 3).

The user session is hence hijacked to the malware task, which contains "mal-A" and the foreground "mal-B" phishing activities. Note that in this attack, the malware need to camouflage as a useful app (e.g. a video player in this case) that users are likely to use.

Method II: As shown in Figure 6(b), the same phishing attack can succeed even when the user selects a benign video player. In s_1, a malware task with two phishing activities lurks in the background. Similarly, HST occurs in $s_1 \rightarrow s_2$, when the user launches a benign video player. However, as shown in the resulting state s_2, instead of joining the banking task, the new video player activity is pushed in the malware task's back stack, such that pressing the "back" button after the video play resumes the phishing activity "mal-B".

This HST is similar to HST#2 (in Table 3) in that the benign video player attempts to be started as a new task, either because of the `NEW_TASK` flag set in the intent by the bank activity, or the "singleTask" launch mode set by the video player. Furthermore, the existing malware task has its `taskAffinity` maliciously set to the benign video player.

Stealthiness: We employ similar methods in the previous spoofing attack to ensure the stealthiness of the background malware tasks in both phishing attack methods. Moreover, we disable the animation of task switching, producing an illusion to the user that the screen transition is within the same task/app.

5.2 Breaching UI Availability

Task hijacking can also be leveraged to restrict the availability of an app's UI components, or in other words, to prohibit user access to part or all functionality of an victim app.

5.2.1 Preventing Apps from Being Uninstalled

In this example, the attacker is able to completely prevent apps from being uninstalled.

Ways to Uninstall An App: There are generally three ways for a user to uninstall an app from the device: (1) uninstall from the system Settings app; (2) dragging the app icon to the "trash bin" on home screen; or (3) uninstall with the help of a third-party app, e.g. an anti-virus app. In these scenarios, the Settings, Launcher, and the third-party apps will respectively generate an request to uninstall the app. Such a request eventually reaches the system package installer, which has the exclusive privilege to install/uninstall apps. Upon receiving the request, package installer pops up a dialog for the user to confirm. The dialog itself is an activity (namely uninstaller activity) from the system package installer and is pushed in the back stack of whoever is making the request (e.g. s_4 in Figure 7). No app can be uninstalled without user confirmation on the uninstaller activity.

Attack Method: The attacker can prevent app uninstallation by restricting user access to the uninstaller activity when it shows up on screen. In this attack, once the uninstaller is found to be in the foreground, a malicious activity is immediately pushed on top of the uninstaller activity in the same back stack, such that the uninstaller is "blocked" and becomes inaccessible to the user.

Figure 7 shows the state transition diagram of this attack targeting Settings app. Similar methods can be easily adopted to block app un-installation from the launcher or the anti-virus apps (e.g. when malware is detected).

In s_1, a task with only one root activity ("mal-root") from the malware is waiting in the background,

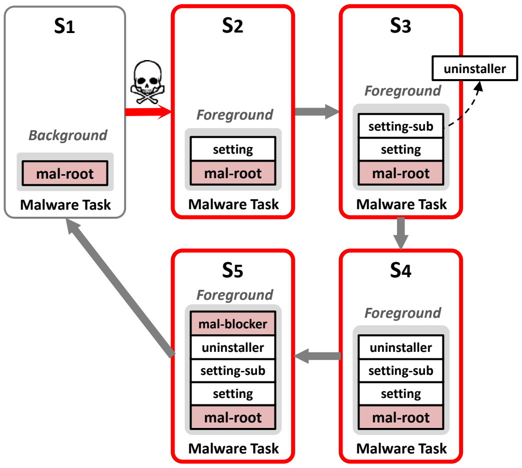

Figure 7: Tasks state transition diagram of application uninstall prevention attack.

with its `taskAffinity` set to the Settings app (com.android.settings). The HST occurs in $s_1 \to s_2$, triggered when the user opens up the Settings from the home screen (we skip Launcher task in the figure). In s_2, instead of hosting the newly-created "setting" activity in a new task, "setting" activity is pushed on top of the malware's back stack because the it is started by the launcher with a `NEW_TASK` flag. As a result, upon start-up, the privileged Settings app is unwittingly "sitting" on a task owned by the malware. This is similar to HST#4 in Table 3.

The user then goes through a few more sub-setting menus to find the app (as shown in s_3) and clicks the uninstall button, after which the uninstaller activity shows up for user confirmation (as shown in s_4). Once this happens, a malicious activity namely "mal-blocker" is immediately (even without user awareness of the uninstaller dialog) launched by a malicious background service, which keeps monitoring the foreground activity. The "mal-blocker" activity, started by a `NEW_TASK` flagged intent and with the same task affinity as the Settings app, is thus pushed in the same task, and effectively blocks the uninstaller as shown in s_5. The "mal-blocker" activity has its "back" button disabled, such that the user has no way to access the uninstaller activity right below it in the back stack whatsoever, and thus cannot confirm the app uninstalling operation.

In fact, the "back" button of "mal-blocker" is not only disabled, but is also augmented with a new event that triggers $s_5 \to s_6$: invoking (call `startActivity()`) the "mal-root" activity with an intent having `CLEAR_TOP` flag set, which results in the killing of the uninstaller and Settings activities in the task.

Preventing Un-installation from adb: An advanced user may resort to *Android Debug Bridge* (adb), a client-server program used to connect Android devices from a computer, and uninstall the malware from adb. However, in order to use adb, the user needs to first enable USB debugging in the Settings. The malware can block it in the Settings using similar technique and prevent the use of adb, as long as the USB debugging is not enabled before the attack (which is the case for most normal users).

5.2.2 Ransomware

Ransomware blackmails people for money in exchange of their data, and it has recently hit Android in a large scale [5]. The attackers may use UI hijacking to implement ransomware.

The malicious background service mentioned above takes the following two responsibilities and is difficult to be completely stopped. (1) Assure the malicious root activity ("mal-root") is alive: it re-creates a new root activity once the activity is found to be destroyed; and (2) monitor the foreground activity: if the target activity shows up, it immediately starts "mal-blocker" to block user access to the target activity, as we have seen in $s_4 \to s_5$. To prevent itself from being killed, the service registers itself in the system alarm service, who fires a pending intent in every given fixed time interval, relaunching the service if it is found to be killed.

By this mean, the ransomware is able to restrict user access to any target apps of attacker's choice, and can potentially render the Android device completely useless.

5.3 Breaching UI Confidentiality

The attack method in Section 5.2 can also be deployed to devise a new spyware, namely "TaskSpy" capable of monitoring the activities within any tasks in the newest Android 5.0.x systems (API 21), without requiring any permissions.

In Android, the system regards the owner of the root activity in a back stack to be the owner of the corresponding task. Android 5.0 allows an app to get the information of the caller app's own tasks (including the activities in the tasks) without requiring any permission. It means that, if a spyware can "own" the tasks of all the apps it intends to spy on, it is able to get the information of these tasks that in fact contain the victim apps' activities. Task hijacking is especially useful to "TaskSpy" in this case. In other words, "TaskSpy" can use the HST presented in Section 5.2 to "own" the tasks of any victim apps and thus stealthily spy on their activities without using any permission. Chen et. al. have achieved the same goal in their work [8] by monitoring and interpreting the shared VM information via public side channels. Compared with their attack, task hijacking can do this in a more direct and reliable way on Android 5.0.x.

Vul. app	Atk #	Vul. conditions	% of vul.	Tol. % of vul.
V	I	Send implicit intent for exported activities	93.9	93.9
	II	Send implicit intent for exported activities and use intent flag NEW_TASK	65.5	
S	II	Contains public exported activity and lauchMode="singleTask"	14.2	14.4
	III	Contains public exported activity and allowTaskReparenting="true"	1.4	

Table 4: Percentage of vulnerable victim apps (V) and "service" apps (S) to the "back hijacking" phishing attacks respectively, among 10,985 most popular Google Play apps.

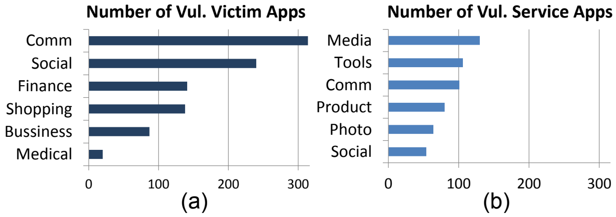

Figure 8: (a) Breakdown of vulnerable victim apps in security-sensitive app categories. (b) Breakdown of vulnerable "service" apps in the most widely useful app categories.

6 Evaluation

We first seek to understand the extent of vulnerable systems and apps to the attacks we have presented in Section 5. By doing large-scale app analysis across various markets, we then provide the current use status of the task control knobs in real implementations. Base on our insights from the result, we provide mitigation suggestions to defend against task hijacking threats in Section 7.

6.1 Vulnerability Analysis

Vulnerable Android Versions: We say an Android version is vulnerable to a particular attack if a malware can successfully launch the attack to a victim app on the system. Since the unique multitasking is part of Android design and most features have been introduced early in Android's evolution, we find that recent Android versions, including 3.x, 4.x and 5.0.x, are vulnerable to all our presented attacks, except the "TaskSpy" attack. As discussed in Section 5.3, "TaskSpy" relies on specific APIs introduced from API 21, and therefore, only affects the newest Android 5.0.x systems.

Apps Vulnerable to Task Hijacking Attacks: As summerized in Table 1, all the apps installed on a vulnerable Android system (including the privileged system apps) are vulnerable to all the attacks presented in this paper, except the "Back Hijacking" phishing attacks, which require certain prerequisites for an app to be vulnerable. Despite the prerequisites, the "Back Hijacking" phishing attacks are extremely stealthy, can be easily crafted and can cause serious consequnces. We try to further understand the scale of apps vulnerable to the "Back Hijacking" phishing attack by analyzing the most popular apps in Google Play.

Apps Vulnerable to "Back Hijacking": In a phishing attack, the attacker would be likely to target the most popular and valuable apps. Therefore, we focus our vulnerability analysis on the most popular 10,985 apps from Google Play, i.e., apps with over 1 million installs.

We indicate a vulnerable app in the phishing attacks to be of either one or both of the following two types: (1) victim app - the target victim app of the phishing attack (e.g. the bank app); and (2) "service" app - the benign app that provides publicly exported activities and is exploitable by the attacker to conduct user phishing on the victim apps (e.g. the benign video player). We do static analysis on the apps. Specifically, we perform inter-procedural analysis to identify all implicit intents (without permissions guarded) and the associated flags, and conduct manifest scan to find all activity attributes and public exported activities (excluding the main activities which are always exported). Table 4 lists the vulnerability conditions, and shows the percentages of both vulnerable victim apps and "service"apps to each and all the attack methods respectively.

As can be seen, 93.9% of the most popular apps in Google Play are vulnerable. This is partially because most apps would send out implicit intents (without permissions guided), which could potentially invoke a malware activity as in attack I. By taking a closer look at the results, among these apps, a majority (65% of apps) are vulnerable to attack II, i.e., they are vulnerable to phishing attack even if users launch trusted benign "service" apps from these apps. Moreover, 14.36% "service" apps can be exploited to "help" attack the apps who invoke these "service" apps, even if the apps being attacked may not be vulnerable by themselves.

The consequence and severity of a phishing attack depend on the content and sensitivity of the stolen information. To have a rough idea of the potential consequences caused by the "Back Hijacking" phishing attacks, we selectively show in Figure 8(a) the population of vulnerable victim apps in a few security-sensitive app categories. Noticeably, We observe that a significant number of security-sensitive apps are vulnerable, including the financial apps like banking and credit card payment (e.g., Citibank, Chase, Google Wallet), the most popular communication and social media apps (e.g. Google Hangouts, facebook), and shopping apps from the ma-

Activity Attribute	% of Apps	Intent Flag	% of Apps
allowTaskReparenting="true"	0.80	NEW_TASK	79.42
launchMode="singleTask"	24.63	CLEAR_TOP	37.59
launchMode= other non-default modes	24.75	EXCLUDE_FROM_RECENTS	10.08
taskAffinity= own pck. name	2.36		
taskAffinity= other	1.60	**Events**	
excludeFromRecents="true"	12.45	onBackPressed()	62.00
alwaysRetainTaskState="true"	2.03	TaskStackBuilder	7.27
		startActivities()	5.47

Table 5: Percentage of 6.8 million market apps that use each of the "security-sensitive " task control knobs.

Task Affinity	# of Apps
com.android.settings	492

jor electronic commerce companies (e.g. Ebay, Amazon Shopping), etc. Similarly, in Figure 8(b), we show the statistics of a few app categories in which the vulnerable "service" apps and their functionality are most widely used, including the most famous photo editing tools, document editors, and file sharing services, etc.

6.2 Market-scale Study on the Use of Task Control Knobs

Due to the task hijacking threats, we have a pressing need for a defense strategy that can mitigate these threats while minimizing the side effects on Android multitasking features. To this end, it is important to first understand the current status about the use of Android multitasking features in real implementation, especially the use of "security-sensitive" task control knobs.

We analyzed 6.8 million Android apps from a variety of markets including Google Play and other 12 popular third-party app markets worldwide (e.g., from China). The analysis does not include duplicated apps (apps with same package name, public key certificate and app version number) distributed across multiple markets.

Table 5 shows the percentage of apps that use each of the task control knobs respectively. As shown in the table, a majority of the task control features are popular with app developers and users. For example, "singleTask" launch mode and NEW_TASK intent flag are used in a significant portion of apps to control the association of new activities with tasks. The flexibility of "back" button customization is widely adopted (as high as 62% apps). One reason is that the `onBackPressed()` callback function is heavily used by ad libs (which embed ads in app activities) for data clean-up before the activities are destroyed. In addition, a significant portion of activities can hide their associated tasks from the overview screen (by defining "excludeFromRecents" attribute or setting EXCLUDE_FROM_RECENTS intent flag).

Case Study - Task Affinity: Since task affinity can be abused in the most dreadful attacks, we are particularly interested in its use. 3.96% apps we studied explicitly declare task affinity. A considerable portion (1.6% of all apps) set their activities' taskAffinity string without containing their own package names. It means that, if there are task affinity conflicts, these 1.6% apps (totally 109 thousand apps) may interfere with the multitasking behaviors of one another. They may even affect other apps if the task affinity attributes are intentionally set to the package name of other apps (recall that the taskAffinity string can be set arbitrarily). We are especially interested in the latter case, and in our analysis, we find a total of 3293 apps of this kind. Table 6 lists the top package names designated as task affinity by these apps.

By reverse engineering a number of these apps, we find that intentionally setting the task affinity as another app is particularly useful in a class of "plug-in" apps, i.e. apps that provide complementary features to existing (and usually popular) apps just like a web browser's plug-ins (except that here the "plug-in" itself is implemented in a separate app). By being in the same task with the popular app, the "plug-in" app can change normal user experience and fulfill its feature functionality in the context of the app it serves. For example, an phone call recorder app namely FonTel can display an array of buttons on screen whenever there is a phone call, letting users to control phone call recording. The control buttons are contained in an mostly transparent activity. By setting the task affinity of the activity to `com.android.phone`, it can be pushed on top of the Android telephony task when a phone call occurs, such that users can access both the recording control buttons and telephony activity at the same time.

In summary, despite the security risks, Android multitasking features are popular with developers and even become indispensable to the normal functions of a significant number of apps that provide favorable features.

7 Defense Discussion

Given the pervasive use of the "security-sensative" task control features, simply disabling these features would greatly hurt app functions and user experience. Mitigating the task hijacking threats become a trade-off between app security and multitasking features.

7.1 Detection in Application Review

Existing app vetting processes such as Bouncer [31] may conduct a inspection over the "sensitive" task control knobs, a light-weight defense strategy without significantly affecting existing multitasking features.

However, specifying a guideline balancing the security/feature trade-off is non-trivial. For example, a tentative guideline could be: `taskAffinity` attribute should be specified in a strict format, e.g., with app package name followed by developer-defined affinity name (now task affinity can be any string); and the task affinity should not contain any other app's package name, except that the two apps are from the same developer. This effectively eliminates a big portion of hijacking state transitions where a malicious activity specifies the victim app as its preferred affinity. However, this rule also restricts useful features and contradicts with an important principle of Android multitasking design - give an activity the freedom to live in its preferred task even though they are from different apps. This contradiction cannot be solved by app review alone in this case. We need system support together with app review to achieve a good balance of security/feature trade-off.

Moreover, detecting problematic events can be sometimes difficult for the app review. For instance, one could confine the behaviors in `onBackPressed()`, preventing it from generating potential hijacking transition event. However, discovering all possible program behaviors using static analysis is an undecidable problem. A skillful attacker can replace class methods (`onBackPressed()` method in `Activity` class) with another method by changing Dalvik internals using native code during runtime, and static analysis does not know this by simply looking at the original `onBackPressed()` method. Dynamic analysis is of little help as well since this behavior can be triggered only after passing the app review.

As a result, completely mitigating task hijacking risks and without affecting existing features in app review remains challenging.

7.2 Secure Task Management

An alternative approach involves security enhancement to the task management mechanism of Android system.

A more secure task management could introduce additional security guides or logic, which draws developers' awareness of the security risk and limits the attacker surface. Take the above task affinity for example, an additional boolean attribute can be introduced for each app to decide if it allows the activities from other apps to have the same affinity as the app. If the boolean is "false" (also by default), the system would not unconditionally relocate the "alien" activities to the app's task or vice versa, even though the "alien" activities declare to have the same task affinity as the app. Likewise, a finer-grained boolean attribute can be further employed for `allowParentReparenting` attribute - determining if to allow "alien" activities to be re-parented to the app's task (even though defining the same task affinity is permitted). For other "security-sensative" features, we suggest first consider the same approach. Considering the serious security hazards that can be prevented, it is well worth of making such changes. At the very least, enhanced security scheme like this has to be applied to assure the security of the most privileged system apps.

Completely defeating task hijacking is not easy. As we have discussed in the last section, it is difficult to identify the exact behavior of pressing "back" in an activity during app review phase. For these popular and security-sensitive features, more powerful runtime monitoring mechanism is required to fully mitigate task hijacking threats.

In summary, we advocate future support for security guidance and/or mechanism, which can protect Android apps from task hijacking threats and bring along a both secure and feature-rich multitasking environment for Android users and developers.

8 Related Work

GUI security : GUI security has been extensively studied in traditional desktop and browser environments [14, 29], e,g., UI spoofing [9], clickjacking [3, 17], etc. Android, on the other hand, is unique in the design of its GUI sub-systems. It has been shown that the GUI confidentiality in Android can be breached by stealthily taking screen shots due to adb flaws [22], via embedded malicious UIs [28, 24], or through side channels, e.g. shared-memory side channel [8] or reading device sensors information [25, 34]. In contrast to existing work, this paper focuses on the fundamental design flaws of the task management mechanism (supported by the AMS), the control center that organizes and manages all existing UI components in the Android system.

Android Vulnerability: The security threats in the inter-component communication (ICC) has been widely studied [13, 23, 10, 20, 32]. Moreover, there has been considerable prior work on emerging Android vulnerabilities and their mitigation measures in many aspects [38, 40, 18, 33, 27, 7, 30, 15, 21]. However, the critical Android multitasking mechanism and the feature provider, the AMS, have not been deeply studied before. This paper fills in this gap by systematically studying the Android multitasking and the security implications of this design.

Android Malware: Many prior efforts focus on large-scale detection of malicious or high-risk Android apps [39], e.g., fingerprinting or heuristic-based methods [26, 41, 16], malware classification based on machine learning techniques [37, 6], and in-depth data flow analysis for app behaviors [11, 35, 36, 6]. The attack surface discovered in this paper can be easily employed by attackers to create a wide spectrum of new malwares, as discussed in Section 5. We report our threat assessment based on over 6 million market apps and provide defense suggestions in order to prevent the outburst of task hijacking threats in advance.

9 Conclusion

This paper systematically investigated the security implications of Android task design and task management mechanism. We discover a plethora of task hijacking opportunities for attackers to launch different attacks that may cause serious security consequences. We find that these security hazards can affect all recent versions of Android. Most of our proof-of-concept attacks are able to attack all installed apps including the most privileged system apps. We analyzed over 6.8 million apps and found task hijacking risk prevalent. We notified the Android team about these issues and we discussed possible mitigation techniques.

Cashtags: Protecting the Input and Display of Sensitive Data

Michael Mitchell, An-I Andy Wang

Peter Reiher
University of California, Los Angeles

Abstract

Mobile computing is the new norm. As people feel increasingly comfortable computing in public places such as coffee shops and transportation hubs, the threat of exposing sensitive information increases. While solutions exist to guard the communication channels used by mobile devices, the visual channel remains largely open. Shoulder surfing is becoming a viable threat in a world where users are often surrounded by high-power cameras, and sensitive information can be extracted from images using only modest computing power.

In response, we present Cashtags: a system to defend against attacks on mobile devices based on visual observations. The system allows users to safely access pieces of sensitive information in public by intercepting and replacing sensitive data elements with non-sensitive data elements before they are displayed on the screen. In addition, the system provides a means of computing with sensitive data in a non-observable way, while maintaining full functionality and legacy compatibility across applications.

1. Introduction

Shoulder surfing has become a concern in the context of mobile computing. As mobile devices become increasingly capable, people are able to access a much richer set of applications in public places such as coffee shops and public transportation hubs. Inadvertently, users risk exposing sensitive information to bystanders through the screen display. Such information exposure can increase the risk of personal, fiscal, and criminal identity theft. Exposing trade or governmental secrets can lead to business losses, government espionage, and other forms of cyber terrorism [12, 13, 14].

This problem is exacerbated by the ubiquity of surveillance and high-power cameras on mobile devices such as smartphones and on emerging wearable computing devices such as Google Glass [57]. Additionally, the trend toward multicore machines, GPUs, and cloud computing makes computing cycles more accessible and affordable for criminals or even seasoned hobbyists to extract sensitive information via off-the-shelf visual analysis tools [58].

This paper presents the design, implementation, and evaluation of Cashtags, a system that defends against shoulder surfing threats. With Cashtags, sensitive information will be masked with user-defined aliases, and a user can use these aliases to compute in public. Our system is compatible with legacy features such as auto correct, and our deployment model requires no changes to applications and the underlying firmware, with a performance overhead of less than 3%.

1.1 The shoulder-surfing threat

The threat of exposing sensitive information on screen to bystanders is real. In a recent study of IT professionals, 85% of those surveyed admitted seeing unauthorized sensitive on-screen data, and 82% admitted that their own sensitive on-screen data could be viewed by unauthorized personnel at times [1]. These results are consistent with other surveys indicating that 76% of the respondents were concerned about people observing their screens [2], while 80% admitted that they have attempted to shoulder surf the screen of a stranger [3].

The shoulder-surfing threat is worsening, as mobile devices are replacing desktop computers. More devices are mobile (over 73% of annual technical device purchases [4]) and the world's mobile worker population will reach 1.3 billion by 2015 [5]. More than 80% of U.S. employees continues working after leaving the office [6], and 67% regularly access sensitive data at unsafe locations [2]. Forty-four percent of organizations do not have any policy addressing these threats [1]. Advances in screen technology further increase the risk of exposure, with many new tablets claiming near 180-degree screen viewing angles [8].

1.2 The dangers are everywhere

Observation-based attacks to obtain displayed sensitive information can come in many forms. There are more than 3 billion camera-enabled phones in circulation [4]. Some of these devices can capture images at 40 megapixels of resolution and over 10 times optical zoom [7]. High-resolution and often insecure "security" cameras are abundant in major metropolitan areas. For example, the average resident of London is captured on CCTV over 300 times per day [9]. Finally, sensitive data can be captured by simple human sight.

Observation-based attacks can be complex. Partial images can be merged, sharpened, and reconstructed, even from reflections. Offline and cloud-based optical character recognition (OCR) solutions have only a small percentage of recognition errors, even on inexpensive low-end devices [10].

Personal information exposure can also enable other attacks, such as social engineering, phishing, and other personal identity theft threats.

1.3 The consequences can be severe

Observation-based leaks of sensitive information have led to significant personal and business losses. Recently, an S&P 500 company's profit forecasts were leaked as a result of visual data exposure [4]. In a different case, government documents were leaked when a train passenger photographed sensitive data from a senior officer's computer screen [11]. Security cameras captured the private details of Bank of America clients through windows [12]. Sensitive information relating to Prince William was captured and published because of a screen exposure to a bystander [13].

The risk of loss from shoulder surfing is also hurting business productivity. Figures show that 57% of people have stopped working in a public place due to privacy concerns and 70% believe their productivity would increase if others could not see their screen [2].

1.4 Current solutions

Techniques are available to limit the visual exposure of sensitive information. However, the focus of these systems has been limited to password entries [22, 23, 24, 25, 33, 34, 35]. Once the user has been successfully authenticated, all of the accessed sensitive information is displayed in full view. Clearly, such measures are insufficient for general computing in public when the need to access sensitive information arises. Unfortunately, many techniques used to prevent visual password leaks cannot be readily generalized beyond password protection, which motivates our work.

2. Cashtags

We present Cashtags, a system that defends against observation-based attacks. The system allows a user to access sensitive information in public without the fear of leaking sensitive information through the screen.

2.1 Threat model

We define the threat model as passive, observation-based attacks (e.g., captured video or physical observation by a human). We assume the attacker can observe both the screen of the user as well as any touch sequences the user may make on the screen, physical buttons, or keyboards. We also assume the absence of an active attack; the observer cannot directly influence the user in any way.

Although sensitive information can be presented in many forms, we focus on textual information to demonstrate the feasibility of our framework. Protecting sensitive information in other forms (e.g., images and bitmaps) will be the subject of future work.

2.2 User model

Conceptually, Cashtags is configured with a user-defined list of sensitive data items (Table 2), each with a respective Cashtags alias or a cashtag (e.g., `$visa` to represent a 16-digit credit-card number). Whenever the sensitive term would be displayed on the screen, the system displays the predefined alias instead (Fig 2.1).

Type	Actual	Alias
Name	John Smith	`$name`
Email	jsmith@gmail.com	`$email`
Username	Jsmith1	`$user`
Password	p@ssw0rd	`$pass`
Street Address	123 Main St.	`$addr`
Phone number	555-111-2222	`$phone`
Birthday	1/1/85	`$bday`
SSN	111-22-3333	`$ssn`
Credit Card	4321 5678 9012 1234	`$visa`
Account number	123456789	`$acct`

Credit Card: $visa
Bank Acct: $bank

Fig. 2.1: On-screen sensitive data (left) and data protected by masking with cashtag aliases (right).

At the point at which the sensitive data would be used internally by the device or app, cashtags will be replaced by their represented sensitive data items, allowing whatever login, communication, computation, transmission, or upload to proceed normally.

Cashtags also provides secure data input. A user can type in a cashtag in place of the sensitive term, permitting complex data-sensitive tasks, such as filling out a reward-card application without risk of observation from a bystander. In addition, cashtags are easier to remember than the actual sensitive data term. For example, `$visa` can be used as a shortcut for entering a 16-digit credit card number.

Users can interact with Cashtags by entering data in either alias or actual form. If the user enters the actual term, it will be converted into its corresponding alias once the full term is entered. This has the potential to inadvertently expose partial private data, an attacker could potentially see all but the last character input. In practice, auto completion is likely to expand the sensitive information within the first few characters and display it in the alias form. Entering data into the system in alias form ensures that no such partial information exposure can occur during input and is the best option to maximize protection.

2.3 Compared to password managers

The user model of Cashtags is similar to that of a password manager. To add an entry to a password manager, a user is required to key in the username and password pair. Typically, subsequent usage of the stored password involves only selecting the respective account pre-populated with the stored password. Therefore, an observer cannot see the keyed-in sequence for passwords. Similarly, Cashtags requires the user to pre-configure the system by first entering the sensitive term to be protected and the corresponding alias to represent the term. When a sensitive term is displayed, our system replaces the sensitive term with its alias without user intervention. To enter a sensitive term, the user can enter the alias, and our system will translate it into the sensitive term prior to being processed by the underlying apps.

While a password-manager-like user model provides a familiar interface, it also shares a similar threat vector of a centralized target and weakened protection in the case of physical theft. However, overcoming the shortcomings of password managers is orthogonal to the focus of this research and threat model. As research in bettering password managers advances, we can apply those techniques to enhance our system.

2.4 Design overview

Although conceptually simple, Cashtags addresses a number of major design points.

Intercepting sensitive data: Cashtags intercepts sensitive data items as they are sent to the display. For apps, this is at their common textual rendering library routines, and for users, this is at the routines that handle software keyboards and physical devices (e.g., USB and wireless input devices).

User interface: Users can type in cashtags instead of sensitive data items to compute in public. This interface allows cashtags to be compatible with existing tools such as auto completion, spellcheckers, and cut and paste. Thus, users can enter the first few characters and auto-complete the full cashtag.

Accessing sensitive data: User-entered cashtags are converted internally to the sensitive data items before the apps access the data. This way, Cashtags will not break applications due to unanticipated input formats.

Variants of data formats: Cashtags can leverage existing libraries to match sensitive data items represented in different formats (e.g., John Smith vs. John Q. Smith).

Development and deployment models: Cashtags uses a code-injection framework. This approach avoids modifying individual apps and the firmware, while altering the behavior of the overall system to incorporate Cashtags at runtime.

Cashtag repository: The mapping of cashtags to sensitive data items is stored in a password-protected repository.

3. Cashtags Design

This section will detail each Cashtags design point.

3.1 Observation-resistant approaches

We considered screen-level-masking and data-entry-tagging system design spaces prior to using the current keyword-oriented design. While all of these approaches can prevent sensitive information from being displayed, the main differences are the interception granularity and the portability of the underlying mechanisms.

Screen-level masking: One coarse-grained approach is to mask the full application window or screen regions when encountering sensitive information [61, 62]. While this approach prevents information leakage, it also prevents the user from computing using the sensitive information. For example, when encountering

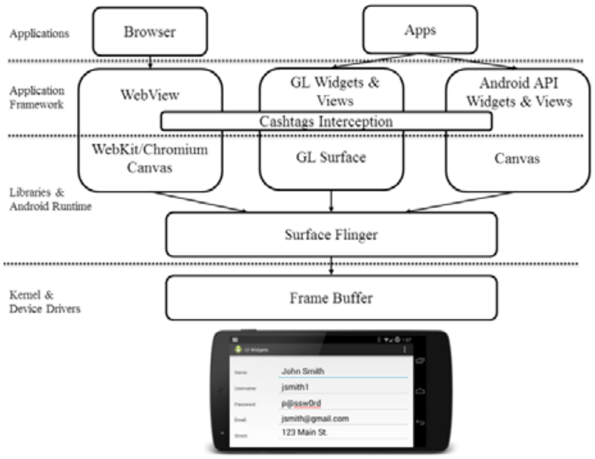

Fig. 3.1. Display data paths for the Android platform.

an online purchase screen, the entire screen could be blurred due to sensitive information, making it unusable.

Tag-based approach: A tag-based approach requires the user to predefine the data elements as sensitive. These data elements are then tracked as they propagate through the system [16]. If a tracked data element is to be displayed on the screen, the rendering is intercepted, and the tracked data element is replaced with its corresponding alias.

This approach requires a significant system modification to support this granularity of data tracking, making it less deployable. In addition, the system resources and required accounting to track the data result in significant processing overhead incurred by the system.

Keyword-based approach: Another approach is to utilize keywords and perform pattern matching on on-screen text elements. Like the tag-based approach, this option works at the individual data element or word granularity. It also has the requirement that the sensitive data element be specified to the system prior to the point of screen rendering and subsequent visual data exposure.

The primary difference, however, is the method in which the sensitive data is identified. Rather than tracking sensitive data as it propagates through the system, this method parses data fields prior to the screen display. If a predefined sensitive element is matched, it is replaced with its alias before being rendered to the screen. We chose this approach because it achieves word granularity protection without the tag-based overhead and deployment issues.

3.2 Where to intercept sensitive data

To decide where to intercept sensitive data, we first need to understand how sensitive data traverses from apps to the screen through various display data paths. Fig. 3.1 shows the display data paths under the Android application development platform. Although different, the display data paths of iOS and Windows generally have one-to-one mappings of the components.

Window manager: A typical app displays information by invoking some user-level display or graphics library routines. Various routines eventually invoke routines in the underlying window management system (e.g., Surface Flinger for Android) before information is processed by the OS and displayed on the screen.

Arguably, the window management system might seem to be a single point at which all sensitive data can be captured. Unfortunately, by the time sensitive information arrives there, some sensitive information may have been translated into bitmaps. While OCR techniques can be used to extract sensitive text, they are still too heavyweight to be used in the display data path, which is critical for user interactions. Replacing sensitive bitmaps with non-sensitive ones would pose other obstacles we would like to avoid.

Applications: Another extreme is to intercept it at the app level, where the sensitive information is introduced. Potentially, we can modify a few popular, general-purpose apps (e.g., browsers) and capture most of the sensitive information. However, such solutions may tie users to specific tools. In addition, statistics show that specific app usage accounts for 86% of user time, trending away from general-purpose browsers [56]. Thus, we would need to initially modify more apps and track their updates to achieve a good coverage.

Library routines: Thus, an intermediary ground is to intercept sensitive data within a few key display and graphics library routines.

3.3 User interface

Early design: In our early user-interface design, users-defined English-like aliases in a repository to indicate sensitive data items that they wish not to be shown (e.g., use John to represent Joe). To discern these aliases when processing, we used an alternative input channel to mark them. This initial design proved problematic.

Our initial prototype was a software keyboard app with elevated privilege to offer input across applications. This implementation would be easier to port across platforms, deploy, install, and update. However, changing keyboards in the midst of a stream of input is cumbersome in practice. This method also interacted poorly with legacy swipe-based inputs, emoticon support, auto correction, and custom dictionaries.

Further, we would need to replace the default keyboard with ours, and provide ways to switch modes between normal and sensitive entries (e.g., a screen tapping sequence). By doing so, we could retain legacy functionalities such as auto correction. On the other hand, the development effort of this approach would have been much higher, and novice users might have trouble replacing the default keyboard.

Direct input of cashtags: While there are other input interface options, the need to switch input modes to allow aliases to appear as normal text seemed superfluous (e.g., using "visa" to represent the 16-digit credit card number).

Thus, we explored the use of cashtags, where aliases are prepended with a `$` sign, to represent sensitive information. By doing so, a user can directly enter cashtags, and the mode change is encoded in the cashtag alias (e.g., use `$fname` to represent John and `$gmail` to represent jsmith@gmail.com). This method can leverage the existing custom dictionary for auto completion, which makes it easier for the user to remember and input the cashtags. This method can also utilize standard application-level development techniques, opening up the range of supported device platforms and decreasing development and installation efforts.

Direct input of sensitive information: Another supported alternative input mechanism (with some information leak) is for a user to enter the initial characters of a sensitive data item. As soon as the auto completion detects that, Jo is likely to mean Joe, for example, it will be automatically masked with `$john`. The user then can choose `$john` and proceed.

Additional Cashtags semantics: Recursion is supported, so we can use `$signature` to represent `$fname $lname $gmail`, which in turn maps to John Smith, jsmith@gmail.com. We disallow circular cashtags mappings (e.g., use `$john` to represent `$joe`, and `$joe` to represent `$john`).

3.4 Accessing sensitive information

One design issue addresses converting cashtags back to the sensitive data for access by apps. Normally, when an app wants to access the sensitive information and to send it back to the hosting server, we must make sure that the conversion is performed prior to access, so that the app would never cache, store, or transmit the cashtags. The concern is that cashtags may break an app due to the violation of the type or formatting constraints.

We also must make sure that the cashtags are actually entered by the user, not just pre-populated by the app. Otherwise, a malicious app can extract sensitive information just by displaying cashtags.

There are certain exceptions where it is desirable to operate directly on cashtags instead of the sensitive information. For example, the auto-completion task will auto complete cashtags (`$fn` to `$fname`), not the sensitive information it represents. By doing so, the handling of text span issues is simplified because cashtags usually differ in text lengths when compared to the sensitive information they represent.

3.5 Variants of data formats

Sensitive data may be represented in multiple formats. For example, names can be represented as combinations of first, last, and middle initials (e.g., John Smith; John Q. Smith). Accounts and social security numbers can be represented using different spacing and/or hyphenation schemes (e.g., 123456789; 123-45-6789). Fortunately, we can leverage existing regular expression libraries (`java.util.regex.*`) to perform such matching.

Another issue involves the type restriction of the input field. For example, a number field (e.g., SSN) may prevent the use of cashtags (`$ssn`). To circumvent these restrictions, we allow users to define special aliases (e.g., 000-00-0000) to represent certain types of sensitive information (e.g., social security numbers).

3.6 Deployment and development models

To avoid modifying individual applications, we considered two options to provide system-level changes: (1) custom system firmware images (ROMs) and (2) code-injection frameworks (e.g., Android Xposed)

By utilizing a custom system firmware image, complete control of the operating system is provided. (This approach assumes that the full source is available.) In addition, ROM-based solutions can offer a more unified testing environment. However, the changes would be restricted to device-specific builds. Only hardware for which the source is built would have access to the modified system. This also limits user preference by restricting use only for a specific system image. It would additionally require regular maintenance, and it would break vendor over-the-air update functionality.

Instead, we used a code-injection framework, which overrides library routines and incorporates our framework into execution prior to the starting of apps.

Code injection offers streamlined development, as standard application development tools can be used. In addition, these modules can be distributed and deployed as applications. Because code injection only relies on the underlying system using the same set of libraries, the resulting system is more portable and less coupled to versions and configurations of system firmware.

The installation and use of the code-injection framework requires root access to the device. This is, however, not a firm requirement and exists only for this prototype; Vendors and OEMs can incorporate Cashtags into system firmware providing the same functionality without exposing root. This deployment model is advisable to further enhance security for a production system.

3.7 Cashtags app and repository

Cashtags aliases and sensitive data items are maintained in a repository. The Cashtags app coordinates the interactions between various apps and the repository. The app also provides password-protected access to add, edit, remove, import, and export sensitive terms and corresponding cashtags.

Cashtags provides per-application blacklisting, excluding specific applications from being code-injected (or activated) with cashtag-replacement code. For example, the cashtag repository itself must be excluded due to circular dependencies. To illustrate, suppose a cashtag entry maps `$fname` to Joe. If Cashtags is enabled, the screen will show that `$fname` is mapped to `$fname`; when saved, Joe will be mapped to Joe. Apps with a low risk to reveal sensitive information can be excluded for performance issues (e.g., games, application launchers, home screens).

4. Implementation

We prototyped Cashtags on the open-source Android platform. Our code-injection framework allows Cashtags to operate on any Android device with the same display and graphics libraries and root access. This section will first detail the Android display data paths, explain the code-injection framework, and discuss how various display data paths are intercepted and how cashtags are stored.

4.1 Android display elements

Fig 3.1 has shown a top-level view of the various ways Android apps and browsers display information on the screen. This section provides further background on Android terminologies. Corresponding terminologies for text widgets on Apple and Windows devices are listed in Table 4.

	Android	Apple	Windows
Text Labels	TextView	UITextView	TextBlock
OpenGL Text	GLES20 Canvas	GLKView	Direct3D
Editable Text	TextView	UITextView	TextBlock
Webapp Text	WebView	UIWebView	WebView
Browser/ WebView	WebView	UIWebView	WebView

Table 4: Widget terminologies on Android, Apple, and Windows platforms.

The Android display is composed of views, layouts, and widgets. `View` is the base class for all on-screen user interface components.

Widgets: The term widget is used to describe any graphic on-screen element. Different widgets can be used to display static text labels (e.g., `TextView`), user input boxes (e.g., `EditText`), controls (e.g., `Buttons`), and other media (e.g., `ImageView`).

`Views` are organized into `ViewGroups`, the base class for all screen layouts. `Layouts` are arrangements of views within vertical or horizontal aligned containers (e.g., `LinearLayout`), or arranged relative to other views. Nesting of `ViewGroups` and `Layouts` allows complex custom composites to be defined.

Collectively, this tree of layouts and widgets forms a view hierarchy. When the screen is drawn, the view hierarchy is converted from logical interface components into a screen bitmap. Fig. 4.1 shows a simple user input form and its composition of various widgets and layouts.

Text rendering: Text can be rendered on the screen through several mechanisms (Fig 3.1), most frequently the `TextView` widget. An `EditText` is an extension of the `TextView` that provides an interface for text input from the user via the on-screen software keyboard, hardware keypads, voice input, and gestures. These widgets can be pre-filled with text by the app internally or through suggestion or auto-correction interfaces.

Text can also be rendered on screen via `OpenGL Canvas`, other graphic rendering libraries, browser rendering engines, and other methods, many of which do not inherit from the base `TextView` widget. This plethora of methods complicates practical capture of all possible ways text could get onto the screen.

Fig. 4.1. Decomposition of on-screen views, layouts, and widgets of a simple app input form.

4.2 Android code-injection framework

Cashtags uses the Android Xposed code-injection framework. The development cycle is accelerated by short-circuiting the need to perform complete device firmware rebuilds from scratch.

Underneath the hood, whenever an app is started, Android forks off a new virtual machine. The Android Xposed framework allows overriding library routines to be inserted into the Java `classpath`, prior to the execution of the new virtual machines. Thus, the overall system behavior is altered without modifying either the apps or the underlying firmware.

Individual class methods can be *hooked*, allowing injected code to be executed prior to, following the completion of, or in place of the base-method calls. Private or protected member fields and functions can also be accessed and modified, and additional fields or functions can be added to the base class or object granularity.

4.3 Sensitive data intercepting points

With the background of the Android display data paths (Fig. 3.1) and the code-injection framework, we can determine where and how to intercept sensitive information. Since all text-displaying screen widgets are descendants of the `TextView` class (Fig. 4.2), we only needed to hook `TextView` (`android.widget.TextView`) to intercept all widgets containing static sensitive text. For user input, we hooked `EditText` (`android.widget.EditText`) to capture sensitive data or cashtags entered via on-screen software keyboards, (integrated, plugged, or wirelessly connected) hardware keypads, voice input, and gestures. For display through the OpenGL libraries, we intercepted GLText (`android.view.GLES20Canvas`). For browsers, we intercepted `WebView` (`android.WebKit/WebView`).

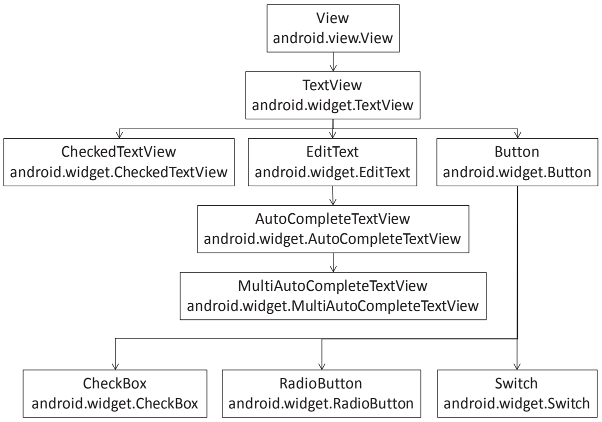

Fig. 4.2. Simplified inheritance hierarchy of Android on-screen views and widgets.

4.4 `TextView`

Fig. 4.3 shows a simplified version of the implementation of the `TextView` widget in the Android API, present since version 1 of the Android SDK. The `getText`() and `setText`() methods of the `TextViews` are hooked and modified (the `setText`() method in `TextView` is inherited by `EditText`, to be detailed later). We also added `mAlias` to map the sensitive text to the corresponding cashtag.

4.5 `EditText`

In addition to the functionality inherited from `TextView`, `EditText` must also handle additional actions that can be performed by the user, app, or system to modify on-screen text.

```
public class TextView extends View
  implements ViewTreeObserver.
  OnPreDrawListener {
    ...
    private CharSequence mText;
    private CharSequence mAlias:
    ...
    public CharSequence getText() {
      return mText;
    }
    ...
    private void setText(CharSequence
     text, BufferType type, boolean
     notifyBefore, int oldlen) {
      ...
      mBufferType = type;
      mText = text;
    }
    ...
  }
```

Fig. 4.3. Simplified TextView implementation. Bolded functions getText() and setText() are hooked and modified. An additional private field mAlias is added for mapping to a displayed cashtag, if applicable.

For cases where the system or app has pre-populated a text box with input, the TextView injection handles the cashtag replacement. Since the EditText class extends from the TextView base class, this functionality is provided through inheritance. This is also the case for nearly every other on-screen text widget, which also descend from the base TextView.

Fig. 4.4 and Fig. 4.5 show how Cashtags interacts with TextView and EditText objects. When these getText() and setText() methods are called by the app or through system processes, such as auto correct or to be rendered on screen, Cashtags will determine whether to return the alias or the sensitive data, depending on the caller.

User input can be entered through software keyboards or through physical devices. In both cases, Cashtags operates similar to, and through the same interface, as the auto-correct service. This TextWatcher (android.text.TextWatcher) interface handles events when on-screen text has been modified. EditTexts internally maintain an array of these TextWatcher event handlers. Cashtags, as one of these handlers, is activated after any character is modified within the text field.

Cashtags

Fig. 4.4. Interactions among Cashtags, TextView, and other software components. getText() returns either the cashtag or actual text depending upon the service making the request.

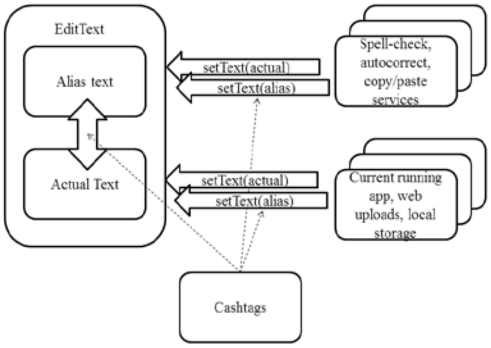

Fig. 4.5. Interactions among Cashtags, EditText, and other software components. setText() returns either the cashtag or actual text depending upon the service making the request.

This functionality is also achieved through the view OnFocusChangeListener (android.view.OnFocusChangeListener). This event handler works at the granularity of the full text field rather than the individual characters of the TextWatcher. This is more efficient, since the text replacement only occurs once per text field. It does, however, risk additional on-screen exposure of sensitive information, since direct input of actual sensitive terms would remain on-screen as long as the cursor remains in that text field. The input of the cashtag alias does not have this risk and further reduces any partial exposure during term input.

In both cases, the constructor of the EditText class is hooked and the corresponding OnFocusChangeListener or TextWatcher object is attached at runtime. User settings allow activation of either or both interception methods.

4.6 `OpenGLES Canvas`

The implementation for `OpenGLES Canvas` is similar to the base `TextView` only with different parameter types. The only distinction is that no accompanying `getText`() equivalent is present in this object, so no manipulation is necessary beyond `drawText`().

4.7 `WebView`

Unlike the previous screen widgets, the relevant interception points for screen rendering for WebKit or Chromium browser engines are all below the accessible Android/Java layer. Thus, they cannot be code-injected through the same mechanisms used for previous screen widget cases. We attempted custom compilations of the browser engines with similar widget display interception, but abandoned the effort for portability concerns.

Instead, `WebView` interception is handled similarly to a web browser plug-in. This decision maintains the portability goal of the system design.

Cashtags intercepts web rendering immediately before it is first displayed on-screen. The HTML is pre-processed with JavaScript to extract the DOM. Cashtags iterates over the text nodes and makes the appropriate text replacements of sensitive data to corresponding cashtags.

Other options were explored using specific browser and proxy requests through the web server. However, all apps that use cross-platform frameworks (PhoneGap, Apache Cordova, JQuery Mobile, etc.) run locally and could not easily be piped though this service. For this reason, we favored the plug-in approach over other alternatives.

4.8 Cashtags repository

Sensitive terms are stored as encrypted `SharedPreference` key/value pairs, which uses the AES encryption from the Java Cryptography Architecture (`javax.crypto.*`). This structure is accessed by enabled apps through the `XposedSharedPreference` interface.

5. Evaluation Methods

Cashtags was evaluated for how well the intercepted points prevent specified information from being displayed on the screen, verified by screen captures and OCR processing. This coverage was measured by enumerating common paths sensitive text can traverse to the screen. We also evaluated user input through popular apps, making sure that the cashtags reverted to the sensitive data items when accessed by the apps. Finally, we evaluated the performance overhead of Cashtags.

5.1 API coverage evaluation

For Android API coverage, we focus on the `TextView` and `EditText` display data paths, which account for 86% of usage hours for mobile devices [56], though Cashtags can also handle the remaining 14% of browser-based access. The selected sensitive information (Table 2) is based on the Personally Identifiable Information (PII) specified by the U.S. government and NIST standards [59]. We enumerate all combinations of the input phrase type (e.g., numbers, strings), case sensitivity, common widget, layout, theme, and lifecycle for these data paths. Each combination is used to demonstrate that the PII terms are not displayed on the screen from the app, as user input of the sensitive data, or as user input of the cashtag alias. In all three cases, we also demonstrate that the PII term is correctly returned from Cashtags when used by the app.

This totals 1,728 tests for the static text widgets and inputs, with 526 additional cases for widgets that permit user input via software keyboards as well as physical devices (on-board hardware, USB, or wireless input devices). Table 5.1 shows the full list of configurations.

For each combination, the Android Debug Bridge [60] and UIautomator tool [36] are used to capture the device layout view hierarchies and screenshots. The contents of the actual and cashtag fields are compared for conversion correctness. The device screenshot is processed using Tessseract OCR [21] to confirm if the actual PII term has been properly masked on the screen.

For each combination, we also demonstrate that both text input as a sensitive term and cashtag are correctly converted to the sensitive term when accessed by the app. Since the access of sensitive data within the app normally involves remote actions, we also emulated this scenario and performed remote verification. Once screen processing is completed, the app accesses the text fields and uploads them to Google Sheets/Form. The uploaded sensitive items and cashtag submissions are compared for accuracy based on expected values.

Our results show that Cashtags behaves correctly for all test cases. For each test case, Cashtags identified input containing sensitive data in both the actual and cashtag form, prevented the display on the screen of the sensitive term, and determined correctly when to convert back to the sensitive data.

Input phrase type (4):	Alphabetic phrase, numeric phrase, alphanumeric phrase, Alphanumeric with symbols.
Phrase case (2):	Case Sensitive Text, Case In-sensitive Text
Widget type (9):	`TextView` (`android.widget.TextView`), `CheckedTextView` (`android.widget.CheckedTextView`), `Button` (`android.widget.Button`), `CheckBox` (`android.widget.CheckBox`), `RadioButton` (`android.widget.RadioButton`), `Switch` (`android.widget.Switch`), `EditText` (`android.widget.EditText`), `AutoCompleteTextView` (`android.widget.AutoCompleteTextView`), `MultiAutoCompleteTextView` (`android.widget.MultiAutoCompleteTextView`)
Layout type (2):	`LinearLayout` (`android.widget.LinearLayout`), `RelativeLayout` (`android.widget. RelativeLayout`)
Theme type (3):	Default theme, System theme, User-defined theme.
Generation method (2):	Static XML, Dynamic Java
Lifecycle type (2):	Activity-based lifecycle, Fragment-based lifecycle

Table 5.1: Android API test combinations.

5.2 App coverage evaluation

The Google Play market has more than one million of published applications accessible by thousands of different hardware devices [70], making the enumeration of all possible users, devices, and application scenarios infeasible. Thus, we chose a representative subset of popular apps to demonstrate coverage of Cashtags. Categorically, these application types are email, messaging, social media, cloud and local storage, office, and finance. Table 5.2 shows the selected apps, arranged according to these categories. These apps were selected using download metrics from the Google Play marketplace, excluding games and utility apps for lack of relevance in terms of displaying sensitive data on screen. The presence of a form of external verification was also used in the application selection. Apps typically bundled with mobile devices were also tested for correct operation.

Email: AOSP Email, Gmail, K9 Mail:	User reads an email containing a sensitive term in its cashtag form. A Cashtags-enabled system should display the email with two instances of the cashtag. User composes an email with a sensitive term and its cashtag. Remote system not running Cashtags should display email with two sensitive term instances.
Messaging: Messaging, Hangouts, Snapchat:	User reads a message containing a sensitive term and cashtag. A Cashtags-enabled system should display the message containing two instances of the cashtag. User composes a message with a sensitive term and its cashtag. A remote system not running Cashtags should receive the message with two sensitive term instances.
Social: Facebook, Twitter, Google+:	User reads text with a sensitive term and its cashtag from a tweet/post/update. A Cashtags-enabled system should display the tweet/post/update with two instances of the cashtag. User composes a new tweet/post/update with a sensitive term and its cashtag. A remote system not running Cashtags should receive the tweet/post/update with two sensitive term instances.
Storage: Dropbox, MS OneDrive, File Manager:	User opens an existing file containing a sensitive term and its cashtag. A Cashtags-enabled system should display the file containing two instances of the cashtag. User creates a file with a sensitive term and its cashtag. A remote system not running Cashtags should display file with two sensitive term instances.
Office: GoogleDocs, MS Office, QuickOffice:	User reads a document containing a sensitive term and its cashtag. A Cashtags-enabled system should display the file with two instances of the cashtag. User creates a document containing a sensitive term and its cashtag. Remote system not running Cashtags should see two sensitive term instances.
Finance: Google Wallet, Paypal, Square:	User reads a document containing a sensitive term and its cashtag. Cashtag-enabled system should display the document with two instances of cashtag. User creates a document containing a sensitive term and its cashtag. A remote system not running Cashtag should see two sensitive term instances.

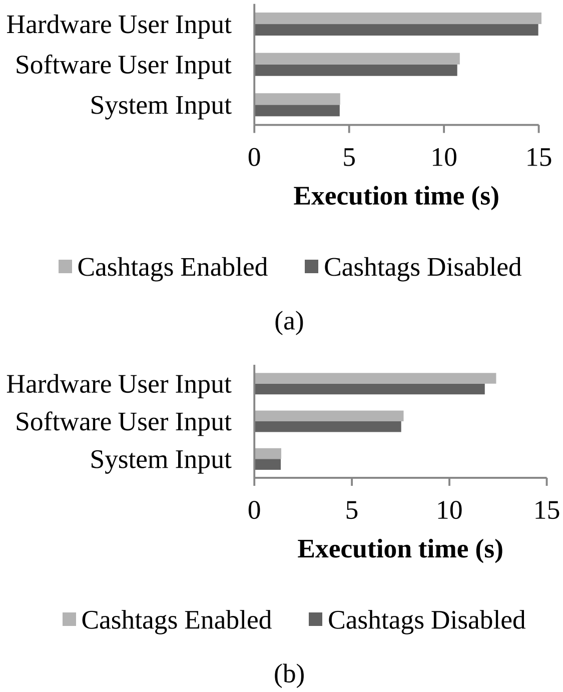
Table 5.2: Per-category app test tasks.

The operation performed on each is based on a commonly performed use case or task for each category. Table 5.2 shows the operation performed for each category and respective app.

Our results show that Cashtags behaves correctly for 97% of task and app combinations, except the MS Office Mobile tests. The reason is because of the custom View (`docRECanvasHost`) used for the primary user interaction, which is not a descendant of an `EditText`. Thus, our system does not intercept it. All of the other apps tested have user input through an `EditText`, or a custom class inheriting from an `EditText`. This exception, as well as other custom views could be made to work with Cashtags using case-specific handling for internal functions and parameters that map to the equivalent `EditText` functions.

5.3 Overhead

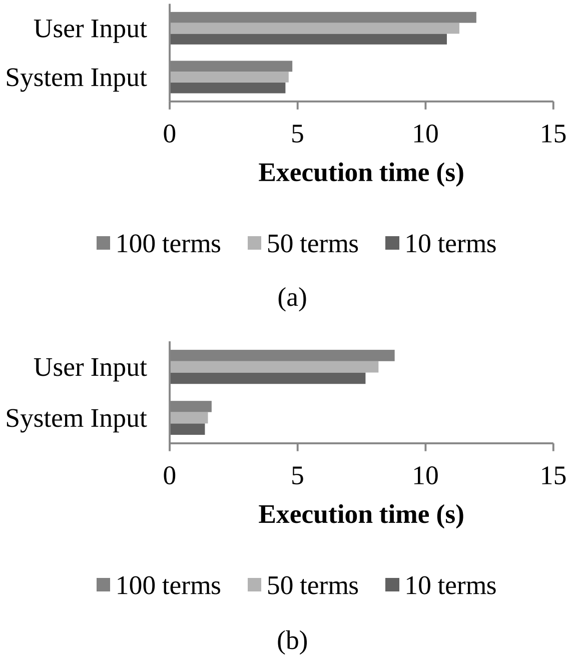
Regarding overhead, we measured the incremental lag Cashtags added to the system. We ran a modified version of the Android API coverage test (Section 5.1) with and without Cashtags enabled. The screenshots, layout hierarchy dumping, and all other non-essential automation elements were removed prior to the test execution. The test execution durations are compared, and the additional lag introduced by the system was calculated. This test was run with and without the remote data verification to determine the effects of network lags on our system overhead.



(a)

(b)

Fig. 5.1. Comparison of mean app task execution time with and without Cashtags enabled, using system, software and hardware text input (a) with and (b) without web request for tests. Hardware refers to input from physically or wirelessly connected hardware keyboard and software refers to input via on-screen software keyboard.



(a)

(b)

Fig. 5.2. Comparison of mean app task execution time with an increasing number of cashtag entries, using system and user inputs (a) with and (b) without web request for tests.

Fig. 5.1(a) shows the Cashtags system incurs an average 1.9% increase in application runtime. For tests including remote verification, Cashtags incurred an average of 1.1% increase over the baseline tests. For tests excluding the time consuming remote verification, Fig. 5.1(b) shows that Cashtags incurred an average of 2.6% over baseline. Therefore, the additional overhead of Cashtags would not be perceivable to the user.

Testing was repeated using 50 and 100 items, which is significantly more than the list of terms specified by PII. Fig. 5.2 show that the performance degrades linearly as the number of cashtags entries increases. However, we can easily replace the data structure to make the increase sublinear.

Cashtags is additionally evaluated for boot-time overhead. Changes to the Cashtags repository currently require a reboot to take full effect. While this operation is not in the critical path, the overhead is relevant. The results of the boot lag are shown in Fig. 5.3.

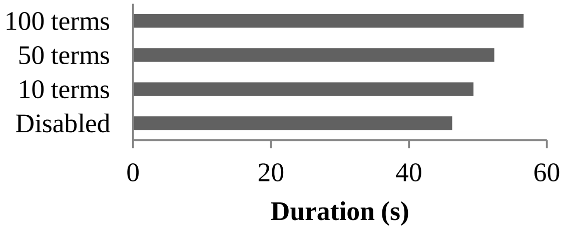


Fig. 5.3. Comparison of device startup times with varying number of cashtag entries and with system disabled.

5.4 Usability overhead

To demonstrate the usability of Cashtags, we calculated the configuration and usage overhead seen by a typical user working on typical data. We used common sensitive data elements with known character lengths (such as credit card numbers) as well as those for which published data on average term length was available (such as common names) [63, 64].

For other elements without known average length availability, we substituted a typical minimum accepted value. Table 5.3 shows the comparison of these fields against the suggested cashtag alias length.

In nearly every case, the cashtag alias is significantly shorter than the average length of the sensitive data element. On a keystroke count basis, the amortized effort of the initial configuration can be overcome with only two or three uses of the Cashtag alias. Longer names and emails require additional keystrokes for initial configuration but yield greater keystroke savings for each time the data element is entered. In addition, the aliases in the table are based on the suggested terms for ease of user recall; even shorter terms could be substituted to reduce additional data entry overhead.

5.5 Quantification of the time savings for an end user

The real efficiency savings for Cashtags is the ability to represent hard-to-recall terms (e.g., account numbers) with easy-to-recall aliases. The user simply assigns the sensitive data a memorable alias and can refer to them.

This also adds convenience when sensitive data changes. For example, consider the case of a stolen credit card. Once the replacement is issued, the user need only to update the underlying data element, continuing to use the alias without the need to memorize a new number. In some cases of personal information change, the defunct data could still be considered sensitive and be prevented from being displayed on the screen. In such cases, the defunct data element could be assigned to a new alias. For example, consider a street address change: the alias `$street` is assigned to the new data, and the past street address can be assigned to `$street_old`.

Type	Actual	Alias	Alias	Diff
First Name	6	`$fname`	6	0
Last Name	6	`$lname`	6	0
Email	20	`$email`	6	14
Username	9	`$user`	5	4
Password	9	`$pass`	5	4
Phone number	10	`$cell`	5	5
Birthday	10	`$bday`	5	5
SSN	9	`$ssn`	4	5
Credit Card	16	`$visa`	5	11
Acct. number	12	`$acct`	5	7

Table 5.3: Typical keystroke counts for common sensitive private data terms [63, 64] and corresponding suggested Cashtag alias.

6. Related Work

Previous works include both systems that secure against observation-based attacks and those that provide similar privacy protection over network channels.

6.1 Visual authentication protection

Prior work on protection against visual exposure is focused on securing the act of authentication. By far the earliest is the technique of Xing out or not printing entered passwords on login screens [15]. Most others can be generalized as an augmentation or replacement of password entry mechanisms.

Password managers: Password managers allow the user to select a predefined username and password pair from a list for entry into the login fields [14]. This also allows a user to use different passwords for different apps without the need to remember each individually.

Hardware-based authentication: Hardware-based authentication techniques utilize specialized USB dongles [17], audio jacks [18], short-range wireless communication [19], or Bluetooth connections [20] to connect to the authenticating machine. Therefore, a bystander cannot obtain the authentication information by observation.

Graphical passwords: Graphical passwords or Graphical User Authentication (GUA) [22] replace the alpha-numeric password with a series of images, shapes, and colors. The user needs to click a sequence of human faces [23], object sequences as part of a story [24], or specific regions within a given image [25].

Biometrics: Biometric authentication mechanisms augment password entry (something one knows) with a feature unique to one's personal biology (something one is). The most commonly used of these biometric identifiers includes contours of the fingerprints [26], iris and retinal configuration of the eye [27], and geometries of the face [28] and hand [29]. Behavioral characteristics such as keystroke latency [30], gait [31], and voice [32] can also be used.

Gesture-based authentication: Gesture-based authentication techniques allow the user to perform specific tap [33], multi-finger presses [34], or swipe sequences on-screen [35] to represent a password.

Cognitive challenges and obfuscation: Other techniques have attempted to make games of the authentication procedure [37]. These techniques utilize challenge-response questions and cognitive tasks to increase the difficulty of the login session [38]. Other techniques use obfuscation (e.g., the hiding of cursors [39], confusion matrices [40], and recognition [41]) rather than recall-based methods, to confuse onlookers.

Alternative sensory inputs: Some systems utilize audio direction [42] or tactile and haptic feedback from the vibration motors on devices [43] to provide the user with the appropriate cue for the necessary response. The user then responds with the passphrase corresponding to the cue via traditional input methods.

There are also systems that extend GUAs by requiring sequential graphical inputs and use mechanics, such as eye tracking, blinking and gaze-based interaction for the user to input the graphical sequence [44]. Systems have even demonstrated the capability of using brain waves for this task; a user may only need to think a specific thought to authenticate with a system [45]. These methods are also useful alternatives for authentication of people with visual or audio sensory disabilities [46].

6.2 Physical barriers and screen filters

Physical barriers can serve as a means of limiting the amount of screen exposure to bystanders. This can be as simple as office cubicles. However, they are clearly not suitable for the increasingly mobile modern workforce. Other solutions, such as the 3M Privacy Filter [67] approach the problem by limiting the field of view of the screen. This may serve to reduce exposure, but larger screens are still visible for a larger area and can be seen by unauthorized viewers directly behind the device.

The Lenovo Sun Visor [68] and Compubody Sock [69] reduce the screen visibility further by completely blocking out all non-direct visual exposure. However, this also blocks the user's own field of view, leaving them susceptible to external threats such as pick pocketing.

6.3 Wearable devices

Wearable headsets such as Google Glass [57] prevent screen exposure by moving the screen directly in front of the user's eyes. However, the current generation devices have limited application support. In addition, much of the user input is performed by audio cues, which translates the visual sensitive data leaks to audio ones.

Oculus Rift [65] and Samsung Galaxy Wearable [66] permit similar private screen viewing. However, they currently do not permit general-purpose computing. Additionally, like physical barriers, these devices block the user's field of view, increasing the vulnerability to external physical threats.

6.4 Digital communication channel protection

Many protocols and systems have been developed to handle other aspects of privacy-oriented attacks through the encryption of the digital communication channel. Transport Layer Security and Secure Sockets Layer can enhance security by providing session-based encryption [47]. Virtual Private Networks can be used to enhance security by offering point-to-point encryption to provide secure resources access across insecure network topologies [48]. Proxy servers [49] and onion routing protocols such as Tor [50], can add extra privacy by providing obfuscation of the location and anonymization of IP addresses.

Other solutions have been developed to enhance privacy of browsers. Do-not-track requests can be included in the HTTP headers to request that the web server or application disable its user and cross-site tracking mechanisms [51]. Many browser extensions and plug-ins exist to block ads [52], analytics, beacons, and other tracking mechanisms [53]. Other systems alert the user when specific sensitive elements are leaked [54]. They prevent the transmission of sensitive data without explicit user permission [55], and the cryptography secures access to sensitive data outside of trusted situations [16].

6.5 Compared to Cashtags

Despite the various mechanisms mentioned, the visual channel remains largely open. A limited number of tools are available to obfuscate sensitive data other than during the act of authentication. Other tools developed for data encryption are not originally designed for such purposes.

Password-based solutions and biometrics are effective in handling visual leaks during the act of authentication, but they cannot be generalized to handle other cases. No existing mechanism is in place to allow arbitrary data to be marked as sensitive. To our best knowledge, Cashtags is the only system that can protect general data from shoulder surfing.

7. Discussion and Limitations

Increased coverage: Cashtags widget-level text manipulation works for apps that use standard text-rendering methods. Should developers deviate from such standards, Cashtags would not capture such cases. Still, the additions required to incorporate these custom methods to work within Cashtags would be minimal if knowledge of the custom text display functions and parameters were provided.

Cashtags currently is optimized for coverage rather than performance. Thus, one future direction is to explore better text-processing methods and data structures.

Common names: Commonly occurring names can be problematic. Consider a user John Smith, with Cashtag aliases of his name: John→`$fname`, and Smith→`$lname`. Therefore, all on-screen instances of John are masked as `$fname`. If John opens his browser and Googles the name John Travolta, all returned search results would be displayed with on-screen representations as `$fname` Travolta. If an on-looker was able to observe the above search queries, and was aware of the operation of Cashtags, he or she might be able to derive the sensitive data from the context. This limitation is isolated to common phrases; numerical phrases would be less subject to this issue.

Data formatting: For data formatting and types, many cases are handled through transformations of text fields, including the removal of spaces and symbols, and capitalization mismatches. However, data that expands across `TextViews` is not recognized (e.g., input fields for a credit card split into parts rather than combined into a single field). Cashtags could handle this if each part of the credit-card number were added to the repository.

Handling business use cases: This paper presents Cashtags in light of protecting personal sensitive information. However, with more advanced cashtag mapping rules internally implemented via regular expression templates, we can extend our framework to handle business use cases. For example, for banking account apps, we can mask all of the dollar amounts to `$#`, with a fixed number of digits. A user can specify common preset amounts using cashtags (e.g., pay `$rent` to `$apt_acct`). For database apps, we can mask fields with specific template formats (e.g., phone numbers, identification numbers with certain prefixes). While such extension will require ways to specify app-specific rules, our core framework remains the same.

Generalization of approach: The Cashtags system was prototyped on Android. However, the general approach of screen rendering and user input interception can easily be generalized.

Human subject study: One aspect that is important to system usability is the frequency that sensitive data is entered or displayed. The actual utility of Cashtags is directly related to how frequently personally identifiable information is accessed and input by the user. Unfortunately, to our best knowledge statistics on the frequency of such accesses are not available. A future human subjects study of Cashtags can help determine this frequency of sensitive data access, as well as further evaluate system effectiveness and usability.

8. Conclusion

Cashtags is a first step toward protection against visual leaks of on-screen data. The system demonstrates that it is possible to perform most mobile computing tasks in public locations without exposing sensitive information. The evaluation of the system shows that this can be accomplished efficiently, with minimal perceived overhead. The app coverage test confirms that the system handles general-purpose tasks and maintains full functionality with nearly all tested common use cases. These results suggest that Cashtags will likely work on most other mobile apps, providing unified, device-wide protection against shoulder surfing.

9. Acknowledgements

We would like to thank our shepherd Tadayoshi Kohno, and anonymous reviews for their invaluable feedback. This work is sponsored by NSF CNS-1065127. Opinions, findings, and conclusions or recommendations expressed in this document do not necessarily reflect the views of the NSF, FSU, UCLA, or the U.S. government.

Abstract

While smartphones and mobile apps have been an essential part of our lives, privacy is a serious concern. Previous mobile privacy related research efforts have largely focused on predefined known sources managed by smartphones. Sensitive user inputs through UI (User Interface), another information source that may contain a lot of sensitive information, have been mostly neglected.

In this paper, we examine the possibility of scalably detecting sensitive user inputs from mobile apps. In particular, we design and implement SUPOR, a novel static analysis tool that automatically examines the UIs to identify sensitive user inputs containing critical user data, such as user credentials, finance, and medical data. SUPOR enables existing privacy analysis approaches to be applied on sensitive user inputs as well. To demonstrate the usefulness of SUPOR, we build a system that detects privacy disclosures of sensitive user inputs by combining SUPOR with off-the-shelf static taint analysis We apply the system to 16,000 popular Android apps, and conduct a measurement study on the privacy disclosures. SUPOR achieves an average precision of 97.3% and an average recall of 97.3% for sensitive user input identification. SUPOR finds 355 apps with privacy disclosures and the false positive rate is 8.7%. We discover interesting cases related to national ID, username/password, credit card and health information.

1 Introduction

Smartphones have become the dominant kind of end-user devices with more units sold than traditional PCs. With the ever-increasing number of apps, smartphones are becoming capable of handling all kinds of needs from users, and gain more and more access to sensitive and private personal data. Despite the capabilities to meet users' needs, data privacy in smartphones becomes a major concern.

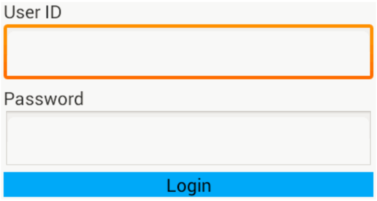

Figure 1: Example sensitive user inputs.

Previous research on smartphone privacy protection primarily focuses on sensitive data managed by the phone OS and framework APIs, such as device identifiers (phone number, IMEI, etc.), location, contact, calendar, browser state, most of which are permission protected. Although these data sources are very important, they do not cover all sensitive data related to users' privacy. A major type of sensitive data that has been largely neglected are the *sensitive user inputs*, which refers to the sensitive information entered by users via the User Interface (UI). Many apps today acquire sensitive credentials, financial, health, and medical information from users through the UI. Therefore, to protect and respect users' privacy, apps must handle sensitive user inputs in a secure manner that matches with users' trust and expectations.

Figure 1 shows an example interface an app uses to acquire users' login credentials via input fields rendered in the UI. When users click the button "Login", the app use the user ID and password to authenticate with a remote service. As the developers may be unaware of the potential risk on the disclosures of such sensitive information, the login credentials are sent in plain text over an insecure channel (HTTP), which inadvertently compromises users' privacy.

In this paper, we propose SUPOR (Sensitive User inPut detectOR), a static mobile app analysis tool for detecting sensitive user inputs and identifying their associated variables in the app code as sensitive information sources. To the best of our knowledge, we are the first to study scalable detection of sensitive user inputs on smartphone platforms.

Previously, there are many existing research efforts [9, 10, 12, 23, 24, 30, 31, 34, 40] on studying the privacy related topics on predefined sensitive data sources on the phone. Our approach enables those existing efforts to be applied to sensitive user inputs as well. For example, with proper static or dynamic taint analysis, one can track the privacy disclosures of sensitive user inputs to different sinks. With static program analysis, one can also identify the vulnerabilities in the apps that may unintentionally disclosure such sensitive user inputs to public or to the attacker controlled output. One could also study how sensitive user inputs propagate to third-party advertisement libraries, etc.

In this paper, to demonstrate the usefulness of our approach, we combine SUPOR with off-the-shelf static taint analysis to detect privacy disclosures of sensitive user inputs.

The major challenges of identifying sensitive user inputs are the following:

(i) How to systematically discover the input fields from an app's UI?

(ii) How to identify which input fields are sensitive?

(iii) How to associate the sensitive input fields to the corresponding variables in the apps that store their values?

In order to detect sensitive user inputs scalably, static UI analysis is much appealing, because it is very difficult to generate test inputs to trigger all the UI screens in an app in a scalable way. For example, an app might require login, which is difficult for tools to generate desirable inputs and existing approaches usually require human intervention [26]. On the other hand, it is also extremely challenging to launch static analysis to answer the aforementioned three questions for general desktop applications.

To this end, we have studied major mobile OSes, such as Android, iOS and Windows Phone systems, and made a few important observations. Then, we implement SUPOR for Android since it is most popular.

First, we find all these mobile OSes provide a standard rapid UI development kit as part of the development framework, and most apps use such a homogeneous UI framework to develop apps. Such UI framework usually leverages a declarative language, such as XML based layout languages, to describe the UI layout, which enables us to statically discover the input fields on the UI.

Second, in order to identify which input fields are sensitive, we have to be able to render the UI, because the rendered UI screens contain important texts as hints that guide users to enter their inputs, which can be used to identify whether the inputs are sensitive. For instance, in Figure 1, the text "User ID" describes the nature of the first input field. Statically rendering UI screens is generally very hard for arbitrary desktop applications. However, with help of WYSIWYG (What You See is What You Get) layout editing feature from the rapid UI development kits of mobile OSes, we are able to statically render the UI for most mobile apps in order to associate the descriptive text labels with the corresponding input fields. Furthermore, due to the relatively small screen size of smartphones, most text labels are concise. As such, current NLP (Natural Language processing) techniques can achieve high accuracy on identifying sensitive terms.

Third, all mobile OSes provide APIs to load the UI layouts made by rapid UI development kits and to bind with the app code. Such a binding mechanism provides us opportunities to infer the relationship between the sensitive input fields from UI layouts to the variables in the app code that store their values.

Our work makes three major contributions:

First, we devise a UI sensitiveness analysis that identifies the input fields that may accept sensitive information by leveraging UI rendering, geometrical layout analysis and NLP techniques. We modify the static rendering engine from the ADT (Android Developer Tools), so that the static rendering can be done with an APK binary instead of source code, and accurately identify the coordinates of text labels and input fields. Then, based on the insight that users typically read the text label physically close to the input field in the screen for understanding the purpose of the input field, we design an algorithm to find the optimal descriptive text label for each input field. We further leverage NLP (nature language processing) techniques [11, 22, 36] to select and map popular keywords extracted from the UIs of a massive number of apps to important sensitive categories, and use these keywords to classify the sensitive text labels and identify sensitive input fields. Our evaluation shows that SUPOR achieves an average precision of 97.3% and an average recall of 97.3% for sensitive user inputs detection.

Second, we design a context-sensitive approach to associate sensitive UI input fields to the corresponding variables in the app code. Instances of sensitive input widgets in the app code can be located using our UI analysis results in a context-insensitive fashion (i.e. based on widget IDs). We further reduce false positives by adding context-sensitivity, i.e. we leverage backward slicing and identify each input widget's residing layout by tracing back to the closest layout loading function. Only if both widget and layout identifiers match with the sensitive input field in the XML layout, we consider the widget instance is associated with the sensitive input field.

Finally, we implement a privacy disclosure detection system based on SUPOR and static taint analysis, and apply the system to 16,000 popular free Android apps collected from the Official Android Market (Google Play). The system can process 11.1 apps per minute on an eight-server cluster. Among all these apps, 355 apps are detected with sensitive user input disclosures. Our manual validation on these suspicious apps shows an overall detection accuracy of 91.3%. In addition, we conduct detailed case studies on the apps we discovered, and show interesting cases of unsafe disclosures of users' national IDs, credentials, credit card and health related information.

2 Background and Motivation Example

In this section, we provide background on sensitive user input identification.

2.1 Necessary Support for Static Sensitive User Input Identification

Modern mobile OSes, such as Android, iOS and Windows Phone system, provide frameworks and tools for rapid UI design. They usually provide a large collection of standard UI widgets, and different layouts to compose the widgets together. They also provide a declarative language, such as XML, to let the developer describe their UI designs, and further provide GUI support for WYSIWYG UI design tools. In order to design a static analysis tool for sensitive user input identification, we need four basic supporting features. The rapid UI development design in modern mobile OSes makes it feasible to achieve such features.

A: statically identify the input fields and text labels;
B: statically identify the attributes of input fields;
C: statically render the UI layout without launching the app;
D: statically map the input fields defined in the UI layouts to the app code.

These four features are necessary to statically identify the sensitive input fields on UIs. In order to infer the semantic meaning of an input field and decide whether it is sensitive, we need (*i*) the attributes of the input field; (*ii*) the surrounding descriptive text labels on the UI. Some attributes of the input fields can help us quickly understand its semantics and sensitiveness. For example, if the input type is password, we know this is a password-like input field. However, in many cases, the attributes alone are not enough to decide the semantics and sensitiveness of the input fields. In those cases, we have to rely on UI analysis. A well-designed app has to allow the user to easily identify the relevant texts for a particular input field and provide appropriate inputs based on his understanding of the meaning of texts. Based on the above observation, we need Feature C to render the UI and obtain the coordinates of input fields and text labels, so that we can associate them and further reason about the sensitiveness of input fields. Once we identify the sensitive input fields, we have to find the variable in the app code used to store the values of the input field for further analysis.

Table 1: UI features in different mobile OSes

	Android	iOS	Windows Phone
Layout format	XML	NIB / XIB / Storyboard	XAML/HTML
Static UI render	ADT	Xcode	Visual Studio
APIs map widgets to code	Yes	Yes	Yes

```
<LinearLayout android:orientation="vertical">
  <TextView android:text="@string/tip_uid" />
  <EditText android:id="@+id/uid" />
  <TextView android:text="@string/tip_pwd" />
  <EditText android:id="@+id/pwd"
       android:inputType="textPassword" />
  <Button android:id="@+id/login"
       android:text="@string/tip_login"/>
</LinearLayout>
```

Figure 2: Simplified layout file *login_activity.xml*.

We have studied Android, iOS and Windows Phone systems. As shown in Table 1, all mobile OSes provide standard formats for storing app UI layouts that we can use to achieve features A and B. All of them have IDEs that can statically render UI layouts for the WYSIWYG UI design. If we reuse this functionality we can achieve static rendering (feature C). Furthermore, all of them provide APIs for developers to map the widgets in layouts to the variables in the app code that hold the user inputs. Combined with static program analysis to understand the mapping, we will be able to achieve feature D.

2.2 Android UI Rendering

For proof of concept, the current SUPOR is designed for the Android platform. An Android app usually consists of multiple activities. Each activity provides a window to draw a UI. A UI is defined by a layout, which specifies the dimension, spacing, and placement of the content within the window. The layout consists of various interactive UI widgets (*e.g.,* input fields and buttons) as well as layout models (*e.g.,* linear or relative layout) that describe how to arrange UI widgets.

At run time, when a layout file is loaded, the Android framework parses the layout file and determines how to render the UI widgets in the window by checking the layout models and the relevant attributes of the UI widgets. At the mean time, all UI widgets in the layout are instantiated and then can be referenced in the code.

An example layout in XML is presented in Figure 2 and the code snippet of the corresponding activity is

```
1  public class LoginActivity extends Activity
       implements View.OnClickListener {
2   private EditText txtUid, txtPwd;
3   private Button btnReset;
4   protected void onCreate(Bundle bundle) {
5    super.onCreate(bundle);
6    setContentView(R.layout.login_activity);
7    txtUid = (EditText) findViewById(R.id.uid);
8    txtPwd = (EditText) findViewById(R.id.pwd);
9    btnLogin = (Button) findViewById(R.id.login);
10   btnLogin.setOnClickListener(this);
11  }
12  public void onClick(View view) {
13   String uid = txtUid.getText().toString();
14   String pwd = txtPwd.getText().toString();
15   String url = "http://www.plxx.com/Users/" +
         "login?uid=" + uid + "&pwd=" + pwd;
16   HttpClient c = new DefaultHttpClient();
17   HttpGet g = new HttpGet(url);
18   Object o = c.execute(g, new
         BasicResponseHandler());
19   // following operations are omitted
20  }
21 }
```

Figure 3: Simplified Activity example.

shown in Figure 3. This layout includes five UI widgets: two text labels (`TextView`), two input fields (`EditText`) and a button. They are aligned vertically based on the `LinearLayout` at Line 1. The first text label shows “User ID” based on the attribute `android:text="@string/tip_uid"`, which indicates a string stored as a resource with the ID `tip_uid`. The *type* attribute of the second input field is `android:inputType="textPassword"`, indicating that it is designed for accepting a password, which conceals the input after the users enter it. Instead of explicitly placing text labels as in Figure 2, some developers decorate an input field with a *hint* attribute, which specifies a message that will be displayed when the input is empty. For instance, developers may choose to display “User ID” and “Password” inside the corresponding input fields using the *hint* attribute.

Figure 1 shows the rendered UI for the layout in Figure 2. The layout including all the inner widgets is loaded into the screen by calling `setContentView()` at Line 6 in Figure 3. The argument of `setContentView()` specifies the reference ID of the layout resource. Similarly, a runtime instance of a widget can also be located through a `findViewById()` call with the appropriate reference ID. For example, the reference ID `R.id.uid` is used to obtain a runtime instance of the input field at Line 7 in Figure 3.

2.3 UI Sensitiveness Analysis

Existing techniques usually consider permission protected framework APIs as the predefined sensitive data sources. However, generic framework APIs, such as `getText()`, can also obtain sensitive data from the user inputs. To precisely detect these sensitive sources, we need to determine which GUI input widgets are sensitive.

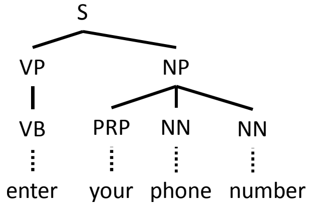

Figure 4: Parse tree of an example sentence.

Two kinds of information are useful for this purpose. First, certain attributes of the widgets can be a good indicator about whether the input is sensitive. Using the `inputType` attribute with a value “textPassword”, we can directly identify password fields. However, not all sensitive input fields use this attribute value. The hint attributes also may contain useful descriptive texts that may indicate the sensitiveness of the input fields.

Besides attributes of UI widgets, we observe that nearby text labels rendered in the UI also provide indication about the sensitiveness of the widgets. For example, a user can easily understand he is typing a user ID and a password when he sees the UI in Figure 1 because the text labels state what the input fields accept. In other words, these text labels explain the purposes of the UI widgets, and guide users to provide their inputs. Based on these observations, we propose to leverage the outcome of UI rendering to build a precise model of the UI and analyze the text labels and hints associated with the widgets to determine their sensitiveness.

The major task of analyzing text labels is to analyze the text labels’ texts, which are written in natural language. As smartphones have relatively small screens, the texts shown in the UI are usually very concise and straightforward to understand. For example, these texts typically are just noun/verb phrases or short sentences (such as the ones shown in Figure 1), and tend to directly state the purposes for the corresponding GUI widgets. Since there is no need to analyze paragraphs or even long sentences, we propose a light-weight keyword-based algorithm that checks whether text labels contain any sensitive keyword to determine the sensitiveness of the corresponding GUI widgets.

2.4 Natural Language Processing

With recent research advances in the area of natural language processing (NLP), NLP techniques have been shown to be fairly accurate in highlighting grammatical structure of a natural language sentence. Recent work has also shown promising results in using NLP techniques for analyzing Android descriptions [13, 30]. In our work, we adapt NLP techniques to extract nouns and noun phrases from the texts collected from popular apps, and identify keywords from the extracted nouns and noun phrases. We next briefly introduce the key NLP techniques used in this work.

Our approach uses **Parts Of Speech (POS) Tagging** [22,36] to identify interesting words, such as nouns, and filter unrelated words, such as conjunctives like "and/or". The technique tags a word in a sentence as corresponding to a particular part of speech (such as identifying nouns, verbs, and adjectives), based on both its definition and its relationship with adjacent and related words in a phrase, sentence, or paragraph. The state-of-the-art approaches can achieve around 97% [36] accuracy in assigning POS tags for words in well-written news articles.

Our approach uses **Phrase and Clause Parsing** to identify phrases for further inspection. Phrase and clause parsing divides a sentence into a constituent set of words (*i.e.,* phrases and clauses). These phrases and clauses logically belong together, *e.g.,* Noun Phrases and Verb Phrases. The state-of-the-art approaches can achieve around 90% [36] accuracy in identifying phrases and clauses over well-written news articles.

Our approach uses **Syntactic parsing** [21], combined with the above two techniques, to generate a parse-tree structure for a sentence, and traverse the parse tree to identify interesting phrases such as noun phrases. The parse tree of a sentence shows the hierarchical view of the syntax structure for the sentence. Figure 4 shows the parse tree for an example sentence "enter your phone number". The root node of the tree is the sentence node with the label *S*. The interior nodes of the parse tree are labeled by non-terminal categories of the grammar (*e.g.,* verb phrases *VP* and noun phrases *NP*), while the leaf nodes are labeled by terminal categories (*e.g.,* pronouns *PRP*, nouns *NN* and verbs *VB*). The tree structure provides a basis for other tasks within NLP such as question and answer, information extraction, and translation. The state of the art parsers have an F1 score of 90.4% [37].

3 Design of SUPOR

In this section, we first present our threat model, followed by an overview of SUPOR. Then, we describe each component of SUPOR in details.

3.1 Threat Model

We position SUPOR as a static UI analysis tool for detecting sensitive user inputs. Instead of focusing on malicious apps that deliberately evade detection, SUPOR is designed for efficient and scalable screening of a large number of apps. Most of the apps in the app markets are legitimate, whose developers try to monetize by gaining user popularity, even though some of them might be a little bit aggressive on exploiting user privacy for revenue. Malware can be detected by existing works [5, 15, 39], which is out of scope of this paper.

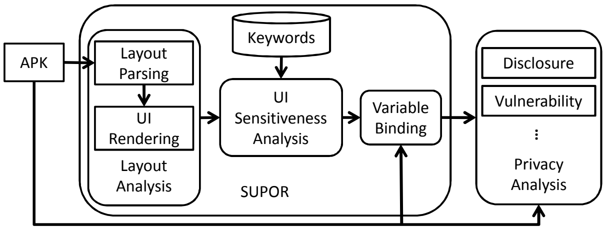

Figure 5: Overview of SUPOR.

Though the developers sometimes dynamically generate UI elements in the code other than defining the UI elements via layout files, we focus on identifying sensitive user inputs statically defined in layout files in this work.

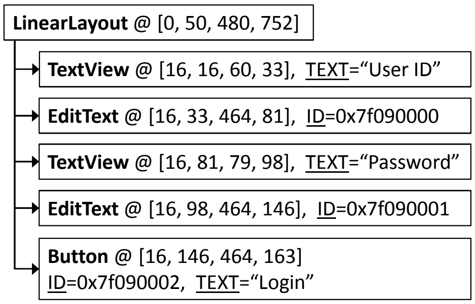
3.2 Overview

Figure 5 shows the workflow of SUPOR. SUPOR consists of three major components: *Layout Analysis*, *UI Sensitiveness Analysis*, and *Variable Binding*. The layout analysis component accepts an APK file of an app, parses the layout files inside the APK file, and renders the layout files containing input fields. Based on the outcome of UI rendering, the UI sensitiveness analysis component associates text labels to the input fields, and determines the sensitiveness of the input fields by checking the texts in the text labels against a predefined sensitive keyword dataset (Section 3.6). The variable binding component then searches the code to identify the variables that store the values of the sensitive input fields. With variable binding, existing research efforts in studying the privacy related topics on predefined well-known sensitive data sources can be applied to sensitive user inputs. For example, one can use taint analysis to detect disclosures of sensitive user inputs or other privacy analysis to analyze vulnerabilities of sensitive user inputs in the apps. Next we describe each component in detail.

3.3 Layout Analysis

The goal of the layout analysis component is to render the UIs of an Android app, and extract the information of input fields: types, hints, and absolute coordinates, which are later used for the UI sensitiveness analysis.

As we discussed in Section 2.3, if we cannot determine the sensitiveness of an input field based on its type and hint, we need to find a text label that describes the purpose of the input field. From the *user's perspective*, the text label that describes the purpose of an input field must be *physically close to the input field* in the screen; otherwise the user may correlate the text label with other input fields and provide inappropriate inputs. Based on this insight, the layout analysis component renders the UIs as if the UIs are rendered in production runs, mimicking how users look at the UIs. Based on the rendered



LinearLayout @ [0, 50, 480, 752]
TextView @ [16, 16, 60, 33], TEXT="User ID"
EditText @ [16, 33, 464, 81], ID=0x7f090000
TextView @ [16, 81, 79, 98], TEXT="Password"
EditText @ [16, 98, 464, 146], ID=0x7f090001
Button @ [16, 146, 464, 163]
ID=0x7f090002, TEXT="Login"

Figure 6: UI model for Figure 1 on 480x800 screen. Only the ID, relative coordinates and text of the widgets are presented here.

UIs, the distances between text labels and input fields are computed, and these distances are used later to find the best descriptive text labels for each input field. We next describe the two major steps of the layout analysis component.

The first step is to identify which layout files contain input fields by parsing the layout files in the APK of an Android app. In this work, we focus on input fields of the type `EditText` and all possible sub-types, including custom widgets in the apps. Each input field represents a potential sensitive source. However, according to our previous discussion, the sensitiveness cannot be easily determined by analyzing only the layout files. Thus, all the files containing input fields are used in the second step for UI rendering.

The second step is to obtain the coordinate information of the input fields by rendering the layout files. Using the rapid UI development kit provided by Android, the layout analysis component can effectively render standard UI widgets. For custom widgets that require more complex rendering, the layout analysis component renders them by providing the closest library superclass to obtain the best result. After rendering a layout file, the layout analysis component obtains a UI model, which is a tree-structure model where the nodes are UI widgets and the edges describe the parent-child relationship between UI widgets. Figure 6 shows the UI model obtained by rendering the layout file in Figure 2. For each rendered UI widget, the coordinates are relative to its parent container widget. Such relative coordinates cannot be directly used for measuring the distances between two UI widgets, and thus SUPOR converts the relative coordinates to absolute coordinates with regards to the screen size.

Coordinate Conversion. SUPOR computes the absolute coordinates of each UI widget level by level, starting with the root container widget. For example, in Figure 6, the root container widget is a `LinearLayout`, and its coordinates are (0, 50, 480, 752), representing the left, top, right, and bottom corners. There is no need to convert the coordinates of the root UI widget, since its coordinates are relative to the top left corner of the screen, and thus are already absolute coordinates. For other UI widgets, SUPOR computes their absolute coordinates based on their relative coordinates and their parent container's absolute coordinates. For example, the relative coordinates of the second UI widget, `TextView`, are (16, 16, 60, 33). Since it is a child widget of the root UI widget, its absolute coordinates is computed as (16, 66, 60, 83). This process is repeated until the coordinates of every UI widget are converted.

Algorithm 1 UI Widget Sensitiveness Analysis

```
Require: $I$ as an input field, $S$ as a set of text labels, $KW$
    as a pre-defined sensitive keyword dataset
Ensure: $R$ as whether $I$ is sensitive
Divide the UI plane into *nine* partitions based on $I$'s boundary
for all $L \in S$ do
    $score = 0$
    for all $(x,y) \in L$ do
        $score \mathrel{+}= distance(I,x,y) * posWeight(I,x,y)$
    end for
    $L.score = score \ / \ L.numOfPixels$
end for
$T = min(S)$
$R = T.text$ matches $KW$
```

In addition to coordinate conversion, SUPOR collects other information of the UI widgets, such as the texts in the text labels and the attributes for input fields (e.g., `ID` and `inputType`).

3.4 UI Sensitiveness Analysis

Based on the information collected from the layout analysis, the UI sensitiveness analysis component determines whether a given input field contains sensitive information. This component consists of three major steps.

First, if the input field has been assigned with certain attributes like `android:inputType="textPassword"`, it is directly considered as sensitive. With such attribute, the original inputs on the UI are concealed after users type them. In most cases these inputs are passwords.

Second, if the input field contains any hint (*i.e.,* tooltip), *e.g.,* "Enter Password Here", the words in the hint are checked: if it contains any keyword in our sensitive keyword dataset, the input field is considered sensitive; otherwise, the third step is required to determine its sensitiveness.

Third, SUPOR identifies the text label that describes the purpose of the input field, and analyzes the text in the label to determine the sensitiveness. In order to identify text labels that are close to a given input field, we provide

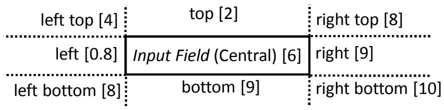


Figure 7: The partition of the UI is based on the boundary of the input field.

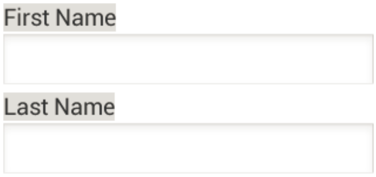

Figure 8: Example for UI widget sensitiveness analysis.

an algorithm to compute correlation scores for each pair of a text label and an input field based on their distances and relative positions.

The details of our algorithm is shown in Algorithm 1. At first, SUPOR divides the UI plane into nine partitions based on the boundaries of the input field. Figure 7 shows the nine partitions divided by an input field. Each text label can be placed in one or more partitions, and the input field itself is placed in the central partition. For a text label, we determine how it is correlated to an input field by computing how each pixel in a text label is correlated to the input field (Line 4). The correlation score for a pixel consists of two parts (Line 5). The first part is the Euclidean distance from the pixel to the input field, computed using the absolute coordinates. The second part is a weight based on their relative positions, *i.e.,* which of the nine partitions the widget is in. We build the position-based weight function based on our empirical observations: if the layout of the apps is top-down and left-right arranged, the text label that describes the input field is usually placed at left or on top of the input field while the left one is more likely to be the one if it exists. We assign smallest weight to the pixels in the left partition and second smallest for the top partition. The right-bottom partition is least possible so we give the largest weight to it. The detailed weights for each partition is shown in Figure 7. Based on the correlation scores of all the pixels, our algorithm uses the average of the correlation scores as the correlation score for the pair of the text label and the input field (Line 7). The label with smaller correlation score is considered more correlated to the input field.

After the correlation scores for all text labels are computed, SUPOR selects the text label that has the smallest score as the descriptive text label for the input field, and uses the pre-defined sensitive keyword dataset to determine if the label contains any sensitive keyword. If yes, the input field is considered as sensitive.

Example. Figure 8 shows an example UI that requires Algorithm 1 for sensitiveness analysis. This example shows a UI that requests a user to enter personal information. This UI contains two input fields and two text labels. Neither can SUPOR determine the sensitiveness through their attributes, nor can SUPOR use any hint to determine the sensitiveness. SUPOR then applies Algorithm 1 on these two input fields to compute the correlation scores for each pair of text labels and input fields. The correlation scores are shown in Table 2. According to the correlation scores, SUPOR associates "First Name" to the first input field and "Last Name" to the second input field. Since our keyword dataset contains keywords "*first name*" and "*last name*" for personal information, SUPOR can declare the two input fields are sensitive.

Table 2: Scores of the text labels in Figure 8.

	First Name	Last Name
1st input field	46.80	218.81
2nd input field	211.29	46.84

Repeating the above steps for every input field in the app, SUPOR obtains a list of sensitive input fields. It assigns an contextual ID to each sensitive input field in the form of `<Layout_ID, Widget_ID>`, where `Layout_ID` is the ID of the layout that contains the input field and `Widget_ID` is the ID of the input field (*i.e.,* the value of the attribute "`android:id`").

3.5 Variable Binding

With the sensitive input fields identified in the previous step, the variable binding component performs context-sensitive analysis to bind the input fields to the variables in the code. The sensitive input fields are identified using contextual IDs, which include layout IDs and widget IDs. These contextual IDs can be used to directly locate input fields from the XML layout files. To find out the variables that store the values of the input fields, SUPOR leverages the binding mechanism provided by Android to load the UI layout and bind the UI widgets with the code. Such a binding mechanism enables SUPOR to associate input fields with the proper variables. We refer to these variables the *widget variables* that are bound to the input fields.

The variable binding component identifies the instances of the input fields in a context-insensitive fashion via searching the code using the APIs provided by the rapid UI development kit of Android. As shown in Section 2.2, `findViewById(ID)` is an API that loads a UI widget to the code. Its argument `ID` is the numeric ID that specifies which widget defined in the XML to load. Thus, to identify the instances of the input fields, SUPOR searches the code for such method calls, and compare their arguments to the widget IDs of the sensitive input fields. If the arguments match any widget ID of the sensitive input fields, the return values of the corresponding `findViewById(ID)` are considered as the widget variables for the sensitive input fields.

One problem here is that developers may assign the same widget ID to UI widgets in different layout files, and thus different UI widgets are associated with the same numeric ID in the code. Our preliminary analysis on 5000 apps discovers that about 22% of the identified sensitive input fields have duplicate IDs within the corresponding apps. Since the context-insensitive analysis cannot distinguish the duplicate widget IDs between layout files inside an app, a lot of false positives will be presented.

To reduce false positives, SUPOR adds context-sensitivity into the analysis, associating widget variables with their corresponding layouts. Similar to loading a widget, the rapid UI development kit provides APIs to load a UI layout into the code. For example, `setContentView(ID)` with a numeric ID as the argument is used to load a UI layout to the code, as shown at Line 6 in Figure 3. Any subsequent `findViewById` with the ID `WID` as the argument returns the UI widget identified by `WID` in the newly loaded UI layout, not the UI widget identified by `WID` in the previous UI layout. Thus, to find out which layout is associated with a given widget variable, SUPOR traces back to identify the closest method call that loads a UI layout[1] along the program paths that lead to the invocation of `findViewById`. We next describe how SUPOR performs context-sensitive analysis to distinguish widget IDs between layout files. For the description below, we use `setContentView()` as an example API.

Given a widget variable, SUPOR first identifies the method call `findViewById`, and computes an interprocedural backward slice [18] of its receiver object, *i.e.,* the activity object. This backward slice traces back from `findViewById`, and includes all statements that may affect the state of the activity object. SUPOR then searches the slice backward for the method call `setContentView`, and uses the argument of the first found `setContentView` as the layout ID. For example, in Figure 3, the widget variable `txtUid` is defined by the `findViewById` at Line 7, and the activity object of this method call is an instance of `LoginActivity`. From the backward slice of the activity object, the first method call `setContentView` is found at Line 6, and thus its argument `R.layout.login_activity` is associated with `txtUid`, whose widget ID is specified by `R.id.uid`. Both `R.layout.login_activity` and `R.id.uid` can be further resolved to identify their numeric IDs, and match with the contextual IDs of sensitive input fields to determine whether `txtUid` is a widget variable for a sensitive input field.

3.6 Keyword Dataset Construction

To collect the sensitive keyword dataset, we crawl all texts in the resource files from 54,371 apps, including layout files and string resource files. We split the collected texts based on newline character (`\n`) to form a list of texts, and extract words from the texts to form a list of words. Both of these lists are then sorted based on the frequencies of text lines and words, respectively. We then systematically inspect these two lists with the help of the adapted NLP techniques. Next we describe how we identify sensitive keywords in detail.

First, we adapt NLP techniques to extract nouns and noun phrases from the top 5,000 frequent text lines. Our technique first uses Stanford parser [36] to parse each text line into a syntactic tree as discussed in Section 2.4, and then traverses the parse tree level by level to identify nouns and noun phrases. For the text lines that do not contain any noun or noun phrase, our technique filters out these text lines, since such text lines usually consist of only prepositions (*e.g.,* to), verbs (*e.g.,* update please), or unrecognized symbols. From the top 5,000 frequent text lines, our technique extracts 4,795 nouns and noun phrases. For the list of words, our technique filters out words that are not nouns due to the similar reasons. From the top 5,000 frequent words, our technique obtains 3,624 words. We then manually inspect these two sets of frequent nouns and noun phrases to identify sensitive keywords. As phrases other than noun phrases may indicate sensitive information, we further extract consecutive phrases consisting of two and three words from the text lists and manually inspect the top 200 frequent two-word and three-word phrases to expand our sensitive keyword set.

Second, we expand the keyword set by searching the list of text lines and the list of words using the identified words. For example, we further find "cvv code" for credit card by searching the lists using the top-ranked word "code", and find "national ID" by searching the lists using the top-ranked word "id". We also expand the keywords using synonyms of the keywords based on WordNet [11].

Third, we further expand the keywords by using Google Translate to translate the keywords from English into other languages. Currently we support Chinese and Korean besides English.

These keywords are manually classified into 10 categories, and part of the keyword dataset is presented in Table 3. Note that we do not use "Address" for the category "Personal Info". Although personal address is sensitive information, our preliminary results show that this

[1] SUPOR considers both `Activity.setContentView()` and `LayoutInflater.inflate()` as the methods to load UI layouts due to their prevalence.

Table 3: Part of keyword dataset.

Category	Keywords
Credential	pin code, pin number, password
Health	weight, height, blood type, calories
Identity	username, user ID, nickname
Credit Card	credit card number, cvv code
SSN	social security number, national ID
Personal Info	first name, last name, gender, birthday
Financial Info	deposit amount, income, payment
Contact	phone number, e-mail, email, gmail
Account	log in, sign in, register
Protection	security answer, identification code

keyword also matches URL address bars in browsers, causing many false positives. Also, we do not find interesting privacy disclosures based on this keyword in our preliminary results, and thus "Address" is not used in our keyword dataset. Although this keyword dataset is not a complete dataset that covers every sensitive keyword appearing in Android apps, our evaluation results (in Section 5) show that it is a relatively complete dataset for the ten categories that we focus on in this work.

4 Implementation

In this section, we provide the details of our implementation of SUPOR, including the frameworks and tools we built upon and certain tradeoffs we make to improve the effectiveness.

SUPOR accepts APK files as inputs, and uses a tool built on top of Apktool [1] to extract resource files and bytecode from the APK file. The Dalvik bytecode is translated into an intermediate representation (IR), which is based on dexlib in Baksmali [3]. The IR is further converted to WALA [4] static single assignment format (SSA). WALA [4] works as the underlying analysis engine of SUPOR, providing various functionalities, *e.g.,* call graph building, dependency graph building, and point-to analysis.

The UI rendering engine is built on the UI rendering engine from the ADT Eclipse plug-ins Besides improving the engine to better render custom widgets, we also make the rendering more resilient using all available themes. Due to SDK version compatibility, not every layout can be rendered in every theme. We try multiple themes until we find a successful rendering. Although different themes might make UI slightly different, the effectiveness of our algorithm should not be affected. The reason is that apps should not confuse users in the successfully rendered themes, and thus our algorithm designed to mimic what users see the UIs should work accordingly.

To demonstrate the usefulness of SUPOR, we implement a privacy disclosure detection system by combining SUPOR with static taint analysis. This system enables us to conduct a study on the disclosures of sensitive user inputs. We build a taint analysis engine on top of Dalysis [24] and make several customizations to improve the effectiveness. The details of the customizations can be found at Appendix A.2.

To identify sensitive user inputs, SUPOR includes totally 11 source categories, including the 10 categories listed in Section 3.6 and an additional category *PwdLike* for the input fields identified as sensitive using their attributes such as `inputType`. The *PwdLike* category is prioritized if it has some overlapping with the other categories. Once the widget variables of the sensitive input fields are found, we consider any subsequent method calls on the variables that retrieve values from the input fields as source locations, such as `getText()`. To identify privacy disclosures of the sensitive user inputs, SUPOR mainly focuses on the information flows that transfer the sensitive data to the following two types of sinks: (1) the sinks of output channels that send the information out from the phone (*e.g.,* SMS and Network) and (2) the sinks of public places on the phone (*e.g.,* logging and content provider writes). More details are shown in Appendix A.1.

Our implementation, excluding the underlying libraries and the core taint analysis engine, accounts for about 4K source lines of code (SLoC) in Java.

5 Evaluations and Experiments

We conducted comprehensive evaluations on SUPOR over a large number of apps downloaded from the official Google Play store. We first evaluated the performance of SUPOR and demonstrated its scalability. We then measured the accuracy of the UI sensitiveness analysis and the accuracy of SUPOR in detecting disclosures of sensitive user inputs. In addition, our case studies on selected apps present practical insights of sensitive user input disclosures, which are expected to contribute to a community awareness.

5.1 Evaluation Setup

The evaluations of SUPOR were conducted on a cluster of eight servers with an Intel Xeon CPU E5-1650 and 64/128GB of RAM. During the evaluations, we launched concurrent SUPOR instances on 64-bit JVM with a maximum heap space of 16GB. On each server 3 apps were concurrently analyzed, so the cluster handled 24 apps in parallel.

In our evaluations, we used the apps collected from the official Google Play store in June 2013. We applied SUPOR to analyze 6,000 apps ranked by top downloads, with 200 apps for each category. Based on the results of the 6,000 apps, we further applied SUPOR on another 10,000 apps in 20 selected categories. Each of the 20 categories is found to have at least two apps with sensi-

Table 4: Statistics of 16,000 apps.

	#Apps	Percentage
Without Layout Files	625	3.91%
Without Input Fields	5,711	35.69%
Without Sensitive Input Fields	4,731	29.57%
With Sensitive Input Fields	4,922	30.76%
Parsing Errors	11	0.07%
TOTAL	16,000	100.00%

tive user input disclosures.

For each app, if it contains at least one input field in layout files, the app is analyzed by the UI sensitiveness analysis. If SUPOR identifies any sensitive input field of the app, the app is further analyzed by the taint analysis to detect sensitive user input disclosures. Table 4 shows the statistics of these apps. A small portion of the apps do not contain any layout files and about 1/3 of the apps do not have any input field in layout files. This is reasonable because many Game apps do not require users to enter information. 35% of the apps without layout files and 17% of the apps without input fields belong to different sub-categories of games. 11 apps (0.07%) cannot be analyzed by SUPOR due to various parsing errors in rendering their layout files. In total, 60.33% of the apps contain input fields in their layout files, among which more than half of the apps are further analyzed because sensitive input fields are found via the UI sensitiveness analysis.

As not every layout containing input fields is identified with sensitive input fields, we show the statistics of the layouts for the 4,922 apps identified with sensitive input fields. Among these apps, 47,885 layouts contain input fields and thus these layouts are rendered. Among the rendered layouts, 19,265 (40.2%) are found to contain sensitive keywords (no matter whether the keywords are associated with any input field). This is the upper bound of the number of layouts that can be identified with sensitive input fields. In fact, 17,332 (90.0%) of the 19,265 layouts with sensitive keywords are identified with sensitive input fields.

5.2 Performance Evaluation

The whole experiment for 16,000 apps takes 1439.8 minutes, making a throughput of 11.1 apps per minutes on the eight-server cluster. The following analysis is only for the 4,922 apps identified with sensitive input fields, if not specified.

The UI analysis in SUPOR includes decompiling APK files, rendering layouts, and performing UI sensitiveness analysis. For each app with sensitive input fields, SUPOR needs to perform the UI analysis for at least 1 layout and at most 190 layouts, while the median number is 7 and the average number is 9.7. Though the largest execution time required for this analysis is about 2 minutes. 96.3% of the apps require less than 10 seconds to render all layouts in an app. The median analysis time is 5.2 seconds and the average time is 5.7 seconds for one app. Compared with the other parts of SUPOR, the UI analysis is quite efficient, accounting for only 2.5% of the total analysis time on average. Also, the UI sensitiveness analysis, including the correlation score computation and keyword matching, accounts for less than 1% of the total UI analysis time, while decompiling APK files and rendering layouts take most of the time.

To detect sensitive user input disclosures, our evaluation sets a maximum analysis time of 20 minutes. 18.1% of the apps time out in our experiments but 73.7% require less than 10 minutes. The apps with many entry points tend to get stuck in taint analysis, and are more likely to timeout. Scalability of static taint analysis is a hard problem, but we are not worse than related work. The timeout mechanism is enforced for the whole analysis, but the system will wait for I/O to get partial results. In practice, we can allow a larger maximum analysis time so that more apps can be analyzed. Among the apps finished in time, the median analysis time is 1.9 minutes and the average analysis time is 3.7 minutes.

The performance results show that SUPOR is a scalable solution that can statically analyze UIs of a massive number of apps and detect sensitive user input disclosures on these apps. Compared with existing static taint analysis techniques, the static UI analysis introduced in this work is highly efficient, and its performance overhead is negligible.

5.3 Effectiveness of UI Sensitiveness Analysis

To evaluate the accuracy of the UI sensitiveness analysis, we randomly select 40 apps and manually inspect the UIs of these 40 apps to measure the accuracy of the UI sensitiveness analysis.

First, we randomly select 20 apps reported *without* sensitive input fields, and manually inspect these apps to measure the false negatives of SUPOR. In these apps, the largest number of layouts SUPOR renders is 5 and the total number of layouts containing input fields is 39 (1.95 layouts per app). SUPOR successfully renders 38 layouts and identifies 57 input fields (2.85 input fields per app). SUPOR fails to render 1 layout due to the lack of necessary themes for a third-party library. By analyzing these 57 input fields, we confirm that SUPOR has only one false negative (FN), *i.e.,* failing to mark one input field as sensitive in the app *com.strlabs.appdietas*. This input field requests users to enter their weights, belonging to the Health category in our keyword dataset. However, the text of the descriptive text label for the input field is “Peso de hoy”, which is “Today Weight” in Spanish. Since our keyword dataset focuses on sensitive keywords in English, SUPOR has a false negative. Such false negatives can be reduced by expanding our keyword dataset to support more languages.

Second, we randomly select 20 apps reported *with* sensitive input fields. Table 5 shows the detailed analysis results. Column "#Layouts " counts the number of layouts containing input fields in each app, while Column "#Layouts with Sensitive Input Fields" presents the number of layouts reported with sensitive input fields. Column "#Input Fields" lists the total number of input fields in each app and Column "#Reported Sensitive Input Fields" gives the detailed information about how many input fields are identified by checking the `inputType` attribute, by matching the hint text, and by analyzing the associated text labels. Sub-Column "Total" presents the total number of sensitive input fields identified by SUPOR in each app. Columns "FP" and "FN" show the number of false positives and the number of false negatives produced by SUPOR in classifying input fields. Column "Duplicate ID" shows if an app contains any duplicate widget ID for sensitive input fields. These duplicate IDs belong to either sensitive input fields (represented by ○) or non-sensitive input fields (●). For all the layouts in these 20 apps, SUPOR successfully renders the layouts except for App 18, which has 29 layouts containing input fields but SUPOR renders only 17 layouts. The reason is that Apktool fails to decompile the app completely.

The results show that for these 20 apps, SUPOR identifies 149 sensitive input fields with 4 FPs and 3 FNs, and thus the achieved true positives (TP) is 145. Combined with the 20 apps identified without sensitive input fields (0 FP and 1 FN), SUPOR achieves an average precision of 97.3% (precision = $\frac{TP}{TP+FP}$ = 145/149) and an average recall of 97.3% (recall = $\frac{TP}{TP+FN}$ = 145/(145+(1+3)).

We next describe the reasons for the FNs and the FPs. SUPOR has two false negatives in App 1, in which the text label "Answer" is not identified as a sensitive keyword. But according to the context, it means "security answer", which should be sensitive. Although this phrase is modeled as a sensitive phrase in our keyword dataset, SUPOR cannot easily associate "Answer" with the phrase, resulting in a false negative. In App 8, SUPOR marks an input field as sensitive because the associated text label containing the keyword "Height". However, based on the context, the app actually asks the user to enter the expected page height of a PDF file. Such issues can be alleviated by employing context-sensitive NLP analysis [19].

SUPOR also has two FPs in App 6 and App 8 due to the inaccuracy of text label association. In App 6 shown in Figure 9, the hint of the "Delivery Instructions" input field does not contain sensitive keywords, and thus SUPOR identifies the close text label for determining its sensitiveness. However, SUPOR incorrectly associates a description label of "Email" to the "Delivery Instructions" input field based on their close distances. Since this description contains sensitive keywords such as email, SUPOR considers the "Delivery Instructions" input field as sensitive, causing a false positive. Finally, SUPOR has both FPs and FNs for App 14, since its arrangements of input fields and their text labels are not accurately captured by our position-based weights that give preferences for left and top positioned text labels.

Your $5 Domino's Dollars™ code will be sent to this email address within 48 hrs of this order being placed. Domino's Dollars™ may be used toward online orders within 10 days of receipt.

Delivery Instructions - Optional

Figure 9: False positive example in UI sensitiveness analysis.

To evaluate the effectiveness of resolving duplicate IDs, We instrumented SUPOR to output detailed information when identifying the widget variables. We did not find any case where SUPOR incorrectly associates the widget variables with the input fields based on the contextual IDs, but potentially SUPOR may have inaccurate results due to infeasible sequences of entry points that can be executed. We next present an example to show how backward slicing help SUPOR distinguish duplicate widget IDs. App 17 has two layouts with the same hierarchy. Layout A contains a sensitive input field with the ID $w1$ while Layout B contains a non-sensitive input field with the same ID $w1$. Both layouts are loaded via `LayoutInflater.inflate` and then `findViewById` is invoked separately to obtain the enclosed input fields. Without the backward slicing, SUPOR considers the input field with the ID $w1$ in the Layout B as sensitive, which is a false positive. With the backward slicing, SUPOR can distinguish the input field with the ID $w1$ in Layout B with the input field with the ID $w1$ in Layout A, and correctly filter out the non-sensitive input field in Layout B.

5.4 Accuracy of Detecting Sensitive User Input Disclosures

In our experiments, 355 apps are reported with sensitive user input disclosures. The reported apps belong to 25 out of the 30 categories in Google Play Store and 20 categories have at least 2 apps reported. We next report the accuracy of detecting sensitive user input disclosures.

Figure 10 shows the number of true positives and the number of false positives by taint source and sink categories. If an app is reported with multiple disclosure flows and one of them is a false positive, the app is considered as a false positive. Through manually evaluating the 104 apps reported cases from the first 6,000 analyzed apps, we find false positives in 9 apps. Therefore, the overall false positive rate is about 8.7%, *i.e.,* the accu-

Table 5: UI analysis details for 20 randomly chosen apps.

App ID	#Layouts	#Input Fields	#Layouts with Sensitive Input Fields	#Reported Sensitive Input Fields				FP	FN	Duplicate ID
				Password	Hint	Label	Total			
1	8	18	4	6	0	3	9		2	○
2	37	77	2	0	0	8	8			
3	3	3	1	0	1	0	1			
4	4	9	3	0	0	6	6			○
5	5	7	1	1	0	0	1

Figure 10: True positives and false positives by source/sink categories for the reported apps.

racy of privacy disclosure detection is 91.3%. We investigated the false positives and found that these false positives were mostly resulted from the limitations of the underlying taint analysis framework, such as the lack of accurate modeling of arrays.

5.5 Case Studies

To improve the community's awareness and understanding of sensitive user input disclosures, we conducted cases studies on four selected apps from the source categories SSN, PwdLike, Credit Card, and Health. These case studies present interesting facts of sensitive user input disclosures, and also demonstrate the usefulness of SUPOR. We also inform the developers of the apps mentioned in this section about the detected disclosures.

com.yes123.mobile is an app for job hunting. The users are required to register with their national ID and a password to use the service. When the users input the ID and password, and then click log in[2], the app sends both their national IDs and passwords via Internet without any protection (*e.g.,* hashing or through HTTPS channel). Since national ID is quite sensitive (similar as Social Security Number), such limited protection in transmission may lead to serious privacy disclosure problems.

The second example app (*craigs.pro.plus*) shows a legitimate disclosure that uses HTTPS connections to send user sensitive inputs to its server for authentication. Even though the password itself is not encoded (*e.g.,* hashing), we believe HTTPS connections provide a better protection layer to resist the disclosures during communications. Also we find that popular apps developed by enterprise companies are more likely to adopt HTTPS, providing better protection for their users.

To better understand whether sensitive user inputs are properly protected, we further inspect 104 apps, of which 44 apps send sensitive user inputs via network. Among these 44 apps, only 10 of them adopt HTTPS connections, while the majority of apps transmit sensitive user inputs in plain text via HTTP connections. Such study

[2] The UI is shown in Figure 12 in Appendix B.1.

results indicate that most developers are still unaware of the risks posed by sensitive user input disclosures, and more efforts should be devoted to provide more protections on sensitive user inputs.

Our last example app (*com.nitrogen.android*) discloses credit card information, a critical financial information provided by the users. Figure 11 shows the rendered UI of the app. The three input fields record credit card number, credit card security number, and the card holder's name. Because these fields are not decorated with `textPassword` input type and they do not contain any hints, SUPOR uses the UI sensitiveness analysis to compute correlation scores for each text label. As we can see from the UI, the text label "Credit Card Number" and the text label "Credit Card Security Number" are equally close to the first input field. As our algorithm considers weights based on the relative positions between text labels and input fields, SUPOR correctly associates the corresponding text labels for these three input fields, and the taint analysis identifies sensitive user input disclosures for all these three input fields to logging. SUPOR also identifies apps that disclose personal health information to logging, and the example app is shown in Appendix B.2.

Although Google tries to get rid of some of the known sinks that contribute most of the public leaks by releasing new Android versions, many people globally may still continue using older Android releases for a very long time (about 14.2% of Android phones globally using versions older than Jelly Bean [2]). If malware accesses the logs on these devices, all the credit card information can be exploited to malicious adversaries. Thus, certain level of protection is necessary for older versions of apps. Also, SUPOR finds that some apps actually sanitize the sensitive user inputs (*e.g.,* hashing) before these inputs are disclosed in public places on the phone, indicating that a portion of developers do pay attention to protecting sensitive user input disclosures on the phone.

6 Discussion

SUPOR is designed as an effective and scalable solution to screening a large number of apps for sensitive user inputs. In this work, we have demonstrated that SUPOR can be combined with static taint analysis to automatically detect potential sensitive user input disclosures. Such analysis can be directly employed by app markets to raise warnings, or by developers to verify whether their apps accidentally disclose sensitive user inputs. Also, SUPOR can be paired with dynamic taint analysis to alert users before the sensitive user inputs escape from the phones.

SUPOR focuses on input fields, a major type of UI widgets to collect user inputs. Such UI widgets record what user type and contain high entropy, unlike yes/no buttons which contain low entropy. It is quite straightforward to extend our current approach to handle more diverse widgets.

SUPOR chooses the light-weight keyword-based technique to determine the sensitiveness of input fields since the texts contained in the associated text labels are usually short and straightforward to understand. Our evaluations show that in general these keywords are highly effective in determining the sensitiveness of input fields. Certain keywords may produce false positives since these keywords have different meanings under different contexts. To alleviate such issues, we may leverage more advanced NLP techniques that consider contexts [19].

7 Related Work

Many great research works [6, 8–10, 12, 14, 16, 23, 24, 34, 38] focus on privacy leakage problems on predefined sensitive data sources on the phone. SUPOR identifies sensitive user inputs, and may enable most of the existing research on privacy studies to be applied to sensitive user inputs. As a result, our research compliments the existing works. FlowDroid [6] also employs a limited form of sensitive input fields—password fields. Compared with FlowDroid, we leverage static UI rendering and NLP techniques to identify different categories of sensitive input fields in an extensible manner. Susi [33] employs a machine learning approach to detect pre-defined source/sinks from Android Framework. In contrast, SUPOR focus on a totally different type of sensitive sources–user inputs through GUI.

Moreover, a few approaches are designed for controlling the known privacy leaks. AppFence [17] employs fake data or network blocking to protect privacy leaks to Internet with user supplied policies. Nadkarni *et al.*provide new OS mechanisms for proper information sharing cross apps [28].

NLP techniques have been used to study app descriptions [13, 30, 31]. WHYPER [30] and AutoCog [31] leverages NLP techniques to understand whether the application descriptions reflect the permission usage. CHABADA [13] also applies topic modelling, an NLP technique to detecting malicious behaviors of Android apps. It generates clusters according to the topic, which consists of a cluster of words that frequently occur together. Then, it tries to detect the outliers as malicious behaviors. CHABADA does not focus on detecting privacy leaks. On the other hand, SUPOR leverages NLP techniques to identify sensitive keywords and further use those keywords to classify the descriptive text labels and the associated input fields.

Furthermore, there are a few important related works using UI related information to detect different types of vulnerabilities and attacks. AsDroid [20] checks UI text to detect the contradiction between expected behavior inferred from the UI and the program behavior represented by APIs. Chen *et al.*study the GUI spoofing vulnerabilities in IE browser [7]. Mulliner *et al.*discover GUI element misuse (GEM), a type of GUI related access control violation vulnerabilities and design GEM Miner to automatically detect GEMs [27]. SUPOR focuses on sensitive user input identification which is different from the problems studied by these existing works.

The closest related work is UIPicker [29], which also focuses on sensitive user input identification. UIPicker uses supervised learning to train a classifier based on the features extracted from the texts and the layout descriptions of the UI elements. It also considers the texts of the sibling elements in the layout file. Unlike UIPicker that uses sibling elements in the layout file as the description text for a UI widget, which could easily include unrelated texts as features, SUPOR selects only the text labels that are physically close to input fields in the screen, mimicking how users look at the UI, and uses the texts in the text labels to determine the sensitiveness of the input fields. Also, their techniques in extracting privacy-related texts could complement our NLP techniques to further improve our keyword dataset construction.

In the software engineering domain, there are quite a few efforts on GUI reverse engineering [25, 26, 32, 35] for GUI testing. GUITAR is a well-known framework for general GUI testing, and GUI ripper [26], a component of GUITAR targets general desktop applications, uses dynamic analysis to extract GUI related information and requires human intervention when the tools cannot fill in proper information in the applications. In [25] and [32], two different approaches have been proposed to convert the hard-coded GUI layout to model-based layout (such as XML/HTML layout). GUISurfer leverages source code to derive the relationships between different given UI widgets. In contract, SUPOR focuses on mobile apps and in particular Android apps, and leverages the facility from existing rapid UI development kits to identify and render UI widgets statically.

8 Conclusions

In this paper, we study the possibility of scalably detecting sensitive user inputs, an important yet mostly neglected sensitive source in mobile apps. We leverage the rapid UI development kits of modern mobile OSes to detect sensitive input fields and correlate these input fields to the app code, enabling various privacy analyses on sensitive user inputs. We design and implement SUPOR, a new static analysis tool that automatically identifies sensitive input fields by analyzing both input field attributes and surrounding descriptive text labels through static UI parsing and rendering. Leveraging NLP techniques, we build mobile app specific sensitive word vocabularies that can be used to determine the sensitiveness of given texts. To enable various privacy analyses on sensitive user inputs, we further propose a context-sensitive approach to associate the input fields with corresponding variables in the app code.

To demonstrate the usefulness of SUPOR, we build a privacy disclosure discovery system by combining SUPOR with static taint analysis to analyze the sensitive information of the variables that store the user inputs from the identified sensitive input fields. We apply the system to 16,000 popular Android apps, and SUPOR achieves an average precision of 97.3% and also an average recall of 97.3% in detecting sensitive user inputs. SUPOR finds 355 apps with privacy disclosures and the false positive rate is 8.7%. We also demonstrate interesting real-world cases related to national ID, username/password, credit card and health information.

Appendix

A Taint Analysis

The details of sinks and customizations of the taint analysi engine are shown in this section.

A.1 Sink Dataset

The sink dataset includes five categories of sink APIs, among which two categories are SMS send (*e.g.,*`SmsManager.sendTextMessage()`) and Network (*e.g.,*`HttpClient.execute()`). The other three are related to local storage: logging (*e.g.,*`Log.d()`), content provider writes (*e.g.,*`ContentResolver.insert()`), and local file writes (*e.g.,*`OutputStream.write()`). Totally there are 236 APIs.

A.2 Customizations of Taint Analysis

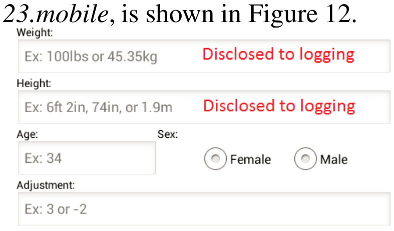
Our taint analysis engine constraints the taint propagation to only variables and method-call returns of `String` type. Therefore, method calls that return primitive types (*e.g.,*`int`) are ignored. There are two major reasons for making this tradeoff. The first is that the sensitive information categories we focus on are passwords, user names, emails, and so on, and these are usually not numeric values. The second is that empirically we found a quite number of false positives related to flows of primitive types due to the incompleteness of API models for the Android framework. This observation-based refinement suppresses many false positives. For example, one false warning we observed is that the length of a tainted string (`tainted.length()`) is logged, and tracking such length causes too many false positives afterwards. Since such flow does not disclose significant information of the user inputs, removing the tracking of such primitive values reduces the sources to track and improves the precision of the tracking.

To further suppress false warnings, we model data structures of key-value pairs, such as `Bundle` and `BasicNameValuePair`. `Bundle` is widely used for storing an activity's previously frozen state, and `BasicNameValuePair` is usually used to encode name-value pairs for HTTP URL parameters or other web transmission parameters, such as JSON. For each detected disclosure flow, we record the keys when the analysis finds method calls that insert values into the data structures, *e.g.,*`bundle.put("key1", tainted)`. For any subsequent method call that retrieves values from the data structures, *e.g.,*`bundle.get("key2")`, we compare the key for retrieving values `key2` with the recorded keys. If no matches are found, we filter out the disclosure flow.

B Example Apps in Case Studies

B.1 Example App for Disclosing National IDs

The UI for the first example app described in Section 5.5, *com.yes123.mobile*, is shown in Figure 12.



Weight:

Ex: 100lbs or 45.35kg — Disclosed to logging

Height:

Ex: 6ft 2in, 74in, or 1.9m — Disclosed to logging

Age: Ex: 34

Sex: ○ Female ○ Male

Adjustment: Ex: 3 or -2

Figure 13: Case study: health information disclosure.

B.2 Example App for Disclosing Health Information

Figure 13 shows the rendered UI of the layout *dpacacl* in app *com.canofsleep.wwdiary*, which belongs to the category HEALTH && FITNESS. This app discloses personal health information through the user inputs collected from the UI. As we can see, even though all input fields on the UI hold hint texts, these texts do not contain any sensitive keywords. Therefore, SUPOR still needs to identify the best descriptive text label for each input field. Based on the UI sensitiveness analysis, SUPOR successfully marks the first three input fields as sensitive, *i.e.,* the input fields that accept *weight*, *height* and *age*. But based on the taint analysis, only the first two input fields are detected with disclosure flows to logging. Similar to financial information, such health information about users' wellness is also very sensitive to the users.

UIPicker: User-Input Privacy Identification in Mobile Applications

Abstract

Identifying sensitive user inputs is a prerequisite for privacy protection. When it comes to today's program analysis systems, however, only those data that go through well-defined system APIs can be automatically labelled. In our research, we show that this conventional approach is far from adequate, as most sensitive inputs are actually entered by the user at an app's runtime: in our research, we inspect 17, 425 top apps from Google Play, and find that 35.46% of them involve sensitive user inputs. Manually marking them involves a lot of effort, impeding a large-scale, automated analysis of apps for potential information leaks. To address this important issue, we present *UIPicker*, an adaptable framework for automatic identification of sensitive user inputs. UIPicker is designed to detect the semantic information within the application layout resources and program code, and further analyze it for the locations where security-critical information may show up. This approach can support a variety of existing security analysis on mobile apps. We further develop a runtime protection mechanism on top of the technique, which helps the user make informed decisions when her sensitive data is about to leave the device in an unexpected way. We evaluate our approach over 200 randomly selected popular apps on Google-Play. UIPicker is able to accurately label sensitive user inputs most of the time, with 93.6% precision and 90.1% recall.

1 Introduction

Protecting the privacy of user data within mobile applications (*apps* for short) has always been at the spotlight of mobile security research. Already a variety of program analysis techniques have been developed to evaluate apps for potential information leaks, either dynamically [19, 23, 41] or statically [15, 26]. Access control mechanisms [27, 22, 33, 17] have also been proposed to enforce fine-grained security policies on the way that private user data can be handled on a mobile system. These techniques are further employed by mobile app marketplaces like Google Play (e.g., Bouncer [7]) to detect the apps that conduct unauthorized collection of sensitive user data.

Identifying sensitive user inputs. Critical to those privacy protection mechanisms is the labeling of sensitive user data. Some of the data are provided by the operating system (OS), e.g., the GPS locations that can be acquired through system calls like `getLastKnownLocation()`. Protection of such information, which we call *System Centric Privacy* data, can leverage relevant data-access APIs to set the security tags for the data. More complicated here is the content the user enters to a mobile app through its user interface (UI), such as credit-card information, username, password, etc. Safeguarding this type of information, called *User-Input Privacy* (UIP) data in this paper, requires understanding its semantics within the app, before its locations can be determined, which cannot be done automatically using existing techniques.

Just like the system-controlled user data (e.g., GPS), the private content entered through the UI is equally vulnerable to a variety of information-leak threats. It has been reported [5, 10, 4, 6] that adversaries can steal sensitive user inputs through exploiting the weaknesses inside existing protection mechanisms. For example, fraud banking apps to steal user's financial credentials with very similarity UIs. Besides, less security-savvy developers often inadvertently disclose sensitive user data, for example, transmitting plaintext content across public networks, which subjects the apps to eavesdropping attacks. Recent work further shows that side channels [18] and content-pollution vulnerabilities [42] can be leveraged to steal sensitive user inputs as well. In our research, we found that among 17,425 top Google-Play apps, 35.46% require users to enter their confidential information.

Given its importance, UIP data urgently needs protection. However, its technical solution is by no means trivial. Unlike system-managed user data, which can be easily identified from a few API functions, sensitive user inputs cannot be found without interpreting the context and semantics of UIs. A straightforward approach is to mark all the inputs as sensitive [15], which is clearly an overkill and will cause a large number of false positives. Prior approaches [43, 15, 36, 38, 40] typically rely on users, developers or app analysts to manually specify the contents within apps that need to be protected. This requires intensive human intervention and does not work when it comes to a large-scale analysis of apps' privacy risks.

To protect sensitive user inputs against both deliberate and inadvertent exposures, it is important to automatically recognize the private content the user enters into mobile apps. This is challenging due to the lack of fixed structures for such content, which cannot be easily recovered without analyzing its semantics.

Our work. To address this issue, we propose our research *UIPicker*, a novel framework for automatic, large-scale User-Input Privacy identification within Android apps. Our approach leverages the observation that most privacy-related UI elements are well-described in layout resource files or annotated by relevant keywords on UI screens. These UI elements are automatically recovered in our research with a novel combination of several natural language processing, machine learning and program analysis techniques. More specifically, UIPicker first collects a training corpus of privacy-related contents, according to a set of keywords and auto-labelled data. Then, it utilizes the content to train a classifier that identifies sensitive user inputs from an app's layout resources. It also performs a static analysis on the app's code to locate the elements that indeed accept user inputs, thus filtering out those that actually do not contain private user data, even though apparently they are also associated with certain sensitive keywords, e.g., a dialog box explaining how a strong password should be constructed.

Based on UIPicker, we further develop a runtime privacy protection mechanism that warns users whenever sensitive data leave the device. Using the security labels set by UIPicker, our system can inform users of what kind of information is about to be sent out insecurely from the device. This enables the user to decide whether to stop the transmission. UIPicker can be used by the OS vendors or users to protect sensitive user data in the presence of untrusted or vulnerable apps. It can be easily deployed to support any existing static and dynamic taint analysis tools as well as access control frameworks for automatic labeling of private user information.

To the best of our knowledge, UIPicker is the first approach to help detect UIP data in a large scale. Although the prototype of UIPicker is implemented for Android, the idea can be applied to other platforms as well. We implemented UIPicker based on FlowDroid [15] and built our identification model using 17,425 popular Google Play apps. Our evaluation of UIPicker over 200 randomly selected popular apps shows that it achieves a high precision (93.6%) and recall (90.1%).

Contributions. In summary, this paper makes the following contributions.

- We measure the distribution of UIP data based on 17,425 classified top free applications from different categories. The results show that in some categories, more than half of applications contain UIP data. Further protection of these UIP data is in urgent need.
- We propose UIPicker, a series of techniques for automatically identifying UIP data in large scale. Lots of existing tools can benefit from UIPicker for better privacy recognition in mobile applications.
- Based on UIPicker, we propose a runtime security enhancement mechanism for UIP data protection, which helps user to make informed decisions when such data prepare to leave the device with insecure transmission.
- We conduct a series of evaluation to show the effectiveness and precision of UIPicker.

Roadmap. The rest of this paper is organized as follows. Section 2 gives the motivation, challenges and identification scope of UIP data, then introduces some background knowledge about Android layout resources. Section 3 gives an overview of UIPicker and illustrates the key techniques applied for identifying UIP data. Section 4 describes the identification approach step by step. Section 5 describes the runtime security enhancement framework based on UIPicker's identification results. Section 6 gives some implementation details about UIPicker. Section 7 gives evaluation and Section 8 discusses the limitation of UIPicker. Section 9 describes related work, and Section 10 concludes this work.

2 Problem Statement

In this section, we first provide a motivating example of users' sensitive input in two UI screens, then we investigate challenges in identifying such data and clarify our identification scope of UIP data. We also give some background knowledge about Android layout resources for further usage.

Figure 1: Examples of User-Input Privacy (UIP) Data

app. In Figure 1(a), the user is required to input his/her detailed address for delivering products. Figure 1(b) requires user to input the credit card credential to accomplish the payment process. Many apps in mobile platform would require such sensitive data for various functional purposes. Most of such data are personal information that users are unwilling to expose insecurely to the public.

Although UIP data can be highly security-sensitive and once improperly exposed, could have serious consequences, little has been done so far to identify them at a large scale. The key issue here is how to automatically differentiate sensitive user inputs from other inputs. In our research, we check the top 350 free apps on Google Play, and find that on average each of them contains 11 fields across 6 UI screens to accept user inputs; however many of these fields do not accommodate any sensitive data. Static analysis tools like FlowDroid [15] only provide options to taint all user inputs as sensitive sources (e.g. *Element.getText()*). Analyzing in this way would get fairly poor results because sensitive user inputs we focus are mixed in lots of other sources we do not care. Such problem also exists in runtime protection on users' sensitive inputs. For example, in order to prevent sensitive user inputs insecurely leaking out, an ideal solution would be warning users when such data leave the device. Alerting all user inputs in this way would greatly annoy the users and reduce the usability because many normal inputs do not need to be treated as sensitive data.

2.2 Challenges

UIP data can be easily recognized by human. However, it is quite challenging for the machine to automatically identify such data with existing approaches in large-scale.

First, UIP data can not be identified through runtime monitoring. As these sensitive data are highly unstructured, they can not be simply matched by regex expressions when users input them. Besides, like any normal inputs, privacy-related inputs are sparsely distributed in various layouts in a single app, and most UI screens contain such private data require login or complex trigger conditions, which makes it very difficult for automatic testing tools like [8, 34] to traverse such UI screens exhaustively without manual intervention.

Identifying UIP data by traditional static analysis approaches is also impractical. In program code's semantic, sensitive input does not have explicit difference compared to normal input. Specifically, all of such input data can be accepted by apps, then transmitted out or saved in local storage in the same way, which makes it difficult to distinguish them through static analysis approaches.

UIPicker identifies UIP data in apps from another perspective, it analyzes texts describing sensitive inputs other than data themselves. This is because texts in UI screens usually contain semantic information that describes the sensitive input. Besides, layout description texts in layout files also contain rich semantic information to reveal what the specific element is intended to be in the UI screen by developers. UIPicker is primarily designed to help identify UIP data in *benign* apps. The identification results can be further used for security analysis or protection of users' sensitive data. Note that in this work we do not deal with malicious apps that intentionally evade our analysis, e.g., malware that constructs its layout dynamically or uses pictures as labels to guide users to input their sensitive data.

2.3 Identification Scope

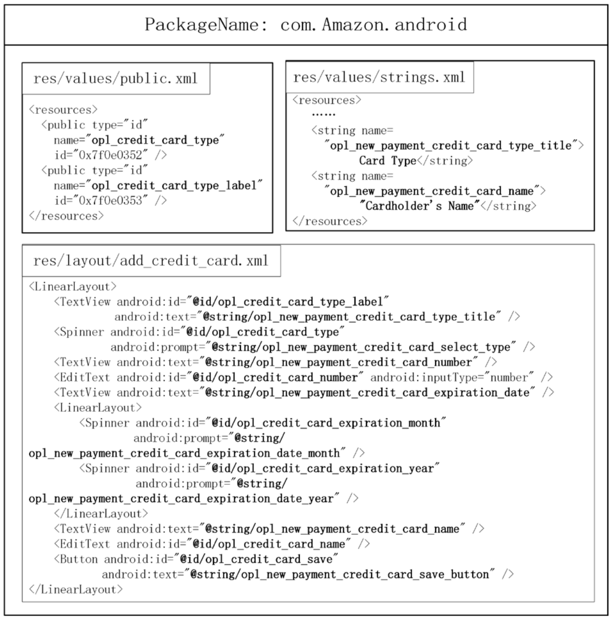
UIP data could be any piece of data that users consider to be sensitive from inputs. In the current version of UIPicker, we consider the following 3 categories as they cover most existing UIP data in current apps:

- **Account Credentials and User Profiles:** Information that reveals users' personal characters when they login or register, which includes but not limited to data such as username, user's true name, password, email address, phone number, birth date.
- **Location:** Plain texts that represent address information related to users. Different from system derived location (latitude and longitude), what we focus here is location data from users' input, e.g., the delivering address in shopping apps or the billing address for credit cards.
- **Financial:** Information related to users' financial activities, e.g., credit card number, expire date and security code.

The objective of UIPicker is to automatically identify such data from app resources in large-scale. Note that UIP data might not be limited to items listed here. UIPicker is capable of expanding its identification scope easily, as further discussed in Section 4.2.

2.4 Android Layout Background

Here we give some background knowledge about Android layout resources which UIPicker will use in our identification approach.



PackageName: com.Amazon.android

res/values/public.xml

```
<resources>
  <public type=″id″
    name=″opl_credit_card_type″
    id=″0x7f0e0352″ />
  <public type=″id″

            android:text=″@string/opl_new_payment_credit_card_save_button″ />
</LinearLayout>
```

Figure 2: Android Layout Description Resources

Layout resources define what will be drawn in the UI screen(s) of the app. In Android, a User Interface is made up of some basic elements (e.g., *TextView*, *EditText*, *Button*) to display information or receive input. Android mainly uses XML to construct app layouts, thus developers can quickly design UI layouts and screen elements they wish to contain, with a series of elements such as buttons, labels, or input fields. Each element has various attributes or parameters which are made up of name-value pairs to provide additional information about the element.

Android layout resources are distributed in different folders in the app package. Layout files for describing UI screens are located in folder *res/layout*. The unique hex digit IDs for identifying each element in layout files are in *res/value/public.xml* and texts showed in UI screens to users are in *res/values/strings.xml*. Resources in *res/values/* are referenced by texts with specific syntax (e.g. *@String, @id*) in the layout files in *res/layout* for ease of development and resource management.

Figure 2 shows some layout resources used for constructing the UI in Figure 1(b). The entry is a layout file named *add_credit_card.xml*. It contains two *EditText* elements to accept the credit card number and the card holder's name, three *Dropdown list* elements (named as *spinner* in Android) to let user select card type and expiration date. In the *EditText* for requesting the card number, it uses *@id/opl_credit_card_number* to uniquely identify this element for the app. Syntax like *android:inputType=number* suggests that this *EditText* only accepts digital input. There is also a *TextView* before *EditText* with attribute *android:text=@string/opl_new_payment_credit_card_number*, which means the content showed in this label will be string referenced to *opl_new_payment_credit_card_number* in */res/values/stings.xml*.

3 System Overview

In this section, we give an overview of UIPicker and describe the key techniques applied in our identification framework.

Overall Architecture. Figure 3 shows the overall architecture of UIPicker. UIPicker is made up of four components to identify layout elements which contain UIP data step by step. The major components can be divided into two phases: model-training and identification. In the model-training phase (Stage 1,2,3), UIPicker takes a set of apps to train a classifier for identifying elements contain UIP data from their textual semantics. In the identification Phase (Stage 1,3,4), UIPicker uses both the trained classifier (Stage 3) and program behavior (Stage 4) to identify UIP data elements.

Pre-Processing. In the Pre-Processing module, UIPicker extracts the selected layout resource texts and reorganizes them through natural language processing (NLP) for further usage. This step includes word splitting, redundant content removal and stemming for texts. Pre-Process can greatly reduce the format variations of texts in layout resources caused by developers' different coding practice.

Privacy-related Texts Analysis. For identifying UIP data from layout resources, the first challenge is how to get privacy-related texts. One can easily come up with a small set of words about UIP data, but it is very difficult to get a complete dictionary to cover all such semantics. In our case, leveraging an English dictionary like WordNet [14] for obtaining semantically related words is limited in the domain of our goals. Many words that are semantically related in privacy may not be semantically related in English, and many words that are semantically related in English may not appear in layout resource texts as well. For example, both "signup" and "register" represent to create a new account in an app's login screen, but

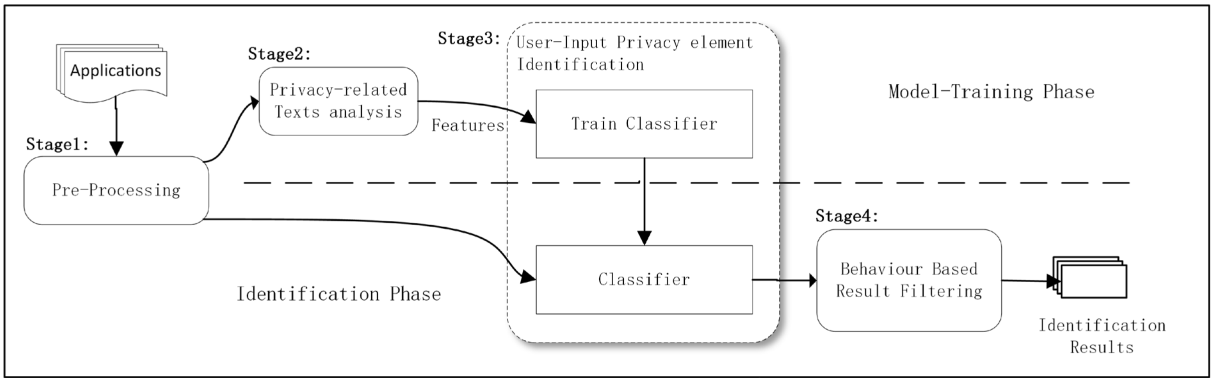

Figure 3: System Overview of UIPicker

they can not be correlated from a dictionary like WordNet.

Besides, UIP data in apps are often described with a single word or very short phrases (e.g. "password" or "input password") in layout resources. Due to the lack of complete sentences describing UIP data, natural language processing techniques [35] like dependency relation pattern extraction is not suitable in our scenario.

UIPicker expands UIP semantic texts with a few privacy-related seeds based on a specific feature extraction approach. It first automatically labels a subset of layouts which could contain UIP data by heuristic rules, then extracts privacy-related semantics from such layouts by applying clustering algorithms. It helps us to automatically extract privacy-related texts with little manual effort. As a result, these inferred texts can be used as features for identifying whether an element is privacy-related or not in the next step.

UIP Data Element Identification. Based on the given set of privacy-related textual semantics from the previous step, to what extent an element contains privacy-related texts can be identified as sensitive? As previous work [37] showed, purely relying on keyword-based search would result in a large number of false positives. For example, sensitive item "username" could always be split into "user" and "name" as two words in apps, and none of the single word can represent "username". Besides, certain words like "address" have a confounding meaning. For instance, such phrase showed in a layout screen "address such problem" does not refer to location information.

In this step, UIPicker uses a supervised machine learning approach to train a classifier based on a set of semantic features generated in the previous stage. Besides, it fully takes the element's context in the whole layout into consideration for deciding whether the element is privacy-related or not. With this trained model, for any given layout element with description texts, UIPicker can tell whether it is related to UIP from its textual semantics.

Behavior Based Result Filtering. Besides identifying elements that contain UIP data from their textual semantics, we also need to check whether a privacy-related element is actually accepting user input. In other words, we need to distinguish user inputs from other static elements such as buttons or labels for information illustration in layout screens. Although Android defines *EditText* for accepting user input, developers can design any type of element by themselves (e.g. customized input field named as *com.abc.InputBox*). Besides, apps also receive user inputs in an implicit way through other system defined elements without typing the keyboard by users. For example, in Figure 1(b), the expire date of credit card is acquired by selecting digits from the *Spinner* element.

We observe that for each privacy-related element identified by UIPicker in the previous stage, the data should be acquired by the app with user's consent if it is actually accepting user input. For example, the user clicks a button "OK" to submit data he/she inputs. When reflected in the program code, the user input data should be acquired by the system under certain event trigger functions. We use static code analysis to check whether an arbitrary element can be matched with such behavior, thus filter out irrelevant elements we do not expect.

4 IDENTIFICATION APPROACH

In this section, we explain the details of four stages in UIPicker's identification approach.

4.1 Stage 1: Pre-Processing

Resource Extraction. We first decode the Android APK package with apktool [2] for extracting related resource files we need. Our main interest is in UI-related content, thus for each app, we extract **UI Texts** and **Layout Descriptions** from its decompiled layout files.

Layout Resource	Sample
UI Texts	Add a new credit card, Credit Card Number Expiration Date, Card Type, Cardholder's name
Layout Descrioptions	@id/opl_credit_card_number @string/opl_new_credit_card_expiration_date_month @string/opl_new_credit_card_save_buton

Table 1: Selected resources of Amazon Online's "Add Credit Card" screen

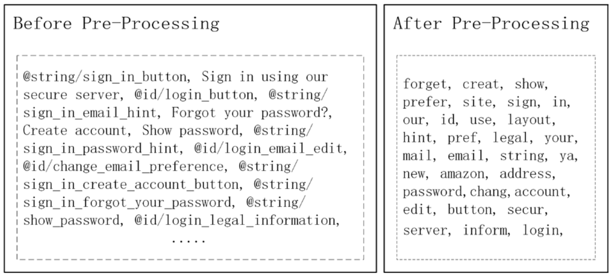
- **UI Texts**. UI texts are texts showed to users in the layout screen. In Android, most of such texts are located in */res/values/strings.xml* and referenced by syntax *@String/[UI text identifier]* in element's attribute. Some *UI texts* are directly written in layout files as attribute values of UI elements, e.g., *android:hint='Please input your home address here'*.
- **Layout Descriptions**. Layout Descriptions are texts only showed in layout files located in */res/layout/*. For these texts, we consider all strings starting with syntax @*id* and @*String* to reflect what the element is intended to be from their textual semantics.

The main difference between *UI texts* and *layout descriptions* is that *UI texts* are purely made up of natural language while *layout descriptions* are mainly name identifiers (both formatted and unformatted) with semantic information. As developers have different naming behaviors when constructing UIs, in most cases, semantic information in *layout descriptions* is more ambiguous than that in *UI texts*.

We extract these groups of resources for further analysis because these selected targets can mostly reflect the actual content of the app's layout. For example, the selected resources about Amazon's "Add Credit Card" screen in Figure 1(b) are showed in Table 1.

Word Splitting. Although most of *layout descriptions* are meaningful identifiers for ease of reading and program development, normally they are delimiter-separated words or letter-case separated words. For example, "phone number" can be described as "phone_number" or "PhoneNumber". Thus we split such strings into separated word sets. Besides, some of *layout descriptions* are concatenated by multiple words without any separated characters. For these data, we split them out by iteratively matching the maximum length word in WordNet [14] until the string cannot be split any more. For example, string "confirmpasswordfield" will be split into "confirm", "password", and "field".

Redundant Content Removal. For all *UI texts* we extracted, we remove non-English strings through encoding analysis. For each word, we also remove non-text characters from all extracted resources such as digits, punctuation. After this, we remove stop words. Stop words are some of the most common words like "the", "is", "have". We remove such contents because they can not provide meaningful help in our analysis process.



```
Before Pre-Processing

@string/sign_in_button, Sign in using our
secure server, @id/login_button, @string/
sign_in_email_hint, Forgot your password?,
Create account, Show password, @string/
sign_in_password_hint, @id/login_email_edit,

mail, email, string, ya,
new, amazon, address,
password, chang, account,
edit, button, secur,
server, inform, login,
```

Figure 4: After Pre-Processing, texts in left are transformed into formats in right

Stemming. Stemming is the process for reducing inflected (or sometimes derived) words to their stem, base or root form. Stemming is essential to make words such as "changed", "changing" all match to the single common root "change". Stemming can greatly improve the results of later identification processes since they reduce the number of words in our resources. We implement *Porter Stemmer* [11] with python NLTK module [9].

Figure 4 shows part of texts before and after preprocessing for Amazon's "Add credit card" layout file. As we can see, all texts concatenated by '_' are split into separated words, "edthomephonecontact" is split into "edt", "home", "phone" and "contact" instead. We also transform words like "forgot", "forget" into a single uniformed format as "forget".

4.2 Stage 2: Privacy-related Texts Analysis

In this stage, we use Chi-Square test [39] to extract privacy-related texts from a subset of specific layouts. The intuition here is that privacy-related words prefer to be correlated in specific UIs such as the login, registration or settings page of the app. If some words appear together in these UI, they are likely to have semantic relevance to users' sensitive information. Thus, we use such layouts to extract privacy-related texts in contrast to other normal layouts.

Chi-Square Based Clustering. Chi-Square (Chi^2) test is a statistical test that is widely used to determine whether the expected distributions of categorical variables significantly differ from those observed. Specifically in our case, it is leveraged to test whether a specific term on UI screens is privacy-related or not according to its occurrences in two opposite datasets (privacy-related or non privacy-related).

Here we choose *UI texts* rather than *layout descriptions* to generate privacy-related texts due to the follow-

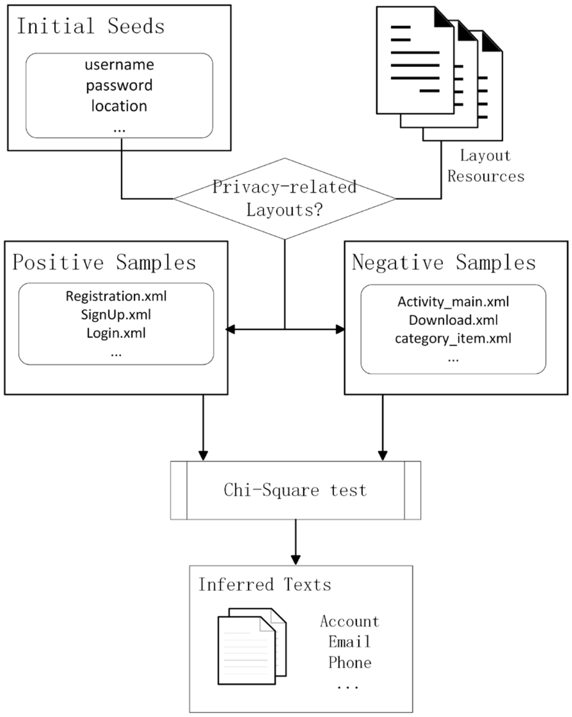

Figure 5: For each word assigned as the initial seed, UIPicker calculates its Chi-Square test for each word in positive samples and appends part of its top results into the privacy-related texts feature set.

ing two reasons: First, *layout descriptions* are not well structured as the naming behaviors vary very differently between apps (or developers), while *UI texts* are in a relatively uniformed format, thus making it easy to extract privacy-related texts from them. For example, a layout requesting a user's password must contain term "password" in the UI screen, while in layout descriptions it could be text like "pwd", "passwd", "pass". Second, as layout descriptions aim for describing layout elements, it may contain too much noisy texts like "button", "text" which would bring negative impact to the privacy-related text extraction.

Figure 5 shows how UIPicker generates privacy-related texts. First, we give a few words that can explicitly represent users' sensitive input we focus (e.g., email, location, credit card), and we call them *initial seeds*. Each layout sample is made up of a set of *UI texts* in its layout screen. Then, the initial seeds will be used to identify whether a specific layout sample is privacy-related or not based on the following two patterns:

- Logical relation between sensitive noun phrase (initial seed) and verb phrase, e.g., the pair (save, password).
- Logical relation between possessive (mainly word "your") and sensitive noun phrase (initial seed), e.g., the pair (your, username).

As such patterns strongly imply actions that the app is requesting the user's sensitive input, for those layout samples satisfying one of these two patterns, we label them as privacy-related (positive samples). On the other hand, for layout samples that do not contain any of texts in the pattern (both noun phrase and verb, possessive phase), we label them as negative samples. Note that we do not label those layouts only containing initial seeds as positive or negative because a single word is insufficient for us to identify whether the layout is privacy-related or not.

Based on the two classified sample sets, for all distinct words appearing in positive samples, we use Chi-Square test and rank their results in a descending order. As a result, texts with higher Chi-Square scores mean they are more representative as privacy-related, which can easily be picked up from the top-ranked words in the test results.

The following example explains our analysis approach for finding financial-related textual semantics. We set "credit card" as an initial seed, then the layout shown in Figure 1(b) will be identified as a positive sample because both "credit card" and verb phrase "add" are included in this layout. Thus in our dataset, other similar layouts will be labeled as positive if it requires users to input credit card information as well. As a result, the positive sample will include more texts such as "expire", "date", "year", "month", which are also related to financial credentials and ranked in top of the Chi-Square test results.

Noisy Text Removal. Although Chi-Square test aims to cluster privacy-related texts, it still unavoidably introduces some irrelevant texts into its clustering results. This is mainly because not all texts in privacy-related layout are necessarily related to privacy. In order to generate a highly precise cluster of privacy-related texts to eliminate false positives in the UIP data element identification process, we introduce a little manual effort here for filtering out such irrelevant texts from the clustering result. Since Chi-Square test already helps us extract texts that are most probably related to privacy, looking through such a list is quite simple and effortless.

Alternative Approaches. In our research, we compared the Chi-Square test with two popular alternatives, frequency based text extraction and TF-IDF [31], both of which are found to be less effective. They all bring in more irrelevant contents than the Chi-Square test, more susceptible to the limitation of the layout level samples, that is, privacy related UI screens often contain a lot of normal texts, which become noises in our sensitive term identification. Also, using these two approaches, we need to continuously adjust their thresholds for selecting privacy-related text when their sample sizes change. This can be avoided when using the Chi-Square test. Nevertheless, we acknowledge that there may exist other feature extraction mechanisms that could perform better, which is one of our future work.

4.3 Stage 3: UIP Data Element Identification

In this stage, we explain the details of our machine-learning approach, which automatically identifies UIP data elements based on their textual semantics. UIPicker uses supervised learning to train a classifier based on a subset of element samples with privacy-related semantic features. As a result, for a given unclassified UI element, this step could identify whether it is semantically privacy-related from its description texts.

Feature Selection. We use privacy-related texts inferred from the previous stage as features for the identification module. A single word alone usually does not provide enough information to decide whether a given element is privacy-related. However, all such features in combination can be used to train a precise classifier. The main reason why these features work is that both *UI texts* and *layout descriptions* do in fact reveal textual semantic information, which a machine learning approach such as ours can discover and utilize. Note that in *layout descriptions*, it is often the case that developers use text abbreviations for simplicity when naming identifiers. For example, “address” in layout descriptions could be “addr”. For this, we construct a mapping list of such texts we visited during the manual analysis. Thus, for each word in layout descriptions, we transform the abbreviation into complete one if it is contained by any privacy-related texts.

Besides, we also take semantic features of layout structure into consideration: the texts of this element’s siblings. We observe that many elements are described by texts in its siblings. For example, In Figure 1(b), most of input fields are described by static labels which contain privacy-related text as instructions for requesting user inputs. As a result, texts from sibling elements can bring more semantic information for better identification results.

The classifier works on a matrix organized by one column per feature (one word) and one row per instance. The dimension for each instance is the size of our feature set (the number of texts from the previous step). The additional column indicates whether or not this instance is a privacy-related element.

Training Data. Since text fields can have different input types for determining what kind of characters are allowed inside the field, Android provides the *android:inputType* attribute to specify what kind of characters are allowed for *EditText*. For example, an element with *inputType* valued *textEmailAddress* means only email address is accepted in this input field. There are several input types explicitly reflect the element containing UIP data we focus on, which can be used as the training data of the identification module. We list such sensitive attribute values[1] in the first column of Table 2.

Privacy Category	Attribute Value
Account Credentials & User Profile	textEmailAddress textPersonName textPassword textVisiblePassword password/email/phoneNumber
Location	textPostalAddress

Table 2: Sensitive attribute values in layout descriptions

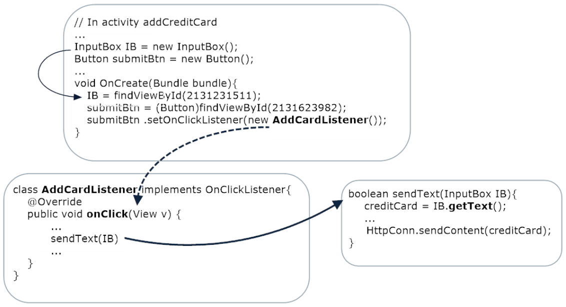
The training data is constructed as follows: First, we automatically label all elements with sensitive attributes as positive samples since they are a subset of UIP data elements. We further manually label a set of elements involving financial information from the category “Financial” because such elements are covered by sensitive attributes Android provides. Besides, a set of negative samples are picked out through human labeling after filtering out the elements that contain any of the privacy-related texts we generated in Stage 2.

Classifier Selection. We utilize the standard support vector machine (SVM) as our classifier. SVM is widely used for classification and regression analysis. Given a set of training examples with two different categories, the algorithm tries to find a hyper-plane separating the examples. As a result, it determines which side of hyper-plane the new test examples belong to. In our case, for an unclassified unknown layout element with corresponding features (whether or not containing privacy-related texts extracted in the previous step) the classifier can decide whether it contains UIP data or not from its textual semantics.

4.4 Stage 4: Behavior Based Result Filtering

As a non-trivial approach for identifying UIP data, for each element identified as privacy-related from its layout descriptions, UIPicker inspects the behaviors reflected in its program code to check whether it is accepting user inputs, thus filtering out irrelevant elements from the identification results in the previous step.

[1] In some older apps, developers also use specific attribute like “android:password=True” to achieve the same goal as *inputType*. We list them in Table 2 and call them sensitive attribute values as well for simplicity.



```
// In activity addCreditCard
...
InputBox IB = new InputBox();
Button submitBtn = new Button();
...
void OnCreate(Bundle bundle){
  IB = findViewById(2131231511);
  submitBtn = (Button)findViewById(2131623982);
  submitBtn .setOnClickListener(new AddCardListener());
}
```

```
class AddCardListener implements OnClickListener{
   @Override
   public void onClick(View v) {
        ...
        sendText(IB)
        ...
   }
}
```

```
boolean sendText(InputBox IB){
   creditCard = IB.getText();
   ...
    HttpConn.sendContent(creditCard);
}
```

Figure 6: Sample codes for requesting a user's credit card number

User input data is generated based on a user's interactions with the app during runtime. In other words, the data will be acquired by the app under the user's consent. In Android, to get any data from a UI screen is achieved by calling specific APIs. Getting such data under user consent means these APIs are called under user-triggered system callbacks. For example, code fragments in Figure 6 shows the behavior reflected in the program when the app gets the user's credit card number in Figure 1(b). Here, the input field *IB* is defined by *IB=findViewById(21...1)* in activity *addCreditCard*. When the user clicks the "Add your card" button, in the program code, the *OnClick()* function in class *AddCardListener()* will be triggered by pre-registered system callback *submitBtn.setOnClickListener()*. Then, it invokes *sendText(IB)*, which sends the inputBox's object by parameter, and finally gets the user's card number by *IB.getText()*. One might consider why don't catch UIP data simply by checking whether the element is invoked by *getText()* API. The reason is that sometimes developers may also get values from UI screens like static text labels as well as user inputs, resulting in false negatives for our identification approach.

5 Runtime Security Enhancement with UIPicker

The security implications about UIP data are rooted from the fact that users have to blindly trust apps when they input sensitive data. With the help of UIPicker differentiating UIP data from other normal inputs, we can use taint tracking techniques to trace users' sensitive inputs and enable users to make informed decisions with a popup window when such data insecurely leave the device, thus effectively mitigating the potential threats posed by apps.

For UIP data, we consider the following two situations as insecure and should inform users to let them decide whether to proceed or not.

Plain Text Transmission. We consider any piece of UIP data should not be transmitted in plain text. Such situation can be easily identified by checking if the tainted sink is HTTP connection in runtime.

Insecure SSL Transmission. Previous works [34] showed that a large number of apps implement SSL with inadequate validations (e.g., app contains code that allows all hostnames or accepts all certificates). Insecure SSL transmission could be more dangerous because they may carry over critical sensitive data in most cases. UIP data should not be transmitted in this way as well.

Since UIPicker is deployed in off-line analysis by customized system vendors, one can also check whether the apps have securely implemented SSL off-line at the same time. We integrate a static analysis framework named MalloDroid [20] with UIPicker to automatically check SSL security risks by evaluating the SSL usage in apps. As MalloDroid can only find broken SSL usage regardless what data is transmitted via this channel, we also use FlowDroid to check if there exists data/control flow intersections between UIP data sources and SSL library invocation sinks in the app, thus confirming whether the UIP data in the app will be transmitted with security risks.

6 IMPLEMENTATION

Dataset. We crawled apps from Google Play Store based on its pre-classified 35 categories in Oct. 2014. For each category, we downloaded the top 500 apps. Excepting some connection errors occurred in the crawling process, totally we collected 17,425 apps as our dataset. This dataset will be used in both model training and evaluation of UIPicker.

Identification Approach. We implement the prototype of UIPicker as a mix of Python Scripts and Java code. The first three steps of UIPicker are developed using Python with 3,624 lines of code (LOC). The last step, static analysis for result filtering, is implemented in Java, which extends FlowDroid[15] and introduces additional 985 LOCs. All experiments are performed on a 32 core Debian server with Linux 2.6.32 kernel and 64GB memory.

For privacy-related text analysis, the initial seeds are assigned as texts in the second column of Table 3 for each privacy category. For each initial seed, we run the Chi-Square test using apps in our dataset. Since Android allows developers to use nested layout structures for flexibility, we also group sub-layout *UI texts* into their root layouts. For each round, we collect the top 80 words from the test results, this threshold is determined by balancing between the number of privacy-related terms that can be detected and the amount of noisy text introduced. After 7 (7 initial seeds) rounds of the Chi-Square test, we collect 273 words from layout samples (some texts are overlapped in different round of Chi-Square test). We then remove 45 words as the noisy text by manual analysis within less than 3 minutes. As a result, UIPicker extracts 228 privacy-related terms from 13,392 distinct words. We list part of them in the third column of Table 3 corresponding to the privacy category they belong to. Such data are used as features for privacy-related element identification in the follow-up step.

Table 3: Initial seeds and part of inferred privacy-related texts from Chi-Square test

The SVM classifier is implemented with scikit-learn[13] in poly kernel. We optimize the classifier parameters (gamma=50 and degree=2) for performing the best results.

For each element identified as privacy-related by the machine learning classifier, UIPicker conducts static taint analysis using FlowDroid[15] to check whether it satisfies specific behavior described in Section 4.4. Since FlowDroid successfully handles android life cycle (system event based callbacks) and UI widgets, the dataflow results should be both precise and complete. We set FlowDroid's layout mode as "ALL" to get each element's propagation chain that starts with function *findViewById([elementId])* and ends in *getText()*. As a result, for any element's info-flow path which contains system event function like *OnClick()*, the element can be identified as accepting user input.

Runtime Enhancement For each app, we use a list of elements containing UIP data identified from UIPicker with their unique IDs as the taint sources of TaintDroid[19] build in Android 4.1. Since TaintDroid allows 32 different taint markings through a 32-bit bitvector to encode the taint tag, for those UIP data elements involved in insecure SSL usage, we label them as "SSL Insecure" in the taint source list, thus provide warnings to users when such data leave the device as well. We add a pop-up window for showing the leaked information to users when sensitive data leave the device. Our modification to TaintDroid is implemented with 730 LOCs in total.

7 Evaluation

In this section, we present our evaluation results. We first show the performance of UIPicker in Section 7.1, then we discuss its effectiveness and precision in Section 7.2 and Section 7.3. Then we evaluate our runtime security enhancement mechanism in Section 7.4.

7.1 Performance

During our experiment, the training phase of the classifier takes about 2.5 hours on average, the identification phase for the whole dataset takes 30.5 hours (6.27 seconds per app). Pre-Processing time for apps is included in both of these two phases. The static analysis for behaviour based result filtering is proceeded in 32 threads concurrently. Since UIPicker mainly targets for customized system vendors or security analysts, we consider such overhead quite acceptable.

7.2 Effectiveness

UIP Data Distribution. We show the general identification results of UIPicker in Table 4. In 17,425 apps, UIPicker finds that 6,179 (35.46%) contain UIP data. We list our results in a descending order of the identified total app amounts. As we can see, in 9 out of 35 categories, more than half of apps contain UIP data.

We make the following observations from this table. First, application categories such as BUSINESS, FINANCE, SHOPPING, COMMUNICATION and SOCIAL are more likely to request Account Credentials and User Profile information, which showed that these apps are closely related to users' personal activities. APP_WIDGETS (54.08%) is also ranked among top of the table. It is a set of apps which have small UIs embedded in the home screen of the device, e.g., Facebook, Youtube, Twitter. Since most of such apps provide login and account-specific functions, they prefer to request more UIP data as well. The SHOPPING category contains many location-related elements (1,605, 37%) because the delivering address are always generated from user inputs. It is also reasonable that both FINANCE and SHOPPING apps require many financial-related sensitive inputs. We believe such apps containing rich UIP data should be treated more carefully in both developing and security vetting process in order to make sure that sensitive data are well protected in both transmission and storage.

Comparative Results. We illustrate the effectiveness of UIPicker from two aspects. First, UIPicker identifies privacy data that system defined APIs do not touch but still be sensitive to users. Second, UIPicker achieves far better coverage than simply identifying UIP data by specific sensitive attribute values from the Android design specification.

Comparison with System Defined Sensitive APIs. As previously mentioned, specific sensitive resources

Application Category	Account Credentials & User Profile		Location		Financial		Total	
	#element	%app	#element	%app	#element	%app	#element	%app

Table 4: UIP data distribution. #element denotes the number of UIP data elements in each category by different privacy type. %app denotes the percentage of apps in which these elements appear (500 per category). The last column shows the total number of UIP data elements and apps that contain UIP data.

Privacy Category	Android System Defined APIs
Account Credentials & User Profile	android.tel...TelephonyManager getLine1Number() android.accounts.AccountManager getAccounts()
Location	and...LocationManager getLastKnownLocation() android.location.Location: getLongitude() android.location.Location: getLatitude()

Table 6: System defined sensitive APIs related to UIPicker's identification scope

such as phonenumber, account and location can be regulated by fixed system APIs which we list in Table 6. We compare the amount of UIPicker's identification results with Android system derived sensitive data, which can help us understand to what extent, system defined sensitive APIs are insufficient to cover users' privacy.

As Table 5 shows, in our dataset, 4,900 apps use system defined APIs for requesting Account Credentials and Profile Information while UIPicker identifies 5,330 (30.59%) apps containing UIP. UIPicker identifies 2,883 (16.26%) apps in the whole dataset that request location privacy data from user inputs. Besides, 1,318 (7.57%) apps request financial privacy data from users, and none of system defined APIs can regulate such data. In general, UIPicker identifies 6,179 (35.46%) apps containing at least one category of UIP data, which have been largely neglected by previous work in privacy security analysis and protection.

As Column 4 in Table 5 shows, there is some overlap between system defined APIs and UIP data (1,340 for Account Credentials & User Profile, 2,282 for Location respectively). For each app, we check whether it contains both the system defined APIs and the UIP data in the same privacy category, e.g., invoking the getLastKnownLocation() API and requesting address information from the user input of the same app. In some cases, the same piece data may come from either UI input or API call. For example, using a phone number as the login account of the app. However in most cases, the overlapped data in the same privacy category may come from different sources without overlapping in code paths. For example, the invocation of get-location APIs is used for realtime geographic locating, while some location input could be

Privacy Category	System Defined APIs (#Apps)			Elements with Sensitive Attribute Values (#Elements)		
	API	UIPicker	Overlap	InputType	UIPicker	Incremental
Account Credentials & User Profile	4,900	5,330	1,340	24,021	46,227	26,087
Location	15,221	2,883	2,282	941	14,311	13,370
Financial	-	1,318	-	-	6,353	-
Total	15,632	6,179	-	24,962	71,224	46,262

Table 5: We compare UIPicker's identification results with apps containing system defined sensitive APIs (column 2-4) and elements containing sensitive attribute values (column 5-7).

a shopping address for delivering goods. Since precisely analyzing which input element may overlap with system defined APIs requires additional information-flow analysis, which is beyond this paper's scope, we leave it as future work for measuring the relationship between these two types of sensitive data.

Comparing to sensitive attribute values. In Section 4.3, we use elements containing sensitive attribute values as part of training data for our identification module. However, they can only cover a portion of UIP data because they are not intended for this purpose. Here we compare the amount of UIPicker's identification results with elements containing sensitive attribute values to show the effectiveness of UIPicker.

As Table 5 shows, in general, UIPicker identifies 46,262 more UIP data elements than simply identifying them by sensitive attribute values (e.g. textPassword). Especially for the Location category, UIPicker identifies 14,311 elements, which is nearly 15 times more than simply identifying them based on attribute "textPostalAddress".

Types of UIP Elements. We list the identification results of UIP data elements other than *EditText* in Table 7. In general, UIPicker finds 18,403 (25.84%) elements other than *EditText* to accept users' sensitive inputs. It is interesting to note that UIPicker also finds a large portion of *TextView* as UIP data elements. In most cases, although data in *TextViews* are not editable, they could be generated by users from other layouts and dynamically filled in *TextView* later. For example, the data from previous steps of a registration form, or fetched from the server after users' login. There are 5,075 (7.13%) customized input elements and 1,962 (2.75%) dropdown lists (*Spinners*) containing UIP data. Type "Others" in table contains elements such as *RadioButton*, *CheckBox*.

7.3 Precision

For evaluating the precision of UIPicker, we perform the evaluation of classifier based on the machine-leaning dataset mentioned in Section 4. We also conduct a manual validation for two reasons. First, since the training data of classifier is not absolutely randomly selected (part of them are labeled by sensitive attributes automatically), a manual validation is required to confirm that the identification results of the classifier carries over the entire dataset. Second, the classifier is only capable of distinguishing UIP data elements from their textual semantics, the manual validation can be used to check whether static text labels are effectively excluded by UIPicker after behaviour based result filtering.

Type	# Elements	% in UIP Data
TextView	10,582	14.86%
Customized	5,075	7.13%
Spinner	1,962	2.75%
Others	784	1.10%
Total	18,403	25.84%

Table 7: Types of UIP Elements Other than EditText

Evaluation of Classifier. The training set contains 53,094 elements in total, which includes 24,962 labeled by sensitive attribute values and financial-related elements, with 25,331 negative samples labeled by manual efforts.

We use ten-fold cross validation which is the standard approach for evaluating machine-learning classifiers. We randomly partition the entire set of sample elements into 10 subsets, and we train the classifier on nine of them and then test the remaining 1 subset. The process is repeated on each subset for 10 times. In the end, the average precision and recall is 92.5% and 85.43% respectively.

As shown in Table 8, we also compare the average precision and recall with other two classifiers, i.e., One-Class Support Vector Machine learning (OC-SVM) [32] and Naive Bayes [30]. The results show that the standard SVM performs the best. We tried OC-SVM with only positive samples (elements containing sensitive attributes) to train the classifier. OC-SVM generated more false negatives than the standard SVM due to the lack of negative samples. Naive Bayes, a traditional probabilistic learning algorithm, also produced very imprecise results. This happens especially when it deals with elements that contain low-frequency privacy-related texts.

Classifier	Avg.Precision	Avg.Recall
SVM	92.50%	85.43%
OC-SVM	93.74%	68.48%
Naive Bayes	95.42%	26.70%

Table 8: Classifier Comparison

Manual Validation. We envision UIPicker to be used as an automated approach for labeling elements that contain UIP data. UIPicker achieves this by using some easily available UIP data (elements containing sensitive attributes or hand-annotated) and then using the classifier to automatically explore larger parts of UIP data. Measuring precision is hard in this setting as there is no entire pre-annotated elements (labeling sensitive or insensitive for all of them) for a set of apps that could compare with UIPicker's identification results.

As a best-effort solution, we randomly select 200 apps from top 10 categories (20 in each) ordered by %apps which UIP data appear most in Table 4 as the manual validation dataset. As such categories may contain much more UIP data than others, it provides the opportunity that our experts can walk through less apps (and activities) to validate more UIP elements. The selected apps are excluded from the classifier's training process to avoid overlap. Such way can greatly improve the effectiveness of the manual validation. Since the subset of apps is randomly picked, we believe that the evaluation results can provide a reasonable accuracy estimation on the entire dataset. For each element that UIPicker identifies as UIP data, we check their corresponding descriptions in XML layout files with some automated python scripts for efficiency (quickly locating the element in layout files and trying to understand it from descriptions). If this is still insufficient for us to identify whether it is a UIP data element, we confirm them by launching the app and find the element in the layout screen. The manual validation over 200 apps shows that UIPicker identifies 975 UIP data elements with 67 false positives and 107 false negatives.

False Positives: The false positive rate is 6.4% (67/1042 elements UIPicker identifies). In most cases, this is caused by the element's neighbors. That is, the element's neighbors contain privacy-related texts while the element itself is not privacy-related. Consider the following example, an *EditText* with only one description "message" while its previous element requires the user to input username with many sensitive textual phrases. As UIPicker takes neighbor elements' texts into consideration for better identification results, the privacy-related texts in its neighbor make UIPicker falsely identify the current element as UIP data. We consider such false alarm as acceptable because once such false alarm happens, their neighbor elements (the actual UIP data elements) are very possible to be identified by UIPicker as well.

False Negatives: We manually inspect each app in the evaluation dataset by traversing their UI screens as much as possible to see whether there exists UIP data elements that missed by UIPicker. In 200 apps, we find 107 elements not identified by UIPicker as privacy-related, and we conclude the reasons as follows: (1) Some very low-frequency texts representing UIP were not inferred from UIPicker by the privacy-related text analysis module. For example, "CVV" represents the credit card's security code, however we find this only happened in 4 Chinese apps. The low occurrence frequency of texts like "CVV" in our croups makes UIPicker fail to add them as features for the identification process. (2) In static analysis for behavior-based element filtering, due to FlowDroid's limitations, the call trace of some element was broken in inter-procedural analysis which makes UIPicker miss such elements in the final output.

Based on the total number of TPs, FPs and FNs (975, 67, 107), we compute the precision and recall of UIPicker as follows:

$$Precision = \frac{TP}{TP+FP} \qquad Recall = \frac{TP}{TP+FN}$$

Overall, UIPicker precisely identified most of UIP data, with 93.6% precision and 90.1% recall.

7.4 Runtime Enhancement Evaluation

System Overhead. We compare the performance overhead with TaintDroid using Antutu Benchmark [3]. We run Antutu 10 times in both systems under a Nexus Prime device, and the average scores are basically the same. This is reasonable because our mechanism only provides additional UIP data sources. We conclude that the security enhancement mechanism does not introduce noticeable additional performance overhead to TaintDroid.

Case Study. We find that some critical UIP data are under threats in Android apps. In Figure 7, a popular travel app "Qunar", which has 37 million downloads in China [12], sends users' credit card information with vulnerable SSL implementation during the payment process. The insecure transmission is reported to the user with a pop-up window when such data leave the device, thus the user can decide whether to proceed or use an alternative payment method to avoid the security risk.

8 Discussion

In this section, we discuss the general applicability of UIPicker, as well as limitations and future work.

UIPicker is able to efficiently handle UIP data which previous work does not concentrate on, nor be able to cover. Compared with existing approaches that focus on System-Centric Privacy data, UIPicker rethinks privacy from a new perspective: sensitive data generated from user inputs, which is largely neglected for a long period. UIPicker provides an opportunity for users to make informed decisions in a timely manner when sensitive data leave the device insecurely, instead of letting users assume the app can be trusted.

UIPicker uses not only texts in UI screens but also texts in layout descriptions for UIP data identification. This framework is generic to all kinds of apps without locality limitation. The way UIPicker correlates UIP data from layout descriptions could also be leveraged by existing work [37, 28] that attempts to map the permission usage with app descriptions.

UIPicker has the following limitations. (1) UIPicker does not consider dynamically generated UI elements, although we have not found any UIP data element being generated at runtime in our experiments. Dynamic UI elements could be analyzed through more sophisticated static/dynamic analysis with the app’s program code, which is our future work. (2) Currently, UIPicker can not handle sensitive user inputs in *Webview* because they are not included in app layout resources. In the future, we plan to download such webpages by extracting their URLs from the app, then analyze their text contents as well.

9 RELATED WORK

Privacy source identification. Existing work [16, 29] focuses on mapping Android system permissions with API calls. PScout [16] proposes a version-independent analysis tool for complete permission-to-API mapping through static analysis. SUSI [29] uses a machine learning approach to classify and categorize more Android sources and sinks which are missed by previous info-flow taint tracking systems. The most similar work with UIPicker is SUPOR [25], which also aims to automatically identify sensitive user inputs using UI rendering, geometrical layout analysis and NLP techniques. SUPER mainly focuses on specific type of UI elements (EditText) while UIPicker is not limited to this.

Text analysis in Android app. Several studies utilize UI text analysis for different security proposes. AsDroid [24] detects stealthy behaviors in Android app by UI textual semantics and program behavior contradiction. However, it only uses a few keywords to cover sensitive operations such as “send sms”, “call phone”. CHABADA [21] checks application behaviors against application descriptions. It groups apps that are similar with each other according to their text descriptions. The machine learning classifier OC-SVM is used in CHABADA to identify apps whose used APIs differ from the common use of the APIs within the same group. Whyper [37] uses natural language processing (NLP) techniques to identify sentences that describe the need for a given permission in the app description. It uses Stanford Parser to extract short phrases and dependency relation characters from app descriptions and API documents related to permissions. AutoCog [28] improves Whyper’s precision and coverage through a learning-based algorithm to relate descriptions with permissions. UIPicker could potentially leverage their techniques to generate more complete privacy-related texts for UIP data identification.

Static analysis. There are lots of work [24, 26, 15, 20, 34] on using static analysis to detect privacy leakage, malware or vulnerabilities in Android apps. AsDroid takes control flow graphs and call graphs to search intent from API call sites to top level functions (Activities). UIPicker’s behavior-based result filtering is similar to AsDroid while they have different goals. SMV-HUNTER [34] uses static analysis to detect possible MITM vulnerabilities in large scale. The static analysis extracts input information from layout files and identifies vulnerable entry points from the application program code, which can be used to guide dynamic testing for triggering the vulnerable code.

10 CONCLUSION

In this paper, we propose UIPicker, a novel framework for identifying UIP data in large scale based on a novel combination of natural language processing, machine learning and program analysis techniques. UIPicker takes layout resources and program code to train a precise model for UIP data identification, which overcomes existing challenges with both good precision and coverage. With the sensitive elements identified by UIPicker, we also propose a runtime security enhancement mechanism to monitoring their sensitive inputs and provide warnings when such data insecurely leave the device. Our evaluation shows that UIPicker achieves 93.6% precision and 90.1% recall with manual validation on 200 popular apps. Our measurement in 17,425 top free apps shows that UIP data are largely distributed in market apps and our run-time monitoring mechanism based on UIPicker can effectively help user to protect such data.

Abstract

In this study we characterize the extent to which cyber security incidents, such as those referenced by Verizon in its annual Data Breach Investigations Reports (DBIR), can be predicted based on externally observable properties of an organization's network. We seek to proactively forecast an organization's breaches and to do so without cooperation of the organization itself. To accomplish this goal, we collect 258 externally measurable features about an organization's network from two main categories: mismanagement symptoms, such as misconfigured DNS or BGP within a network, and malicious activity time series, which include spam, phishing, and scanning activity sourced from these organizations. Using these features we train and test a Random Forest (RF) classifier against more than 1,000 incident reports taken from the VERIS community database, Hackmageddon, and the Web Hacking Incidents Database that cover events from mid-2013 to the end of 2014. The resulting classifier is able to achieve a 90% True Positive (TP) rate, a 10% False Positive (FP) rate, and an overall 90% accuracy.

1 Introduction

Recent data breaches, such as those at Target [35], JP Morgan [25], and Home Depot [49] highlight the increasing social and economic impact of such cyber incidents. For example, the JP Morgan Chase attack was believed to be one of the largest in history, affecting nearly 76 million households [25]. Often, by the time a breach is detected, it is already too late and the damage has already occurred. As a result, such events call into the question whether these breaches could have been predicted and the damage avoided. In this study we seek to understand the extent to which one can forecast if an organization may suffer a cyber security incident in the near future.

Machine learning has been used extensively in the cyber security domain, most prominently for *detection* of various malicious activities or entities, e.g., spam [44, 45] and phishing[39]. It has been used far less for the purpose of *prediction*, with the notable exception of [51], where textual data is used to train classifiers to predict whether a currently benign webpage may turn malicious in the near future. The difference between detection and prediction is analogous to the difference between diagnosing a patient who may already be ill (e.g., by using biopsy) vs. projecting whether a presently healthy person may become ill based on a variety of relevant factors. The former typically relies on identifying known characteristics of the object to be detected, while the latter on factors believed to correlate with the prediction objective.

To explore the effectiveness of forecasting security incidences we begin by collecting *externally* observed data on Internet organizations; we do not require information on the internal workings of a network or its hosts. To do so, we tap into a diverse set of data that captures different aspects of a network's security posture, ranging from the *explicit* or *behavioral*, such as externally observed malicious activities originating from a network (e.g., spam and phishing) to the *latent* or *relational*, such as mismanagement and misconfigurations in a network that deviate from known best practices. From this data we extract 258 features and feed them to a Random Forest (RF) classifier. We train and test the classifier on these features and more than 1,000 incident reports taken from the VERIS community database [55], Hackmageddon [42], and the Web Hacking Incidents Database [31] that cover events from mid-2013 to 2014. The resulting classifier can be configured over a wide range of operating points including one with 90% True Positive (TP) rate, 10% False Positive (FP) rate and an overall accuracy of 90%.

We posit that such cyber incident forecasting offers a completely different set of characteristics as compared to detection techniques, which in turn enables entirely new classes of applications that are not feasible with detection techniques alone. First and foremost, prediction allows *proactive* policies and measures to be adopted rather than *reactive* measures following the detection of an incident. Effective proactive actions can substantially reduce the potential cost incurred by an incident; in this sense prediction is complementary to detection. Cyber incident prediction also enables the development of effective risk management schemes such as cyber insurance, which introduces monetary incentives for the adoption of better cyber security policies and technologies. In the wake of recent breaches, the market for such policies has soared, with current written annual premiums estimated to be between $500M and $1B [47].

The remainder of the paper is organized as follows. Section 2 introduces the datasets used in this study and details the rationale for their use as well as our processing methodology. We then define the features we use in constructing the classifier and show why they are relevant in predicting security incidents in Section 3. We present the main prediction results as well as their implications in Section 4. In Section 5 we discuss a number of observations and illustrate several major data breaches in 2014 in the context of this prediction methodology. Related work is detailed in Section 6, and Section 7 concludes the paper.

2 Data Collection and Processing

Our study draws from a variety of data sources that collectively characterize the security posture of organizations, as well as security incident reports used to determine their security outcomes. These sources are summarized in Table 1 and detailed below; a subset of these has been made available at [7].

2.1 Security Posture Data

An organization's network security posture may be measured in various ways. Here, we utilize two families of measurement data. The first is measurements on a network's misconfigurations or deviations from standards and other operational recommendations; the second is measurements on malicious activities seen to originate from that network. These two types of measurements are related. In particular, in [58] Zhang et al. quantitatively established varying degrees of correlation between eight different mismanagement symptoms and the amount of malicious activities from an organization. The combination of both of these datasets represents a fairly comprehensive view of an organization's externally discernible security posture.

2.1.1 Mismanagement Symptoms

We use the following five mismanagement symptoms in our study, a subset of those studied in [58].

Open Recursive Resolvers: Misconfigured open DNS resolvers can be easily used to facilitate massive amplification attacks that target others. In order to help the network operations community address this wide spread threat, the Open Resolver Project [14] actively sends a DNS query to every public IPv4 address in port 53 to identify misconfigured DNS resolvers. In this study, we use a data snapshot collected on June 2, 2013. In total, 27.1 million open recursive resolvers were identified.

DNS Source Port Randomization: In order to minimize the threat of DNS cache poisoning attacks [13], current best practice (RFC 5452 [34]) recommends that DNS servers implement both source port randomization and a randomized query ID. Many servers however have not been patched to implement source port randomization. In [58], over 200,000 misconfigured DNS resolvers were detected based on the analysis over a set of DNS queries seen by VeriSign's .com and .net TLD name server on February 26, 2013. This is the data used in this study.

BGP Misconfiguration: BGP configuration errors or reconfiguration events can cause unnecessary routing protocol updates with short-lived announcements in the global routing table [40]. Zhang et. al detected 42.4 million short-lived routes with BGP updates from 12 BGP listeners in the Route Views project [32] during the first two weeks of June 2013 [58]; this data is used in our study.

Untrusted HTTPS Certificates: Secure websites utilize X.509 certificates as part of the TLS handshake in order to prove their identity to clients. Properly configured certificates should be signed by a browser-trusted certificate authority. It is possible to detect misconfigured websites by validating the certificate presented during the TLS handshake [33]. An Internet scan performed on March 22, 2013 found that only 10.3 million out of a total of 21.4 million sites presented browser-trusted certificates [58]. We use this dataset in our study.

Open SMTP Mail Relays: Email servers should perform filtering on the message source or destination to only allow users in their own domain to send email messages. This is documented in current best practice (RFC 2505 [38]), and misconfigured servers can be used in large scale spam campaigns. Though small in number, these represent a severe misconfiguration in an organizations' infrastructure. In this study, we use data collected on July 23, 2013, which detected 22,284 open mail relays [58].

None of the datasets mentioned above is necessarily directly related to a vulnerability. The presence of misconfigurations in an organization's networks and infras-

Category	Collection period	Datasets
Mismanagement symptoms	February 2013 - July 2013	Open Recursive Resolvers, DNS Source Port Randomization, BGP misconfiguration, Untrusted HTTPS Certificates, Open SMTP Mail Relays [58]
Malicious activities	May 2013 - December 2014	CBL[4] , SBL[22], SpamCop[19], WPBL[24], UCEPROTECT[23], SURBL[20], PhishTank[16], hpHosts[11], Darknet scanners list, Dshield[5], OpenBL[15]
Incident reports	August 2013 - December 2014	VERIS Community Database [55], Hackmageddon [42], Web Hacking Incidents [31]

Table 1: Summary of datasets used in this study. Mismanagement and malicious activity data are used to extract features, while incident reports are used to generate labels for the training and testing of a classifier.

tructure is, however, an indicator of the lack of appropriate policies and technological solutions to detect such failures. The latter increases the potential for a successful data breach.

Also, note that all of the above datasets were collected during roughly the first half of 2013. As we shall be using the mismanagement symptoms as features in constructing a classifier/predictor, it is important that these features reflect the condition of a network *prior* to the incidents. Consequently, our incident datasets (detailed in Section 2.2) cover incidents that occurred between August 2013 and December 2014. Note also that we use only a single snapshot of each of the symptoms; this is because such symptomatic data is relatively slow-changing over time, as systems are generally not reconfigured on a daily or even weekly basis.

2.1.2 Malicious Activity Data

Another indicator of the lack of policy or technical measures to improve security at an organization is the level of malicious activities observed to originate from its network assets and infrastructure. Such activity is often observed by well-established monitoring systems such as spam traps, darknet monitors, or DNS monitors. These observations are then distilled into blacklists. We use a set of reputation blacklists to measure the level of malicious activities in a network. This set further breaks down into three types: (1) those capturing spam activities, including CBL[4] , SBL[22], SpamCop[19], WPBL[24], and UCEPROTECT[23], (2) those capturing phishing and malware activities, including SURBL[20], PhishTank[16], and hpHosts[11], and (3) those capturing scanning activities, including the Darknet scanners list, Dshield[5], and OpenBL[15]. We use reputation blacklists that have been collected over a period of more than a year, starting in May 11, 2013 and ending in December 31, 2014. Each blacklist is refreshed on a daily basis and consists of a set of IP addresses seen to be engaged in some malicious activity. This longitudinal dataset allows us to characterize not only the presence of malicious activities from an organization, but also its dynamic behavior over time.

2.2 Security Incident Data

In addition to the security posture data described in the previous section, we require data on reported cyber-security incidents to serve as ground-truth in our study; such data is needed for the purpose of training the classifier, as well as for assessing its accuracy in predicting incidents (testing). In general, we believe such incidents are vastly under reported. In order to obtain a good coverage, we employ three collections of publicly available incident datasets. These are described below.

VERIS Community Database (VCDB) [55]: This dataset represents a broad ranging public effort to gather cyber security incident reports in a common format [55]. The collection is maintained by the Verizon RISK Team, and is used by Verizon in its highly publicized annual Data Breach Investigations Reports (DBIR) [56]. The current repository contains more than *5,000* incident reports, that cover a variety of different types of events such as server breach, website defacements, and physically stolen assets. Table 7 (in the Appendix) provides some example reports from this repository; a majority (64.99%) is from the US.

Of the full set, roughly 700 unique incidents were relevant to our study: we include only incidents that occurred after mid-2013 so that they are aligned with the security posture data, and those directly reflecting cyber-security issues. We therefore exclude those due to physical attacks, robbery, deliberate mis-operation by internal actors (e.g. disgruntled employees) and the like, as well as unnamed or unverified attack targets. We show several such examples in Table 2. Also note that even though the same IPs may appear in both the malicious and incident data, the independence of the features from ground-truth data is maintained because malicious activities only reveal botnet presence, which is *not* considered an incident type by or reported in any of our incident datasets.

Incident report	Reason to exclude
Student of a college changed score	Unknown target
Road construction sign hacked	Physical tampering
Praxair Healthcare Inc. asset stolen	Physical theft
Lucile Packard Child. Hosp.l asset stolen	Physical theft
Medicare Privilege Misuse	Deliberate internal misuse

Table 2: Examples of excluded VCDB incidents.

Hackmageddon [42]: This is an independently maintained cyber incident blog that aggregates and documents various public reports of cyber security incidents on a monthly basis. From the overall set we extract 300 incidents, in which the reported dates are aligned with our security posture data, between October 2013 and February 2014, and for which we are able to clearly identify the affected organizations.

The Web Hacking Incidents Database (WHID) [31]: This is an actively maintained cyber security incident repository; its goal is to raise awareness of cyber security issues and to provide information for statistical analysis. From the overall dataset we identify and extract roughly 150 incidents, for which the reported dates are aligned with our security posture data, between January 2014 and November 2014.

A breakdown of the incidents by type from each of these datasets is given in Table 5. Note that Hackmageddon and WHID have similar categories while VCDB has much broader categories.

Incident type	SQLi	Hijacking	Defacement	DDoS
Hackmageddon	38	9	97	59
WHID	12	5	16	45
Incident type	Crimeware	Cyber Esp.	Web app.	Else
VCDB	59	16	368	213

Table 3: Reported cyber incidents by category. Only the major categories in each set are shown. The "Else" category by VCDB represents incidents lacking sufficient detail for better classification.

2.3 Data Pre-processing

Though our diverse datasets give us substantial visibility into the state of security at an organizational level, the diversity also presents substantial challenges in aligning the data in both time and space. All of the security posture datasets – mismanagement and malicious activities – record information at the host IP-address level; e.g., they reveal whether a particular IP address is blacklisted on a given day, or whether a host at a specific IP address is misconfigured. On the other hand, a cyber incident report is typically associated with a company or organization, not with a specific IP address within that domain.

Conceptually, it is more natural to predict incidents for an organization for the following reasons. Firstly, our interest is in predicting incidents broadly defined as a way to assess organizational cyber risk. Secondly, while some IP addresses are statically associated with a machine, e.g., a web server, others are dynamically assigned due to mobility, e.g., through WiFi. In the latter case predicting for specific IP addresses no longer makes sense.

This mismatch in resolution means that we will have to (1) map an organization reported in an incident to a set of IP addresses and (2) aggregate mismanagement and maliciousness information over this set of addresses. To address the first step we will first retrieve a *sample IP address* in the network of the compromised organization, which is then used to identify an *aggregation unit* – a set of IP addresses – that allows us to recover the network asset involved in the incident. Sample IP addresses are obtained by manually processing each incident report, and the aggregation units are identified by using registration information from Regional Internet Registries (RIR) databases. These databases are collected separately from ARIN [3], LACNIC [12], APNIC [2], AFRINIC [1] and RIPE [18], who keep records of IP address blocks/prefixes that are allocated to an organization. ARIN, APNIC, AFRINIC and RIPE databases keep track of the IP addresses that have been allocated, along with the organizations they have been allocated to, labeled with a maintainer ID. LACNIC provides a less detailed database, only keeping track of allocated blocks and not the owners. In this case, we take the last allocation that contains our sample IP address – note a single IP address might be reallocated several times, as part of different IP blocks – i.e., the smallest block, as its owner.

2.3.1 Mapping Process

In the following paragraphs we explain in detail the manual process of (1): (1a) extracting sample IP addresses through a number of examples, and (1b) identifying the aggregation unit using the sample IP address. The general outline of the process for (1a) is that we first read the report concerning each incident, and extract the website of the company involved. If the website is the intrusion point in the breach, or indicative of the compromised network, then we take the address of this website to be our sample IP address. The website is determined to be indicative of the compromised network when the owner ID for the sample IP address matches the reported name of the victim network. Occasionally the victim network can be identified separately regardless of the website address, but in most cases this is found to be an effective way of quickly obtaining the owner ID.

Our first example [21] is a website defacement targeting the official website of the City of Mansfield, Ohio. Since the point of intrusion is clearly the website, we take its address as our sample IP address for this incident. Note that in this case the website might be managed by a 3rd party hosting company, a possibility discussed further when we explain the process to address (1b). The second example [6] is on Evernote resetting all user passwords following an attack on its online system. For this incident we identify said domain (evernote.com), and trace it to an IP block in ARIN's database registered to Evernote Corporation. Since this network is maintained by Evernote itself, we take evernote.com to be our sample IP address. Our final example [10] involves the defacement of Google Kenya and Google Burundi websites. As the report suggests, the hackers altered the DNS records of the domains by hacking into the Kenya and Burundi NICs. Since the attack was not through directly compromising the defaced websites, we excluded this incident – the victim in this incident is neither Google Kenya nor Google Burundi, but the networks owned by the NICs.

The above examples provide insight into the manual process of mapping incident to a network address. For a large portion of the reports the incident descriptor is unique and should therefore be treated as such; this is the main reason that such a mapping is primarily done manually. For a significant portion ($\sim$ 95%) of the reports we are able to identify the compromised network with a high level of confidence – in such cases either the report explicitly cites the website as the intrusion point (first example), or the network identified by the website is registered under the victim organization (second example). When neither of these conditions is satisfied, this incident is excluded unless we can identify the victim network through alternative means; such cases are few. Overall our process is a conservative one: we only include an incident when there is zero or minimal ambiguity. Finally, we also remove duplicate owner IDs in order to avoid a bias against commonly used hosting companies (e.g. Amazon, GoDaddy) in our training and testing process.

We now explain the process used in (1b) to map an obtained sample IP address (as well as the identified owner ID) to network(s) operated by a single entity. The general outline of this process is as follows: we take all the IP blocks that have the same owner ID listed in the RIR databases, excluding sub-blocks that have been reallocated to other organizations, as our aggregation unit. Continuing with the same set of examples, in the case of Evernote (second example) we reverse search ARIN's database and extract all IP blocks registered to Evernote Corporation, giving us a total of 520 IP addresses. For the case of the City of Mansfield website, using records kept by ARIN we see that its web address belongs to Linode, a cloud hosting company. Obviously Linode is also hosting other entities on its network without reported incidents. Nonetheless, in this case we take the network owned by Linode as our aggregation unit, since we cannot further differentiate the source IP address(es) more closely associated with the city. The inclusion of such cases is a tradeoff as excluding them would have left us with too few samples to perform a meaningful study. More on this is discussed in Section 2.4.

2.3.2 A global table of aggregation units

The above explains how we process the incident reports to identify network units that should be given a label of “1”, i.e., victim organizations. For training and testing purposes we also need to identify network units that should be given a label of “0”, i.e., non-victim organizations. To accomplish this, we built a global table using information gathered from the RIRs that provides us with a global aggregation rule, containing both victim and non-victim organizations. Our global table contains 4.4 million prefixes listed under 2.6 million owner IDs. Note that the number of prefixes in the RIR databases is considerably larger than the global BGP routing table size, which includes roughly 550,000 unique prefixes [41]. This is partly due to the fact that the prefixes in our table can overlap for those that have been reallocated multiple times. In other words, the RIR databases can be viewed as a tree indicating all the ownership allocations and reallocations over the IP address space. On the other hand, the BGP table tends to combine prefixes that are located within the same Autonomous System (AS), in order to reduce routing table sizes. Therefore, the RIR databases provide us with a finer-grained look into the IP address space. By taking all the IP addresses that have been allocated to an organization, and have not been further reallocated, we can break the IP address space into mutually exclusive sets, each owned and/or maintained by a single organization. Out of the 4.4 million prefixes, 300,000 of them are assigned by LACNIC and therefore have no owner ID. Combined with the 2.6 million owner IDs from the other registries, the IP address space is broken, by ownership (or LACNIC prefixes), into 2.9 million sets. Each set constitutes an aggregation unit that is given a label of “0”, except for those already identified and labeled as “1” by the previous process.

2.3.3 Aggregation Process

Once these aggregation units are identified, the second step (2) is relatively straightforward. For each mismanagement symptom we simply calculate the fraction of symptomatic IPs within such a unit. For malicious activities, we count the number of unique IP addresses listed on a given day (by a single blacklist, or by blacklists monitoring the same type of malicious activities) that belong to this unit; this results in one or more time series for each unit. This step is carried out in the same way for both victim and non-victim organizations.

2.4 A Few Caveats

As already alluded to, our data processing consists of a series of rules of thumb that we follow to make the data useable, some perhaps less clear-cut than others. Below we summarize the typical challenges we encounter in this process and their possible implications on the prediction performance.

As described in Section 2.3, the aggregation units are defined using ownership information from RIR databases. One issue with the use of ownership information is that big corporations tend to register their IP address blocks under multiple owner IDs, and in our processing these IDs are treated as separate organizations. In principle, as long as each of the aggregation units is non-trivial in size, each can have its own security posture assessed. Furthermore, in some cases it is more accurate to treat such IDs separately, since they might represent different sections of an organization under different management. The opposite issue also exists, where it may be impossible to distinguish between the network assets of multiple organizations; recall, e.g. our first example where multiple organizations are hosted on the same network. As mentioned before, we have chosen in such cases to use the owner ID as the aggregation unit. While this mapping process is clearly non-ideal, it is a best-effort attempt at the problem, and will instead provide the classifier with the average value of the features over all organizations hosted on the identified network.

The labels for our classifier are extracted from real incident reports, and we can safely assume that the amount of false positives in these reports, if any, is negligible. However data breach incidents are only reported when an external source detects the data breach (e.g. website defacements), or an organization is obligated to report the incident due to private customer information getting compromised. In general, organizations tend not to announce incidents publicly, and security incidents remain largely under-reported. This will affect our classifier in two ways: First, by failing to incorporate all incidents in our training set, we may fail to identify all of the factors that might affect an organization's likelihood of suffering a breach. Second, when choosing non-victim organizations, it is possible that we select some of them from unreported victims, which could further impact the accuracy of our classifier. We have tried to overcome this challenge by using three independently maintained incident datasets. Ultimately, however, this can only be addressed when timely incident reporting becomes the norm; more on this is discussed in Section 5.

Last but not least, all the raw security posture data (mismanagement symptoms and blacklists) could contain error, which we have no easy way of calibrating. However, two aspects of the present study help mitigate the potential impact of these noises. Firstly, we use many different datasets from independent sources; the diversity and the total volume generally have a dampening effect on the impact of the noise contained in any single source. Secondly and perhaps more importantly, our ultimate verification and evaluation of the prediction performance are not based on the security posture data, but on the incident reports (with their own issues as noted above). In this sense, as long as the prediction performance is satisfactory, the noise in the input data becomes less relevant.

3 Forecasting Methodology

The key to our prediction framework is the construction of a good classifier. We will primarily focus on the Random Forest (RF) method [37], which is an ensemble classifier and an enhancement to the classical random decision tree method. It uses randomly selected subsets of samples to construct different decision trees to form a forest, and is generally considered to work well with large and diverse feature sets. In particularly, it has been observed to work well in several Internet measurement studies, see e.g., [57]. As a reference, we will also provide performance comparison by using the Support Vector Machine (SVM) [27], one of the earliest and most common classifiers. To train a classifier, we need to identify a set of features from the measurement data. Below, we first detail the set of features used, and then present the training and testing procedures.

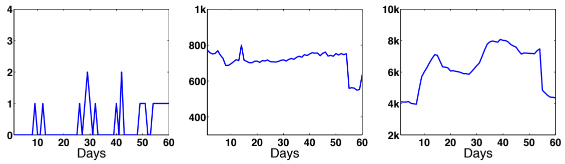
3.1 Feature Set

We shall use two types of features, a primary set and a secondary set. The primary set of features consists of the raw data, while the secondary set is derived or extracted from the raw data, i.e., in the form of various statistics. In all, 258 features are used, including 5 mismanagement features, 180 primary features, 72 secondary features, and a last feature on the organization size.

3.1.1 Primary Features (186)

Mismanagement symptoms (5). There are five symptoms; each is measured by the ratio between the number of misconfigured systems and the total number of systems in an organization. For instance, for the untrusted HTTPS certificates, this ratio is between the number of misconfigured certificates over the total number of certificates discovered in an organization. Similarly, for open SMTP mail relay this ratio is between the number of misconfigured mail servers and the total number of mail servers. The only exception is in the case of open recursive resolver: since we do not know the total number of open resolvers, this ratio is between the number of misconfigured open DNS resolvers and the total number of IPs in an organization. These ratios are denoted as $\mathbf{m}_i \in [0,1]^5$ for organization i.

Malicious activity time series (60 × 3). For each organization we collect three separate time series, one for each malicious activity type, namely spam, phishing, and scan. Accordingly, for organization i, its time series data are denoted by $\mathbf{r}_i^{SP}, \mathbf{r}_i^{PH}, \mathbf{r}_i^{SC}$. These time series data are directly fed in their entirety into the classifier. Several examples of $\mathbf{r}_i^{SP}$ are given in Fig. 1; these are collected over a two-month (60 days) period and show the total number of unique IPs blacklisted on each day over all spam blacklists in our dataset.



(a) Org. 1 (b) Org. 2 (c) Org. 3

Figure 1: Examples of malicious activity time series of three organizations; Y-axis is the number of unique IP addresses listed on all spam blacklists in each day over a 60-day period.

Size (1). This refers to the size of an organization in terms of the number of IP addresses identified within that organization's aggregation unit as outlined in the previous section. For organization i, this is denoted by s_i.

The relevance of these symptoms to an organization's security posture is examined more closely by comparing their distributions among the victim and the non-victim populations, as shown in Fig. 2. We see a clear difference between the two populations in their untrusted HTTPS and Openresolver distributions. This difference suggests that these symptoms are meaningful distinguishers, and thus hold predictive power. This is indeed verified later when these two symptoms emerge as the most indicative of the five. By contrast, the other three mismanagement symptoms appear much less powerful.

The relevance of the malicious activity time series will be examined more closely in the next section, within the context of their secondary features. Lastly, the organization size can to some extent capture the likelihood of an organization becoming a target of intentional attacks, and is therefore included in the feature set.

3.1.2 Secondary Features (72)

In determining what type of statistics to extract to serve as secondary features, we aim to capture distinct behavioral patterns in an organization's malicious activities, particularly concerning their dynamic changes. To illustrate, the three examples given in Fig. 1 show drastically different behavior: Org. 1 shows a network with consistently low level of observed malicious IPs (and possibly within the noise inherent in the blacklists), while Examples 2 and 3 show much higher levels of activity in general. These two, however, differ in how persistent they are at those high levels. Example 2 shows a network with high levels throughout this period, while Example 3 shows a network that fluctuates much more wildly. Intuitively, such dynamic behavior reflects to a large degree how responsive the network operators are to blacklisting, i.e., time to clean up, time to resurfacing of malicious activities, and so on.

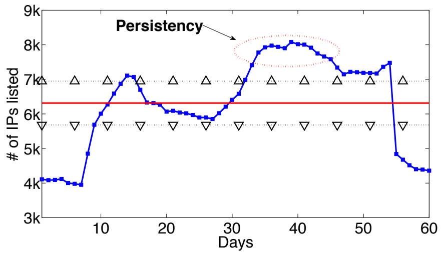


Figure 3: Extracting secondary features. The solid red line indicates time-average of the signal while the two dotted lines denote the boundary of different regions. The region above is "bad" with higher-than-average malicious activities, while the region below is "good" with lower-than-average activities. Persistency refers to the duration the time series persist in the same region.

These observed differences motivate us to collect statistics summarizing such behavioral patterns by measuring their persistence and change, e.g., how big is the change in the magnitude of malicious activities over time and how frequently does it change. To balance the expressiveness of the features and their complexity, we shall do so by first value-quantizing a time series into three regions relative to its time average: "good", "normal" and "bad". An illustration is given in Fig. 3 using one of the examples shown earlier (Org. 3). The solid line marks the average magnitude of the time series over the observation period; the dotted lines then outline the "normal" region, i.e., a range of magnitude values that are relatively close (either from above or below) to its time-average. The region above the top dotted line is accordingly referred to as the "bad" region, showing large number of malicious IPs, and the region below the bottom dotted line the "good" region, with a smaller number of malicious IPs, both relative to its average[1].

An additional motivation behind this quantization step is to capture certain onset and departure of "events", such as a wide-area infection, or scheduled patching and software update, etc. Viewed this way, the duration an orga-

[1] The choice on the size of the normal region may lead to differences in classifier performance, which is discussed in more detail in Section 5.3. In most of our experiments ±20% of the time average is used.

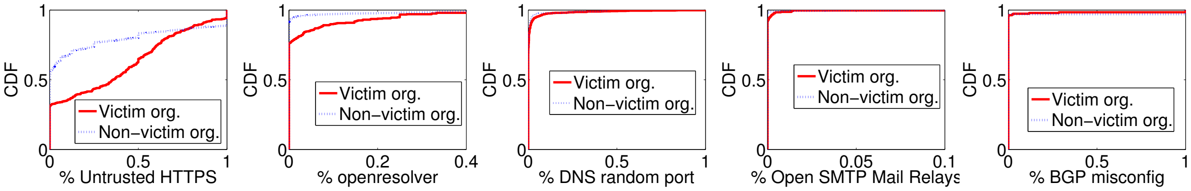

Figure 2: Comparison of mismanagement symptoms between the victim and non-victim populations. There is a clear separation under the first two, while the other three appear to be much weaker predictors.

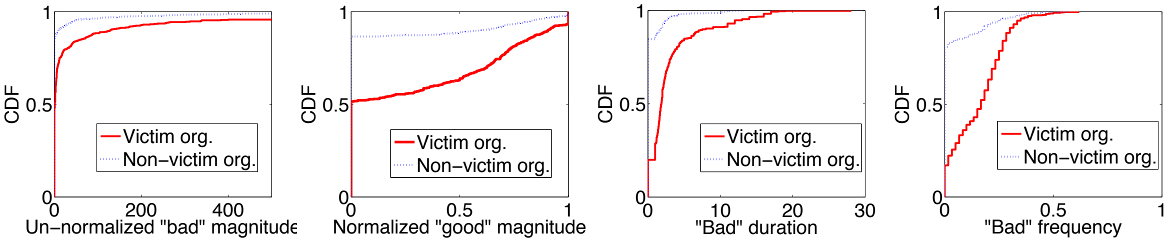

Figure 4: Profile of selected temporal features extracted from the scanning time series over the period Nov. 13-Dec.13.

nization spends in a "bad" region could be indicative of the delay in responding to an event, and similarly, how frequent it re-enters a "bad" region could be indicative of the effectiveness of the solutions taken in remaining clean.

Accordingly, for each region we then measure the average magnitude (both normalized by the total number of IPs in an organization and unnormalized), the average duration that the time series persists in that region upon each entry (in days), and the frequency at which the time series enters that region. This results in four summary statistics for each region, thus 12 values for each time series. Since each organization has three time series, one for each malicious activity type, we obtain a total of 36 derived features per organization i. These will be collectively denoted by the feature vector F_i. Note that the set of 36 values are collected from time series of a certain duration. Here we further distinguish between statistics extracted from a longer period of time vs. from a shorter, most recent period of time. In this study we use two such feature vectors, one referred to as *Recent-60* features that are collected over a period of 60 days (typically leading up to the time of incident) and the other *Recent-14* features collected over a period of 14 days (leading up to the time of incident).

To give a sense of why these features may be expected to hold predictive power, we similarly compare the distribution of these feature values among the victim and non-victim populations. Fig. 4 shows this comparison for four examples: un-normalized magnitude in a bad period, normalized magnitude in a good period, average duration during bad periods, and the frequency of entering a bad period. We see that in each case there is a clear difference between the two populations in how these feature values are distributed, e.g., victim organizations tend to have longer bad periods, indicative of slow response time, and also higher bad/good magnitudes, etc. As we discuss further in Section 4.4, these features have varying degrees of influence over the prediction outcome.

3.2 Training and Testing Procedure

We now describe the construction of the predictor using the set of features defined above. This consists of a training step and a testing step. The training step uses the following two sets of subjects.

A subset of incident or victim organizations. This will be referred to as Group(1) or the incident group. Depending on the experiments, this subset may be selected from one of the three incident datasets (if we train the classifier and conduct testing based solely on one incident dataset), or from the union of all three. This subset is selected based on the time stamps of the reported incidents, and its size is determined by a training-testing ratio, e.g., 70-30 split or 50-50 split of the given dataset. If we use a 50-50 split, it means that we select the first half (in terms of time of occurrence) of the incidents as Group(1); a 70-30 split means using the first 70% of incidents as Group(1). The remaining victim organizations are used in the testing step.

A randomly selected set of non-victim organizations (with size comparable to that of Group(1) in any given experiment). These are taken from the global table described in Section 2.3.2. This will be referred to as

Group(0), or the non-incident group. As mentioned earlier, since there are close to three million non-victim organizations compared to less than a thousand victim organizations, the random sub-sampling is necessary to avoid the common problem of imbalance in the machine learning literature[2]; this issue has also been discussed in [51]. This random selection of non-victim organizations is repeated numerous times, each time training a different classifier. The reported testing results are averages over all these versions.

For a victim organization i in Group(1), its complete feature set $\mathbf{x}_i$ includes the mismanagement symptoms $\mathbf{m}_i$, the three time series $\mathbf{r}_i^{SP}, \mathbf{r}_i^{PH}, \mathbf{r}_i^{SC}$ over the two months prior to the month in which the incident in i occurred[3], secondary features F_i collected over the same time period as the time series, namely Recent-60, and that collected over the two weeks prior to the month of the incident occurrence, namely Recent-14. Each such feature set is associated with the label (or ground-truth or group information in machine learning) $L_i = 1$ for incident. For a non-victim organization j in Group(0), its complete feature set $\mathbf{x}_j$ consists of exactly the same components listed above, with the only difference that the time series and the secondary features are for the two months prior to the month of the first incident in Group(1). It is also associated with the label $L_j = 0$ for non-incident.

The collections of $\{[\mathbf{x}_i, L_i]\}$ and $\{[\mathbf{x}_j, L_j]\}$ constitute the training data used to train the classifier. The testing step then uses the following two inputs: (1) The subset of victim organizations not included in Group(1); denote this group by Group(1^c). (2) A randomly selected set of non-victim organizations not used in training. Unlike in training where we try to keep a balance between the victim and non-victim sets, during testing we use a much larger set of non-victim organizations to better characterize the classifier performance.

For these two subjects their complete feature sets $\mathbf{x}_i$ are obtained in exactly the same way as for those used in training. For the non-victim organizations selected for testing, the features are collected over the two months prior to the incident month of the first incident in Group(1^c). For the victim organization used for testing we further consider two scenarios. In the *short-term forecast* scenario, we collect these features over the two months prior to the incident month for an organization in Group(1^c), while in the *long-term forecast* scenario, we collect these features over the two months prior to the incident month of the first incident in Group(1^c). In the short-term forecast scenario, since in each incident test case the incident occurred within a month of collecting the features, the TP rate is essentially for a forecasting window of one month. In the long-term forecast scenario, an incident may occur months after collecting the features (up to 12 months in the case of VCDB), thus the TP rate is for a forecasting window of up to a year. Note that the short-term forecast can be repeatedly done over time to produce prediction for the immediate future. The differences between these two forecast schemes are also illustrated in Fig. 5.

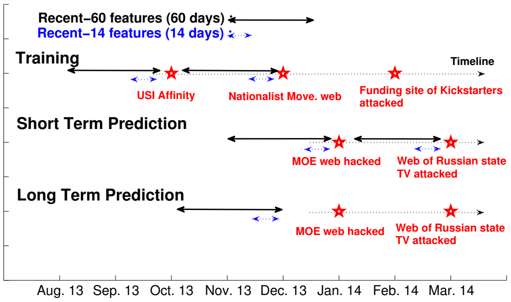

Figure 5: Feature extraction, short-term and long-term forecasting. In training, features are extracted from the most recent period leading up to an incident. In testing, the same is done when we perform short-term forecast. In long-term forecast, features are extracted from periods leading up to the time of the first incident used in testing.

These inputs are then fed into the classifier to produce a label (or prediction). The output of Random Forest is actually a risk probability; a threshold is then imposed to obtain a binary label. For instance, if we set the threshold at 0.5, then all output > 0.5 means a label of 1. By moving this threshold we obtain different prediction performances, which constitute a ROC curve.

4 Incident Prediction

In this section, we present our main prediction results and investigate their various implications.

4.1 Main Results

Using the methodology outlined in the previous section, we performed prediction using the three incident datasets separately, as well as collectively. When used collectively, we removed duplicate reports of the same incident whenever applicable. The separation between training and testing for each dataset is done chronologically, as shown in Table 4. For each dataset, these separations

[2] If we use all three million non-victims in training, the resulting classifier will simply label all of them as non-victims, and achieve performance very close to 100% overall. But clearly this classifier would be of little use, as it will also have 0 true positive probability.

[3] Most incident occurrences in our dataset are timestamped with month and year information.

result in an approximate 50-50 split of the victim set between the training and testing sample sizes. In addition, for each test we randomly sample non-victim test cases from the non-victim organization set.

	Hackmageddon	VCDB	WHID
Training	Oct 13 – Dec 13	Aug 13 – Dec 13	Jan 14 – Mar 14
Testing	Jan 14 – Feb 14	Jan 14 – Dec 14	Apr 14 – Nov 14

Table 4: Chronological separation between training and testing samples for each incident dataset; the split is roughly 50-50 among the victim population.

There is one point worth clarifying. When processing non-sequential data, the split of samples for the purpose of training and testing is often done randomly in the machine learning literature. In our context this would mean to choose a later incident for training and use an earlier incident for testing. Due to the sequential nature of our data, we intentionally and strictly split the data by time: earlier ones are for training and later ones for testing. Because of this, our testing results are indeed “prediction” results; for the same reason, we did not set aside a third, separate dataset for the purpose of “more testing” as is sometimes done in the literature, as this purpose is already served by the second, test dataset.

The prediction results are summarized in the set of ROC (receiver operating characteristic) curves shown in Fig. 6. Recall that the RF classifier outputs a probability of incident for each input sample. To test its accuracy, a threshold is adopted that maps this value into a binary prediction: 1 if it exceeds the threshold and 0 otherwise. This binary prediction is then compared against the ground-truth: a sample from an incident dataset has a true label of 1, while a sample from the non-victim organization set has a true label of 0. Since our non-victim set for training (to balance) is randomly selected from the total non-victim population, the above test is repeated 20 times for a given threshold value, each time for a different random non-victim set. The average TP and FP over these repeated tests form one point on the ROC curve.

We see the prediction performance varies slightly between the datasets, but remain very satisfactory, generally achieving combined (TP, FP) values of $(90\%, 10\%)$ or $(80\%, 5\%)$. In particular, when we combine the three datasets, we can achieve an accuracy level of $(88\%, 4\%)$. A summary of some of the most desirable operating points are given in Table 5.

The above prediction results substantially outperform what has been shown in the literature to date; e.g., the web maliciousness prediction study in [51] reported a combination of $(66\%, 17\%)$ for (TP, FP). It is also worth pointing out that TP and FP values are independent of the sizes of the respective populations of the victim and non-victim organizations (these are conditional probability estimates), whereas the overall accuracy does depend on the two population sizes as it is the unconditioned probability of making correct predictions. Since based on our dataset we have a minuscule victim population (accounting for $\ll 1\%$ of the overall population), the overall accuracy is simply $\sim$ (1-FP). Therefore, if the overall accuracy is of interest, the best classifier would be a naive one that simply labels all inputs as “0”. This would lead to 0% TP, 0% FP, and an overall accuracy of $> 99\%$. However, despite achieving maximum overall accuracy, such a classifier is clearly useless. This point is also emphasized in [51] for similar reasons. Additionally, in the context of forecasting, where the goal is to facilitate preventative measures at an organizational level, having a high TP is perhaps more relevant than having a low FP; this is in contrast to spam detection, where the cost of FP is much higher than a missed detection. Therefore, the three measures in Table 5 should be taken as a whole.

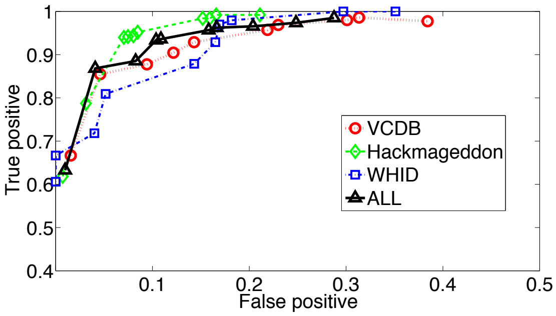

Figure 6: Prediction results. There are variations between the datasets, but an operating point – combined (TP, FP) values – of $(90\%, 10\%)$ or $(80\%, 5\%)$ is achievable. In particular, when we use all three datasets together, we can achieve an accuracy level of $(88\%, 4\%)$.

Accuracy	Hackmageddon	VCDB	WHID	All
True Positive (TP)	96%	88%	80%	90%
False Positive (FP)	10%	10%	5%	10%
False Negative (FN)	4%	12%	20%	10%
Overall Accuracy	90%	90%	95%	90%

Table 5: Best operating points of the classifier for the best combinations of (TP, FP) values.

4.2 Impact of Training:Testing Ratio

The results in Fig. 6 are obtained under a 50-50 split of the victim set into training and testing samples, based on the incident time. Furthermore, they are obtained using the short-term forecasting method described in Section 3.2. In general, one can improve the prediction performance by increasing the training sample size. There is no exception in our study, as shown in Fig. 7 where we compare results from a 70-30 training and testing sample split of the victim set to that from the 50-50 split, for the VCDB data. A best operating point is now around $(94\%, 10\%)$, indicating a clear improvement. Note that, a 70-30 split is not generally regarded high in the machine learning literatures, see e.g., in [57] a 90-10 split was used. We however believe a 50-50 split gives a more objective measure of the prediction performance.

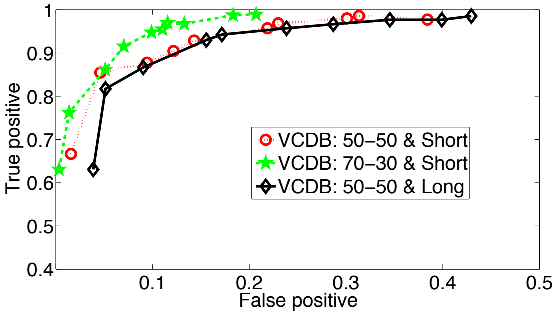

Figure 7: The impact of larger training set and size of forecasting window; all results are obtained using VCDB. The three curves: (1) using a 50-50 split of the victim set between training and testing under the short-term forecasting scenario (this curve is identical to the one in Fig 6); (2) using a 70-30 split of the victim set between training and testing under the short-term forecasting scenario; (3) using a 50-50 split of the victim set between training and testing under the long-term forecasting scenario.

4.3 Short-term vs. Long-term Forecast

Also shown in Fig. 7 are our long-term forecasting results under a 50-50 training and testing sample split of the victim set, again for VCDB. As seen, the prediction performance holds even when we move from a one-month to a 12-month forecasting window. The use of mismanagement symptoms and long-term malicious behaviors in the features contributes to this: they generally remain stable over time and have relatively high importance in the prediction, discussed in greater detail in the next section.

4.4 Relative Importance of the Features

In addition to the prediction output, the RF classifier also outputs a normalized relevance score for each feature used in training [17]; the higher the value, the more important the feature in the prediction. In this section, we examine these scores more closely. This study will further help us understand the extent to which different features determine the chance of an organization becoming breached in the near future. For brevity, the experiments presented in this section are based on a combination of all three datasets.

The importance of each category of features is summarized in Table 6. We make a number of interesting observations. First, note that the mismanagement features stand out as the most important category in prediction. Second, the Recent-60 secondary features are almost as important as the time series data, despite the fact that the former are derived from the latter. This is because the use of time series data has the effect of capturing synchronized behavior between malicious activities of different organizations, while the secondary features are aimed at capturing the dynamic behavior over time within an organization itself. That the latter adds value to the predictor is thus validated by the above importance comparison. Last but not least, the Recent-60 features appear much more important than Recent-14 features.

Feature category	Normalized importance
Mismanagement	0.3229
Time series data	0.2994
Recent-60 secondary features	0.2602
Organization size	0.0976
Recent-14 secondary features	0.02

Table 6: Feature importance by category. The mismanagement features are the most important category in prediction. Secondly, the Recent-60 secondary features are almost as important as the time series data; the former capture dynamic behavior over time within an organization whereas the latter capture synchronized behavior between malicious activities of different organizations.

A closer look into each category reveals that among the mismanagement features, untrusted HTTPS is by far the most important (0.1531), followed by Openresolver (0.0928), DNS random port (0.0469), Mail relay (0.0169), and BGP misconfig. (0.0132). The more significant role of untrusted HTTPS in prediction as compared to Openresolver is consistent with the bigger difference in distributions seen earlier in Fig. 2; that is, a victim organization tends to have a higher percentage of mis-configured HTTPS for their network assets. A possible explanation is that a majority of the incidents in our dataset are web-page breaches; these correlate with the untrusted HTTPS symptom, which reflect poorly managed web systems.

Similarly, a closer look at the secondary features (both Recent-60 and Recent-14) suggests that the dynamic features (duration and frequency together, totaling 0.1769) are far more important than static features (magnitude, totaling 0.0834). This suggests that dynamic changes over time, or in other words, organizations' response time in terms of cleaning up the origin of their malicious activities, is more indicative of security risks.

4.5 The Power of Dataset Diversity

A question that naturally arises is what if only a single feature category is used to train the classifier. For instance, given the prominent score of mismanagement features in prediction, would it be sufficient to only use these in prediction? The answer, as shown in Fig. 8, turns out to be negative. In this figure, we compare the prediction performance by using the following four categories of features separately to build the classifier: mismanagement, time series data, organization size, and the entire set of secondary features. While it is expected that using only one feature set leads to worse prediction performance, it is somewhat surprising that the secondary features are more powerful than mismanagement features or the time series when used separately. Recall that the secondary features were designed specifically to capture the organizational behavior, including their responsiveness and effectiveness in dealing with malicious acti-vities. One explanation of this result is that the human and process element of an organization is the most slow-changing compared to the change in the threat landscape, and thus holds the most predictive power.

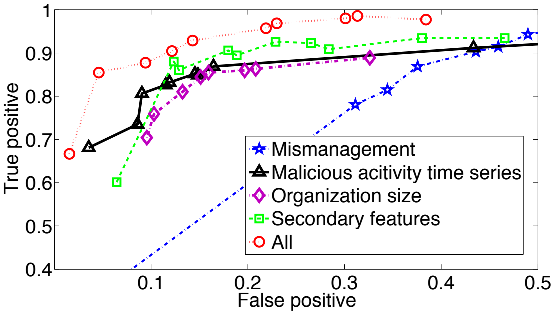

Figure 8: Independent prediction performance using only one set of features. The secondary features are shown to be the most powerful in prediction when used alone. Mismanagement features perform the worst, even though they have the highest importance factor. This is because the factors reflect conditional importance, given the presence of other features. This means that mismanagement features alone are poor predictors but they add valuable information to the other features.

Note that this is not inconsistent with the relative importance given in Table 6, as the latter is a measure of conditional importance of one feature given the presence of other features. In other words, the relative importance suggests how much we lose in performance if we *leave out* a feature, whereas Fig. 8 shows how well we do when using *only* that feature. What's seen here is that mismanagement features add very significant (orthogonal) information to the other features, but they are poor predictors in and by themselves. Perhaps most importantly, the results in Fig. 8 validate the idea of using a diverse set of measurement data that collectively form predictive descriptions of an organization's security risks.

4.6 Comparison with SVM

As a reference, we also trained classifiers using SVM; the prediction results are much poorer compared to using RF. For instance, using the VCDB data, the best operating point under SVM (with a 50-50 training-testing split of the victim population and short-term forecasting) is around (70%, 25%). This observation is consistent with existing literature, see e.g., [57].

5 Discussion

5.1 Top Data Breaches of 2014

In Fig. 9, we plot the distribution (CDF) of the predictor output values for the VCDB victim set and a randomly selected non-victim set used in testing. We use an example threshold of 0.85 for illustration. All points to the right of a threshold is labeled “1”, indicating positive prediction, and all to its left “0”. Three incident examples are also shown, falling into the categories of true-positive (ACME), false-positive (AXTEL), and false-negative (BJP Junagadh).

Also highlighted in Fig. 9 are the top five data breaches of 2014 [43], namely JP Morgan Chase, Sony pictures, Ebay, Home Depot, and Target. Using the suggested threshold value, our prediction method would have correctly labeled four of these incidents, and only narrowly missed the Target incident. It is worth noting that the Target incident was brought on by one of its contractors; however, the fact that Target did not have a more secure vendor policy in place is indicative of something else amiss (e.g., lack of consistent procedure between IT and procurement) that could also have manifested itself in the data and features we examined.

These examples highlight that, in addition to enabling proactive measures by an organization, there are potential business uses of the prediction method presented in this study. The first is in vendor or third party evaluation. Consider Online Tech, the hosting service used by JP Morgan Chase, as an example. As shown in Fig. 9, Online Tech posed very high security risks; this information could have been used in determining whether to use this vendor. Furthermore, information provided by our prediction method can help underwriters better customize terms of a cyber-insurance policy. The insurance

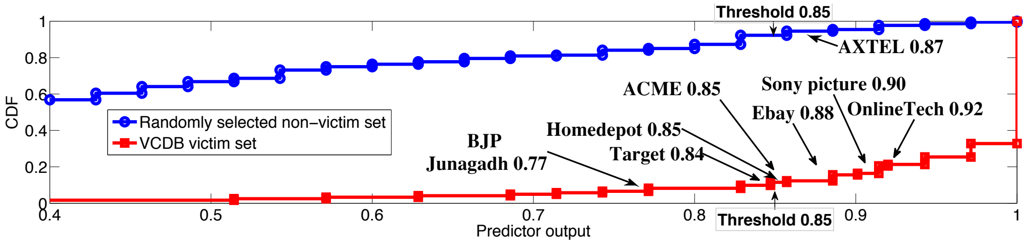

Figure 9: Distribution of predictor outputs with an example threshold value 0.85 (with 91% TP, 10% FP). On the curve with circles (non-victim) to the right of the threshold are FPs; on the curve with squares (victim) to the right of the threshold are TPs. Three types of incidents are shown, presenting true-positive (ACME), false-positive (AXTEL), and false-negative (BJP Junagadh). Also highlighted are top data breach events in 2014.

payout in the case of Target was reported to be around $60M; with this much at stake, it is highly desirable to be able to accurately predict the risk of an insured and adjust terms of the contracts.

5.2 Prediction by Incident Type

For a majority of the incident types, we do not have enough sample points to serve both training and testing purposes, except for the 368 reports of the type "web applications incident" in VCDB. This allows us to train a classifier to predict the probability of an organization being hit with a "web app incident". The corresponding results are similar in accuracy to those obtained earlier (e.g., at (92%, 11%)). This suggests that our methodology has the potential to make more precise predictions as we accumulate more incident data.

Similarly, the current forecasting methodology is not aimed at predicting highly targeted attacks motivated by geo-political reasons (e.g., the Sony Picture breach). Nor does it use explicit business sector information (e.g., a bank may be a bigger target than a public library system). In this sense, our current results represent more the likelihood of an organization falling victim provided it is being targeted. However, an ever increasing swath of the Internet is rapidly under cyber threats to the point that all major organizations should simply assume that they are someone's target. The use of explicit business sector information does allow us to make more fine-grained predictions. In a more recent study [48], we leverage a broad array of publicly available business details on victim organizations reported in VCDB, including business sector, employee count, region of operation and web statistics information from Alexa Web Information Service (AWIS), to generate risk profiles, the conditional probabilities of an organization suffering from specific types of incident, given that an incident occurs.

5.3 Robustness against adversarial data manipulation and other design choices

One design choice we made in the feature extraction process is the parameter δ which determines how a time series is quantized to obtain secondary features. Below we summarize the impact of of having different δ values. In the results shown so far, a value of $\delta = 0.2$ is used. In Fig. 10 we test the cases with $\delta = 0.1$ and $\delta = 0.3$. We see that this parameter choice has relatively minor effect: with $\delta = 0.3$ a desirable TP/FP combination is around $(91\%, 9\%)$, and for $\delta = 0.1$, we have $(86\%, 6\%)$. It appears that having a higher value of δ leads to slightly better performance; a possible explanation is that quantizing using $\delta = 0.2$ retained more noise and fluctuation in the time series, while quantizing using $\delta = 0.3$ may be more consistent with the actual onset of events.

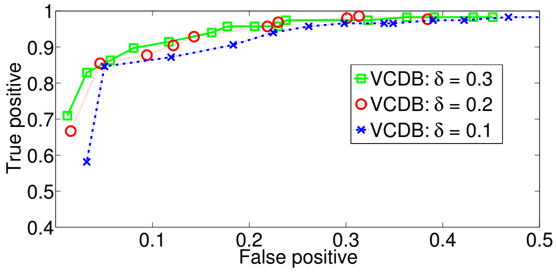

Figure 10: Experiment results under different δ.

Throughout the paper we have assumed the data are truthfully reported (though with noise/error). It is thus reasonable to question how robust is the prediction against possible (malicious) manipulation of the data used for training, a subject of increasing interest and commonly referred to as *adversarial* machine learning. For instance, an entity may attempt to set up fake networks with clean data (no malicious activities) but with fake reported incidents, and vice versa, to mislead the classifier. Without presenting a complete solution, which remains a direction of future research, below we test the robustness of our current prediction technique using two scenarios: (1) In the first we randomly flip the labels of victim organizations from 1 to 0; those flipped to 0 are now part of the non-victim group, thus contaminating the training data. (2) In the second scenario we do the opposite: randomly flip the labels of non-victim organizations, effectively adding them to the victim group. Incidentally, the former scenario is akin to under-reporting by randomly selected organizations.

Experimental results suggest no performance difference for case (1). The reason lies in the imbalance between the victim and non-victim population sizes. Recall that because of this, in our experiment we randomly select a subset of non-victim organizations with size comparable to the victim organizations (on the order of $O(1,000)$). Then in each training instance, the expected number of victims selected as part of the non-victim set is no more than $N_v \cdot O(1,000)/N$, with N_v denoting the number of fake non-victims and N the total number of non-victims. Since $N \sim O(1,000,000)$, even if one is able to inject $N_v \sim O(100)$ victims into the non-victim population, on average no more than one fake non-victim will actually be selected for training, resulting in negligible contamination effect unless such alterations can be done on a scale larger than the actual victim population.

For case (2), we indeed observe performance degradation, albeit slight, in the true positive, as shown in Fig. 11 at the 20% contamination level (20% of non-victim organization labels are flipped).

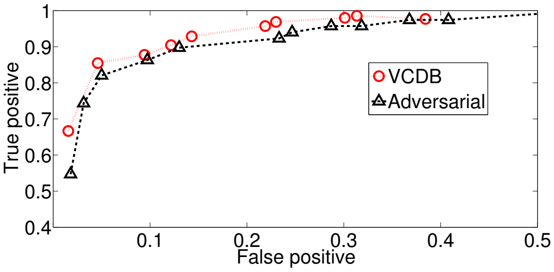

Figure 11: Adversarial case (2) with 20% contamination.

5.4 Incident Reporting

One of the main obstacles in studies of this nature is the acquisition of high quality incident data, without which we can neither train nor verify with confidence. Our result here demonstrates that machine learning techniques have the power to make accurate incident forecasts, but data collection is lagging by comparison. The research community would benefit enormously from more systematic and uniform incident reporting.

6 Related Work

As mentioned in the introduction, a large part of the literature focuses on detection rather than prediction. The work in [44] is one such example. Among others, Lee et al. [36] built sophisticated Hidden Markov Model techniques to detect spam deobfuscation, and in [57] Wang et al. applied (adversarial) machine learning techniques to the detection of malicious accounts on Weibo.

Relatively fewer studies have focused on prediction; even fewer are on the type of prediction presented in this paper where the predicted variable (classifier output) is of a different type from the input variables (feature input). For instance, the predictive IP-based blacklist works in [50, 30] have the same input and output variables (content of the blacklist). Similarly, in [54] the evolution of spam of a certain prefix is predicted using past spam activities as input. Predictive studies similar to ours include the aforementioned [51] that predicts whether a website will turn malicious by using textual and structural analysis of a webpage. The performance comparison has been given earlier. It is worth pointing out that the intended applications are also different: whereas webpage maliciousness prediction can help point to websites needing improvement or maintenance, our prediction on the organizational level can help point to networks facing heightened probability of a broader class of security problems. Also as mentioned earlier, our study [48] examines the prediction of incident types, conditional on an incident occurring, by using an array of industry, business and web visibility/population information. Other predictive studies include [28], where it is shown that by analyzing user browsing behavior one can predict whether a user will encounter a malicious page (attaining a 87% accuracy), [52], where risk factors are identified at the organization level (industry sector and number of employees) and the individual level (job type, location) that are positively or negatively correlated with experiencing spear phishing targeted attacks, and [53], where risk factors for web server compromise are identified through analyzing features from sampled web servers.

Also related are studies on reputation systems and profiling of networks. These include e.g., [26], a reputation assigning system trained using DNS features, reputation systems [8, 9] based on monitoring Internet traffic data, and those studied in [29, 46].

7 Conclusion

In this study, we characterize the extent to which cyber security incidences can be predicted based on externally observable properties of an organization's network. Our method is based on 258 externally measurable features collected from a network's mismanagement symptoms and malicious activity time series. Using these to train a Random Forest classifier, it is shown that we can achieve fairly high accuracy, such as a combination of 90% true positive rate and 10% false positive rate. We further analyzed the relative importance of the features sets in the prediction performance, and showed our prediction outcome for the top data breaches in 2014.

Abstract

Most modern malware download attacks occur via the browser, typically due to social engineering and drive-by downloads. In this paper, we study the "origin" of malware download attacks experienced by real network users, with the objective of improving malware download defenses. Specifically, we study the *web paths* followed by users who eventually fall victim to different types of malware downloads. To this end, we propose a novel *incident investigation system*, named WebWitness. Our system targets two main goals: 1) automatically *trace back and label* the sequence of events (e.g., visited web pages) preceding malware downloads, to highlight how users reach attack pages on the web; and 2) leverage these automatically labeled in-the-wild malware download paths to better understand current attack trends, and to *develop more effective defenses*.

We deployed WebWitness on a large academic network for a period of ten months, where we collected and categorized thousands of *live* malicious download paths. An analysis of this labeled data allowed us to design a new defense against drive-by downloads that rely on injecting malicious content into (hacked) legitimate web pages. For example, we show that by leveraging the incident investigation information output by WebWitness we can decrease the infection rate for this type of drive-by downloads by almost *six times*, on average, compared to existing URL blacklisting approaches.

1 Introduction

Remote malware downloads currently represent the most common infection vector. In particular, the vast majority of malware downloads occur via the browser, typically due to social engineering attacks and drive-by downloads. A large body of work exists on detecting drive-by downloads (e.g., [10, 11, 19, 23, 33, 40]), and a few efforts have been dedicated to studying social engineering attacks [6, 31, 37]. However, very little attention has been dedicated to investigating and categorizing the *web browsing paths* followed by users *before* they reach the web pages from which the attacks start to unfold.

Our Work. In this paper, we study the *web paths* followed by *real users* that become victims of different types of malware downloads, including social engineering and drive-by downloads. We have two primary goals: 1) provide context to the attack by automatically identifying and labeling the sequence of web pages visited by the user *prior to the attack*, giving insight into how users reach attack pages on the web; and 2) leverage these annotated in-the-wild malware download paths to better understand current attack trends and to *develop more effective defenses*.

To achieve these goals we propose a novel malware download *incident investigation system*, named WebWitness, that is designed to be deployed passively on enterprise scale networks. As shown in Figure 1, our system consists of two main components: an *attack path traceback and categorization* (ATC) module and a *malware download defense* (MDD) module. Given all (live) network traffic generated by a user's browsing activities within a time window that includes a malware download event, the ATC module is responsible for identifying and linking together all HTTP requests and responses that constitute the web path followed by the user from an "origin" node (e.g., a search engine) to the actual malware download page, while filtering out all other irrelevant traffic. Afterwards, a statistical classifier automatically divides all collected malware download paths into *update*, *social engineering* and *drive-by* attacks. We refer to the output of the ATC module as *annotated malware download paths* (AMP).

The AMPs are continuously updated as new malware downloads are witnessed in the live traffic, and can therefore be used to aid the study of recent attack trends. Furthermore, the AMP data is instrumental in designing and building new defenses that can be plugged into the MDD

module (see Figure 1). As an example, by investigating real-world web paths leading to drive-by malware downloads, we found that it is often possible to automatically trace back the domain names typically used in drive-by attacks to inject malicious code into compromised web pages (e.g., via the source of a malicious `script` or `iframe` tag). The injected code is normally used as an attack trigger, directing the browser towards an actual exploit and finally to a "transparent" malware download and execution. We empirically show that automatically discovering and promptly blocking the domain names serving the injected malicious code is a much more effective defense, compared to the more common approach of blacklisting the URLs that directly serve the drive-by browser exploits themselves or the actual malware executables (see Section 4.4).

Main Differences from Previous Work. Most previous works that study the network aspects of malware downloads focus on building malware detection systems, especially for drive-by exploit kits and related attacks (e.g., [13,30,38,40]).

Our work is different from these studies, because our goal is *not* to build a drive-by detection system; rather, we aim to passively trace back and automatically label the network events that *precede* different types of in-the-wild malware downloads, including both drive-by and social engineering attacks. We show that our investigation approach can aid in the design of more effective malware download defenses.

Some recent studies focus primarily on detecting malicious redirection chains as a way to identify possible malware download events [16,18,20,36]. WebWitness is different because we devise a *generic path trace back* approach that does not rely on the properties of redirection chains. Our work aims to provide *context* around malicious downloads by reconstructing the *full web path* (not just redirection chains) that brought the victim from an "origin" page to the download event. In addition WebWitness is able to classify the *cause* of the download (e.g., drive-by or social engineering) and to identify the roles of the domains involved in the attack (e.g., trick page, code injection, exploit, or malware hosting). We further discuss related work in Section 6.

Summary of Contributions. In summary, we make the following contributions:

- We investigate the *web paths* followed by *real network users* who eventually fall victim to different types of malware downloads, including social engineering and drive-by downloads. Through this investigation, we provide quantitative information on attack scenarios that have been previously explained only anecdotally or through limited case studies.

- To enable a continuous collection and study of web paths leading to malware download attacks, we build a system called WebWitness. Our system can automatically trace back and categorize in-the-wild malware downloads. We show that this information can then be leveraged to design more effective defenses against future malware download attacks.

- We deployed WebWitness on a large academic network for a period of ten months, where we collected and categorized thousands of *live* malicious download paths. Using these web paths, we were able to design a new defense against drive-by downloads that rely on injecting malicious content into (hacked) legitimate web pages. For example, we show that by leveraging the incident investigation information output by WebWitness, on average we can decrease the infection rate for this type of drive-by downloads by almost *six times*, compared to existing URL blacklisting approaches.

2 In-The-Wild Malware Download Study

Goals: In this section we report the results of a large study of *in-the-wild* malware downloads captured on a live academic network. Through this study, we aim to create a labeled dataset of download paths that can be used to design (including feature engineering), train, and evaluate the ATC and MDD modules of WebWitness shown in Figure 1. A detailed discussion of ATC and MDD is reported in Sections 3.

2.1 Collecting Executable File Downloads

To collect executable file downloads we use deep packet inspection to perform on-the-fly TCP flow reconstruction, keeping a buffer of all recent HTTP transactions (i.e., request-response pairs) observed on a live network. For each transaction, we check the content of the response to determine if it contains an executable file. If so, we retrieve all buffered HTTP transactions related to the client that initiated the download. Namely, we store all HTTP traffic a client generated preceding (and including) an executable file download; this allows us to study what *web path* users follow *before* falling victim to malware downloads. All data is saved in accordance with the policies set forth by our Institutional Review Board and are protected under a nondisclosure agreement.

2.2 Identifying Malicious Executables

Since many legitimate applications are installed or updated via HTTP (e.g., Windows Update), we immediately exclude all executable downloads from a manually-compiled whitelist of domain names consisting of approximately 120 effective second level domains (e2LDs) of popular benign sites (e.g., `microsoft.com`, `google.com`, etc.). For the remaining downloads, we scan them with more than 40 antivirus (AV) engines, using `virustotal.com`. In addition, we rescan them periodically because many "fresh" malware files are not immediately detected by AV scanners, allowing us to also take into account some "zero-day" downloads. We label a file as malicious if at least one of the top five AV vendors (w.r.t. market share) and a minimum of two other AVs detect it as malicious. The remaining downloads are considered benign until the rescan. In addition, we discard binary samples that are assigned labels that are too generic or based purely on AV detection heuristics.

2.3 Overview of Study Data

To gather our study data we deployed our collection agent (Section 2.1) on a large academic network serving tens of thousands of users for a period of 6 months. Notice that the system was deployed for a total of 10 months, with the study conducted in the first 6 months and the evaluation in the 4 months that followed (see Section 4 details on the evaluation). During these 6 months, we collected a total of $174,376$ executable downloads from domains that were not on our whitelist. Using the malicious executable identification process defined in Section 2.2, we labeled $5,536$ downloads as malicious.

However, many of these malicious downloads were related to *adware*. As we are primarily interested in studying *malware* downloads, because they are potentially the most damaging ones, we devised a number of "best effort" heuristics to separate *adware* from *malware*. For example, given a malicious file, if the majority of AV labels contain the term "adware", or related empirically derived keywords that identify specific unwanted applications (e.g., "not-a-virus", "installer", "PUP", etc.), we label the file as *adware*. The malicious executables not labeled as *adware* by our heuristics were manually reviewed to determine if they were truly *malware*. This resulted in $1,064$ *malware* downloads, with a total of 533 unique samples.

For these 533 unique malware downloads, we performed extensive manual analysis of their download paths, including reverse engineering web pages, heavy javascript deobfuscation, complex plugin content analysis, etc. This time-consuming analysis produced a set of labeled paths, with 164 drive-by, 41 social engineering and 328 update/drop malware download events.

Study Data Limitations: Our collection agent was deployed on an existing production network monitoring sensor. This sensor had limited hardware resources; in addition, our data collection system had to run alongside production software whose functionality could not be disrupted. We therefore collected downloads only during off-peak hours, due to traffic volumes that would oversubscribe the sensor and result in dropped packets during other periods of the day. Thus, the malicious downloads in our study represent only a sample of the ones that occurred during the six month monitoring period. In addition, our system monitors the network in a *purely passive* way; therefore, any malicious downloads preemptively blocked by existing defenses (e.g., URL blacklists such as Google Safe Browsing) were not observed. Yet, based on our extensive manual analysis, we believe the 533 malware downloads to be sufficiently diverse and representative of the overall set of malware downloads that occurred during our study period.

2.4 Download Path Traceback Challenges

One of the goals of our system is to automatically trace back the sequence of steps (i.e., HTTP transactions) that lead victims to be infected via a malware download. One may think that reconstructing the *web path to infection* is fairly easy, because we could rely on the `Referer` and `Location` header fields to link subsequent HTTP transactions together (see RFC2616). For example, a simple strategy would be to start from the download transaction and "walk back" the sequence of transactions by following the `Referer` header found in the HTTP requests.

Unfortunately, in practice download path traceback is much more difficult than it may seem at first. Depending on the particular version of the browser, JavaScript engine, and plugin software running on the client, the `Referer` and/or `Location` headers may be suppressed (e.g., see [14]), resulting in the inability to correctly reconstruct the entire sequence of download path transactions in a given network trace.

Deriving and Measuring Surrogate Features: As part of our study, we reviewed hundreds of malicious download traces. In most cases we cannot rely completely on the `Referer` and `Location` headers, and we therefore derive surrogate "referrer indicator" features and heuristics, which can be used to perform a more complete download path traceback. Next, we define each of the features we observed, and then provide a measure of how prevalent they are for malware download paths. While in this section we simply *measure their prevalence*, we later use these features to automate path traceback (Section 3).

First, let us more precisely define what we mean with *download path traceback*. Let T_d indicate an HTTP transaction carrying an executable file download initiated by client C. Given the recording of all web traffic generated by C during a time window preceding (and including) T_d, we would like to reconstruct the sequence of transactions $(T_1, T_2, \ldots, T_d)$ that led to the download, while filtering out all unrelated traffic. This sequence of transactions may be the consequence of both explicit user interactions (e.g., a click on a link) and actions taken by the browser during rendering (e.g., following a page redirection). Notice that the traffic trace we are given may contain a large number of transactions that are completely unrelated to the download path, simply because the user may have multiple browser tabs open and multiple web-based applications active in parallel. Thus, potentially producing a large amount of overlapping unrelated traffic.

Let T_1 and T_2 be two HTTP transactions. We found that the features/heuristics listed below can be used to determine whether T_1 is a *likely source* of T_2, therefore allowing us to "link" them with different levels of confidence. Table 1 summarizes the prevalence of each feature in both drive-by and social engineering downloads (we discuss how we can distinguish drive-by from social engineering later in Section 2.5). A detailed discussion of how WebWitness uses these features for automated download path traceback is given in Section 3.

(1) **Location**: According to RFC2616, if transaction T_2's URL matches T_1's `Location` header, it indicates that T_2 was reached as a consequence of a server redirection from T_1.

(2) **Referrer**: Similarly, if T_1's URL matches T_2's `Referer` header, this indicates that the request for T_2 originated (either directly or through a redirection chain) from T_1, for example as a consequence of page rendering, a click on a hyperlink, etc.

(3) **Domain-in-URL**: We observed that advertisement URLs often embed the URL of the page that displayed the ad. So, if T_1's domain name is "embedded" in T_2's URL, it is likely that T_1 was the "source" of the request, even though the `Referer` is not present. This is especially true if there is only a small time gap between the transactions.

(4) **URL-in-Content**: If T_1's response content includes T_2's URL (e.g., within an HTML or non-obfuscated JavaScript code), this indicates there is (potentially) a "source of" relationship that links T_1 to T_2.

(5) **Same-Domain**: By investigating numerous drive-by malware downloads, we found that in many cases the exploit code and the malware executable file itself are served from the same domain. This approach is likely chosen by the attackers because if the exploit is successfully served, it means that the related malicious domain is currently reachable and serving the malware file from the same domain helps guarantee a successful infection (a similar observation was made in [13]). Therefore, if T_1 and T_2 share the same domain name and are temporally close, this likely indicates that T_1 is the "source of" T_2.

(6) **Commonly Exploitable Content (CEC)**: In our observations, most drive-by downloads use "commonly exploitable" content (e.g., .jar, .swf, or .pdf files that carry an exploit) to compromise their victims. The exploit downloads the malicious executable; thus, if T_1 contains commonly exploitable content (CEC) and T_2 is an executable download that occurred within a small time delta after T_1, this indicates that T_1 may be the "source of" T_2.

(7) **Ad-to-Ad**: In some cases, we observed chains of ad-related transactions where the `Referer` and `Location` header are missing (e.g., due to JavaScript or plugin-driven redirections). Therefore, if T_1 and T_2 are consecutive ad-related requests (e.g., identified by matching their URLs against a large list of known ad-distribution sites) and were issued within a small time delta, this indicates there may be a "source of" relationship.

Table 1: Success rate of traceback method and "Source-of" relationships in malware download paths. The numbers indicate the percentage of analyzed download paths.

Traceback method success rate	Drive-by	Social Eng.
Only Referrer and Location	0%	53%
All surrogate referrer features	96%	95%

Feature	Drive-by	Social Eng.
Location	69%	73%
Referrer	97%	100%
Domain-in-URL	0%	5%
URL-in-Content	17%	17%
Same-Domain	97%	20%
CEC	5%	0%
Ad-to-Ad	6%	10%

As a confirmation to the fact that tracing back malware download paths is challenging, we found that not a single drive-by download in our dataset could be traced back by relying only on the `Referer` and `Location` headers. For example, even if 97% of the drive-by download paths contained at least one pair of requests linked via the `Referer`, all drive-by paths contained at least some subsequence of the path's transactions that could not be "linked" by simply using the `Referer` header.

For social engineering paths, we found that 53% of the downloads could be traced back using only the `Referer` and `Location` headers. When this was not possible, the main cause was the presence of requests made via JavaScript and browser plugins. In some cases, we were not able to fully trace back the download path. The cause for the majority of the untraceable drive-by (4%) and social engineering (5%) downloads, when using all the features, was missing transactions likely due to our system not observing all related packets.

2.5 Drive-by vs. Social Engineering

We label a malware download path as *social engineering* if explicit user interaction (e.g., a mouse click) is required to initiate a malware download. In contrast, we label as *drive-by* those malware downloads that are transparently delivered to the victim via a browser exploit. As mentioned earlier (Section 2.3), during our study, we were able to manually review and label 164 drive-by and 41 social engineering malware downloads.

What distinguishes drive-by from social-engineering: In the following we report the characteristics that we observed for different types of paths. In particular, some of these characteristics could be leveraged as statistical features to build a classifier that automatically distinguishes between drive-by and social engineering downloads (see Section 3). We also discuss characteristics of malware updates/drops that could be used to filter out download paths that belong neither to the drive-by nor to the social-engineering class. Table 2 summarizes the prevalence of each of the characteristics described below.

Table 2: Download path properties.

Feature	Drive-by	Social eng.
Candidate Exploit Domain Age	0	-
Drive-by URL Similarity	69%	0%
Download Domain Recurrence	0.6%	34%
Download Referrer	0.6%	95%
Download Path Length	6	7
User-Agent Popularity	95%	98%

(1) **Candidate Exploit Domain "Age":** Drive-by download attacks often exploit their victims by delivering exploits via files of popular content types such as `.jar`, `.swf`, or `.pdf` files; we simply refer to these file types as "commonly exploitable" content (CEC). For example, during our study, we found that 94% of the drive-by download paths at some point delivered the exploit via CEC. The domains serving these exploits tend to be short-lived compared to domains serving benign content of the same type. Therefore, CEC served from a recently registered domain is an indicator of a possible drive-by download path. On the other hand, none of the social engineering download paths we observed during our study had this property. Table 2 reports the median domain name "age", computed as the number of days of activities for the domain of a page serving CEC, measured over a very large passive DNS database. The median age is less than one day for drive-by paths, and is not indicated for social engineering paths, because none of the nodes in the social engineering path served content of the type we consider as CEC (the overall traffic traces included HTTP transactions that carried content such as `.swf` files, but none of those were on the download path).

(2) **Drive-by URL Similarity:** The majority of drive-by downloads (about 70% of our observations) are served by a small number of exploit kits. Therefore, in many cases the exploit delivery URLs included in drive-by download paths share a structural URL similarity to known exploit kit URLs. Table 2 reports the fraction of drive-by download paths that had a similarity to known exploit kit URLs greater than 0.8, measured using the approach proposed in [26].

(3) **Download Domain Recurrence:** Most domains serving drive-by and social engineering malware download are contacted rarely, and often only once by one particular client at the time of the attack. On the other hand, malicious software regularly checks for executable updates. To approximately capture this intuition, we measured the number of queries to the malware download domain. As shown in Table 2, only 0.6% of the malware download domains in our drive-by paths are queried mulitple times within a small time window (two days, in our measurements). The higher percentage of social engineering malware paths with download domain recurrence is due to the fact that a significant fraction of the ones we observed used a free file sharing website for the malware download and that we count the domain query occurrences in aggregate, rather than per client.

(4) **Download Referrer:** In case of social engineering attacks, the HTTP transaction that delivers the malicious file download tends to carry a `Referer`, usually due to the direct user interaction that characterizes them. On the other hand, drive-by attack malware file delivery happens via a browser exploit. The request initiated from the shell code typically does not have a `Referer` header. Similarly, malware updates/drops initiated by malicious applications are already running on a compromised machine, and usually do not carry any referrer information. Table 2 shows that only 0.6% of all drive-by paths, in contrasts to 95% of social engineering paths, carried a `Referer` in the download node.

(5) **Download Path Length:** Drive-by and social engineering attacks typically generate download paths consisting of several nodes, mainly because a user has to first browse to a site that eventually leads to the actual attack. In addition, the malware distribution infrastructure is often built in such ways that enables malware downloads "as a service", which entails the use of a number of "redirection" steps. In contrast, download paths related to malware updates or drops tend to be very short. Table 2 reports the median number of nodes for drive-by and social engineering paths. In case of malware updates/drops, the median length for the path was only one node.

(6) **User-Agent Popularity:** The download paths for both drive-by and social engineering downloads typically include several nodes that report a popular browser user-agent string, as the victims use their browser to reach the attack. On the other hand, in most cases of a malware drop/update, it is not the browser, but the update software making the requests. In practice, we observed that the majority of malware update download paths did not report a popular user-agent string (only 36% of them did). Table 2 reports the percentage of paths that include a popular user-agent string.

3 WebWitness

Inspired by our study of real-world malware download paths, we develop a system called WebWitness that can automate the investigation of new malware download attacks. The primary goal of this system is to provide *context* around malicious executable downloads. To this end, given a traffic trace that includes all web traffic recorded during a time window preceding (and including) a malicious executable file download, WebWitness automatically traces back and categorizes the web paths that led the victim to the malicious download event.

In this section, we describe the components of our system, which are shown in Figure 2.

3.1 ATC - Download Path Traceback

Given a malicious file download trace from a given client, WebWitness aims to trace back the *download path* consisting of the sequence of web pages visited by the user that led her to a malware download attack (e.g., via social engineering or to a drive-by exploit). As detailed in Section 2.4, the trace may contain many HTTP transactions that are unrelated to the download. Furthermore, it is not always possible to correctly link two related consecutive HTTP transactions by simply leveraging their HTTP `Referer` or `Location` headers.

To mitigate the limitations of referrer-only approaches and more accurately trace back the download path, we devise an algorithm that leverages the features and heuristics we identified during our initial study of in-the-wild malware downloads presented in Section 2.4. In summary, we build a *transactions graph*, where nodes are HTTP transactions within the download trace, and edges connect transaction according to a "probable source of" relationship (explained in detail below). Then, starting from the node (i.e., the HTTP transaction) related to the malware file download, we walk back along the most probable edges until we find a node with no predecessor, which we label as the "origin" of the download path. In the following, we provide more details on our traceback algorithm.

Transactions Graph. Let D be the dataset of HTTP traffic generated by host A before (and including) the download event. We start by considering all HTTP transactions in D, and construct a weighted directed graph $G = (V,E)$. The vertices are A's HTTP transactions and the edges represent the relation "probable source of" for pairs of HTTP transactions. As an example, the edge $e = (v_1 \rightarrow v_2)$ implies that HTTP transaction v_1 likely produced HTTP transaction v_2, either automatically (e.g., via a server-imposed redirection, javascript, etc.) or through explicit user interaction (e.g., via a hyperlink click). Thus, we can consider v_1 as the "source of" v_2. Each edge has a weight that expresses the level of confidence we have on the "link" between two nodes (the weights are ordinal so their absolute values are not important). For example, the higher the weight assigned to $e = (v_1 \rightarrow v_2)$, the stronger the available evidence in support of the conclusion that v_1 is the "source of" v_2 (edge weights are further discussed below). Also, let t_1 and t_2 be the timestamp of v_1 and v_2, respectively. Regardless of any available evidence for a possible edge, the two nodes may be linked only if $t_1 \leq t_2$.

Heuristics and Edge Weights. To build the graph G and draw its edges, we leverage the seven features that we indentified in Section 2.4. Specifically, given two nodes (essentially, two URLs) in the directed graph G described earlier, an edge $e = (v_1 \rightarrow v_2)$ is created if any of the seven features is satisfied. For example, if v_1 and v_2 can be related via the "Domain-in-URL", we draw an edge between the two nodes. We associate a weight to each of the seven features; the "stronger" the feature, the higher its weight. For example, we assign a weight value $w_e = 7$ to the "Location" feature, $w_e = 6$ to the "Referrer" feature, and so on, with the "Ad-to-Ad" receiving a weight $w_e = 1$. The weight values are conveniently assigned simply to express relative importance and precedence among the edges to be considered by our greedy algorithm. If more than one feature happens to link two nodes, the edge will be assigned a weight equal to the maximum weight among the matching features.

Traceback Algorithm. Once G has been built, we use a *greedy algorithm* to construct an approximate "backtrace path". We start from the graph node related to the executable download event, and walk backwards on the graph by always choosing the next edge with the highest weight. Consider the example graph in Figure 3, in which thicker edges have a higher weight. We start from the download node d. At every step, we walk one node backwards following the highest weight edge. We proceed until we reach a node with no predecessor, which we mark as the *origin* of the download path. If a node has more than one predecessor whose edges have the same weight, we follow the edge related to the predecessor node with the smaller time gap to the current node (measured w.r.t. the corresponding HTTP transactions).

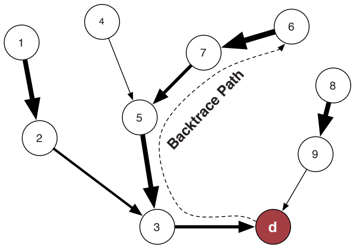

Figure 3: Example of download path traceback.

Possible False and Missing Edges: Naturally, the heuristics we use for tracing back the download path may in some cases add "false edges" to the graph or miss some edges. However, notice that these challenges are mitigated (though not always completely eliminated) by the following observations:

i) Our algorithm and heuristics aim to solve a much narrower problem than finding the correct "link" between all possible HTTP transactions in a network trace, because we are only concerned with tracing back a sequence of HTTP transactions that terminate into a malicious executable download.

ii) The "false edge" problem is mitigated by the fact that we always follow the strongest evidence. For example, consider Figure 3. Suppose the edge $(2 \rightarrow 3)$ was drawn due to rule (6), while edge $(5 \rightarrow 3)$ was drawn due to rule (2). In this case, even though edge $(2 \rightarrow 3)$ was mistakenly drawn (i.e., nodes 2 and 3 have no real "source of" relationship), the mistake is irrelevant, because our algorithm will choose $(5 \rightarrow 3)$ as part of the path, which is supported by stronger evidence.

iii) Our algorithm can output not only the sequence of HTTP transactions, but also the nature (and confidence) of every edge. Therefore, a threat analyst (or a downstream post processing system) can take the edge weights into account, before the reconstructed download path is used to make further decisions (e.g., remediation or takedown of certain domains in the download path).

3.2 ATC - Download Cause Classification

After we trace back the download path, we aim to label the reconstructed path as either *social engineering* or *drive-by* download. As shown in Figure 2, the output of this classification step allows us to obtain the annotated malware download paths (AMPs), which are then provided as input to the defense module (MDD).

While we are mainly interested in automatically identifying social engineering and drive-by download paths, we build a three-class classifier that can distinguish between three broad download causes, namely *social engineering*, *drive-by*, and *update/drop*. Essentially the *update/drop* class allows us to more easily identify and exclude malware downloads that are not caused by either social engineering or drive-by attacks.

To automatically classify the "cause" of an executable file download, WebWitness uses a supervised classification approach. First, we describe how we derive the features needed to translate malware download events into feature vectors that can be given as input to a statistical classifier. Then, we discuss how we derive the dataset used to train the classifier. To actually build the classifier, we used the random forest algorithm [7] (see Section 4).

Features: To discriminate between the three different classes, we engineered six statistical features that reflect, with a one-to-one mapping, the six characteristics of drive-by and social-engineering malware download paths that we discussed and measured in Section 2.5. For example, we measure binary feature (1) "Download Referrer" as true if the HTTP request that initiated the download has a `Referer` header; a numerical feature (2) representing the "age" of domains serving "commonly exploitable" content; etc.

Training dataset: To train the classifier, we use the dataset of in-the-wild malware download paths that we collected and manually labeled during our initial investigation of in-the-wild malware downloads discussed in Section 2.5. Our training dataset contained the following number of labeled download paths: 164 instances of *drive-by* download paths, 191 instances of *social engineering* paths, and 328 *update/drop* samples.

3.3 MDD - Drive-by Defense

The annotated download paths output by ATC provide a large and up-to-date dataset of real-world malware download incidents, including the web paths followed by the victims (see Figure 2). This information is very useful for studying new attack trends and developing more effective defenses. As new defenses are developed, they can be plugged into the MDD module, so that as new malware download paths are discovered we can automatically derive appropriate countermeasures.

As an example that demonstrates how WebWitness can enable the development of more effective malware download defenses, we develop a new defense against drive-by download attacks based on code injections. While code injection attacks are not new, current defenses rely mainly on blacklisting the URLs serving the actual drive-by exploit or malware download, rather than blocking the URLs from which malicious code is injected. Our results (Section 4) show that by automatically tracing back drive-by download paths and identifying the code injection URLs, we can enable better defenses against future malware attacks.

Identifying code injection URLs: Given a *drive-by* download path output by the ATC module, we aim to automatically identify the *landing*, *injection*, and *exploit* nodes within the download path.We tackle this problem using a supervised classification approach. Namely, we train a separate classifier for each of the three types of nodes on a drive-by download path. The final output is a labeled drive-by download path.

Exploit Page Classifier: The exploit classifier takes as input a drive-by download path and labels its nodes as *exploit* or *non-exploit*. We define an exploit node as a page that carries content that exploits a vulnerability on the victim's machine, causing it to eventually download a malicious executable. The search for exploit nodes proceed "backwards", starting from the node prior to the executable download and ending at the root. It is not uncommon to have more than one exploit node in one path (e.g., some exploit kits try several exploits before success). Thus, multiple nodes could be labeled as *exploit*.

To build the classifier, we use the following features:

(1) *Hops to the download page*. Number of nodes on the download path between the considered node and the final malware download node. *Intuition*: It is typical for the exploit node to only be a few hops away from the actual download. In many cases, the node prior to the download event is an exploit node, because once the exploit succeeds the executable is downloaded immediately.

(2) *"Commonly exploitable" content*. Boolean feature that indicates if a node contains content for Java, Silverlight, Flash or Adobe Reader. *Intuition*: Browser plug-ins are a popular exploitation vector. The exploit is typically delivered though their content.

(3) *Domain age*. The number of days since the first observation of the node's effective second level domain in a large historic passive DNS database. *Intuition*: Exploit domains tend to be short-lived and often only active for one day.

(4) *Same domain*. Boolean feature that is true if the node's domain is equal to the download domain. *Intuition*: It is common for the exploit and download to be served by the same domain, as also noted in [13].

Landing Page Classifier: Once the exploit node(s) is labeled, we attempt to locate the landing page URL. Essentially, the landing page is the web page where the drive-by attack path begins. Often, the landing page itself is a non-malicious page that was previously compromised (or "hacked"). The landing page classifier calculates the probability that a node preceding the exploit node (labeled by the exploit page classifier discussed earlier) is a landing page. Nodes with a probability higher than a tunable detection threshold (50% in our experiments) are classified as "candidate landing" nodes. If there are multiple candidates, the one with the highest probability is labeled as the landing node.

To label a node as either *landing* or *non-landing*, we engineered the following statistical features:

(1) *Hops to the exploit page*. This feature set consists of the number of non-redirect nodes and unique effective second level domains between the node and the exploit node. *Intuition*: Often, all the nodes between the landing and exploit node are redirects [36]. Also, most drive-by downloads use one to three types of malicious domains (injection, exploit, download). Therefore, in most cases there are zero or one domains (the one being the injection domain) on the download path between the landing and exploit nodes.

(2) *Domain age*. We use two features based on domain age. The first feature is the age of the node's effective second level domain as computed from a passive DNS database. *Intuition*: The domains associated to ("hacked") landing pages tend to be long-lived. Furthermore, "older" landing pages tend to offer more benefits to the attackers, as they often attract more visitors (i.e., potential victims), because it takes time for legitimate pages to become popular. The second feature is the age of the oldest domain between the node and the exploit node. *Intuition*: Nodes on the download path between the landing and exploit nodes tend to be less than a year in age. This is because they are typically malicious and recently registered.

(3) *Same domain*. Boolean feature that is true if the node's domain is equal to the exploit domain. *Intuition*: It is uncommon for an exploit to be served

from the same domain as the landing page. They are typically kept separate because installing an exploit kit on a compromised website may increase the likelihood of detection by the legitimate site's webmaster. In addition, it is much easier to manage a centralized exploit kit server than keep all the compromised websites up-to-date with the latest exploits.

Injection Page Classifier: We define the injection page to be the source of the code inserted into the "hacked" landing page. Typically, the injection and exploit nodes are separate and are served via different domain names. This provides a level of indirection that allows the exploit domain to change without requiring an update to the landing page. The injection node by definition is a successor to the landing page, but depending on the injection technique it may or may not be directly present in the download path traced back by the ATC module. Therefore, the classifier calculates the injection page probability for each direct successor of the landing node in the transactions graph, instead of only considering nodes in the reconstructed download path. The successor of the landing page node with the highest probability is labeled as the injection page node.

To identify the *injection* page, for each successor of the *landing* node we measure the following features:

(1) *On path*. Boolean feature indicating if the node is on the download path. *Intuition*: Being on the download path and a successor of the landing page, makes it a good candidate for the injection node. However, the injection node is not always on the download path due to the structure of some drive-by downloads.

(2) *Advertisement*. Boolean feature that is true if the node is an ad. *Intuition*: By definition, the injection page is not an ad, but code injected into the landing page. It is common for ads that are not related to the malicious download to be served on a landing page. This feature help us exclude those ad nodes.

(3) *Domain age*. The number of days since the first observation of the node's effective second level domain in passive DNS. *Intuition*: Injection pages typically have the sole purpose of injecting malicious code. They are rarely hosted directly on compromised pages, because this would expose the malicious code to cleanup by the legitimate site owners, ending the attacker's ability to exploit visitors. Consequently, injection pages are hosted on "young" domains that are typically active for the lifetime of a website compromise.

(4) *Successors*. There are two features that are derived from the node's successors. First is the number of direct successors. *Intuition*: Injection nodes tend to have only one direct successor. They typically perform an HTTP redirect or dynamically update the DOM to include the URL of the exploit domain. Benign pages often have more than one direct successor because they load content from many different files or sources. The second feature is boolean and it is true if one of the node's successors is on the download path. It indicates there is a possible "source of" relationship between it and a node on the download path. Even though the node itself may not be on the download path.

(5) *Same domain*. There are two boolean features that compare domain names. The first checks for equality between the node's domain and the landing domain. *Intuition*: It is uncommon for the landing domain to equal the injection domain for reasons similar to those described in the landing page classifier's "same domain" feature described earlier. The second feature compares the node's domain to the exploit domain. *Intuition*: In approximately 70% of the observations in our measurement study (Section 2), the exploit and injection domains were different.

4 Evaluation

In this section, we evaluate WebWitness' ATC and MDD modules. We also demonstrate the overall benefits of our new defense approach against drive-by downloads, by measuring the effectiveness of blacklisting the injection domains discovered by WebWitness. We show that while blacklisting the injection domains provides a better defense, compared to blacklisting only the exploit and download domains, injection domains appear very rarely in current blacklists, including Google Safe Browsing and a variety of large public blacklists.

4.1 ATC - Download Cause Classification

The download cause classifier uses a supervised learning approach to label each download path as either *social engineering*, *drive-by* or *update/drop* (Section 3.2). To evaluate its accuracy, we use WebWitness to traceback and classify all malicious downloads collected from the large academic network (Section 2) in the months *following* our initial study and development of the system. Specifically, all download events and samples used during evaluation have *no overlap* with the data we used for the study presented in Section 2, to design WebWitness' features and heuristics, or to train our classifiers. Each malicious download observed during the *testing period* was then classified as one of the following: *drive-by*, *social engineering* or *update*. From each of the three predicted classes we randomly sampled 50 downloads for manual verification. We limited the sample size to a total of 150 downloads because of the extensive manual analysis required to determine the ground truth, including reverse engineering web pages, heavy javascript deobfuscation, complex html and plugin content analysis, etc. This time consuming review process allowed us to identify the correct web path and the *true cause* of download, creating our *ground truth* for the evaluation. Table 3 reports the confusion matrix for the cause classifier.

Table 3: Cause Classifier - Confusion Matrix Results

		Predicted Class		
	Class	Drive-by	Social	Update/Drop
Ground Truth	Drive-by	47	1	0
	Social	2	46	3
	Update/Drop	1	3	47

The classifier correctly labeled over 93% of the downloads. Notice that these results represent the overall system performance of the ATC module, because the download paths used in the experiment (i.e., input to the cause classifier) were extracted using our download path traceback algorithm (Section 3.1). The two social engineering samples classified as drive-by downloads both had commonly exploitable content (CEC) on the download path. They were misclassified even though the CEC domain ages were greater than 200 days. The three update/drop samples classified as social engineering was caused by invalid download paths resulting from the false edges described in the next section. Finally the three social engineering downloads misclassified as update/drop was a result of small downloads paths (all were length 3) and high download domain recurrence (all greater than 20 of the 48 hourly buckets).

4.2 ATC - Download Path Traceback

To evaluate the accuracy of our download path traceback algorithm (Section 3.1), we use the 150 manually reviewed downloads; i.e., our ground truth, from Section 4.1. For path traceback, we consider two types of errors for review: (1) missing nodes: the traceback stops short, before reaching the origin of the download path (recall that the traceback algorithm works its way backwards from the download node to the path origin); (2) false node: a node that should not appear in the download path. Table 4 summarizes the results of our evaluation.

Table 4: Download Path Traceback Results.

	Paths	Correctly Traced Back	Missing	False
Drive-By	48	45	3	0
Social	51	46	2	3
Update/Drop	51	47	0	4

The results show that 92% of the download paths were correctly traced back by our system. The 5 with missing nodes all had a *referer* header in the origin node's request, but a matching URL was not contained in the trace. This was likely due to our system not observing all the packets related to those transactions. The 7 with the false nodes were all caused by the "same-domain" heuristic incorrectly connecting the paths of an update and a social engineering download. The heuristic failed because the updates were performed by a malicious executable seconds after the user was socially engineered into downloading it from the same domain as the update.

4.3 MDD - Detecting Injection Domains

As discussed in detail in Section 3.3, we aim to automatically identify the malicious code injection domains often employed in drive-by download attacks. To achieve this goal, we use a cascade of three classifiers: an *exploit*, a *landing*, and an *injection* classifier (Section 3.3). In the following, we evaluate the performance of each one.

To build the training dataset, we use 117 drive-by malware downloads collected and manually labeled during our six-month malware study described in Section 2. These 117 drive-by paths contained 246 exploit nodes (notice that it is not uncommon for a drive-by attack to serve more than one exploit, especially when the first exploit attempt fails). There is only one landing node and one injection node per download path.

Table 5: Node Labeling for Drive-By Download Paths

Experiment	Classifier	Correctly Labeled	Incorrectly Labeled
Cross-Validation	Exploit	99.19%	0%
	Landing	96.58%	0.17%
	Injection	94.87%	0.07%

We performed 10-fold cross-validation tests using the dataset described above. Table 5 summarizes the results. As can be seen, all classifiers are highly accurate. The results of the the injection page classifier represent the performance of the final injection domain detection task. This is due to fact that all tests were conducted using the three classifiers (exploit, landing, and injection) in cascade mode to mirror an actual deployment of WebWitness' MDD module. Thus, overall, we obtained a minimum of 94.87% detection rate at 0.07% false positives.

There were a total 7 domains mislabeled as injection by our system. The most common error was labeling the exploit domain as the injection domain; i.e., missing the fact that a separate injection domain existed. This was the case for 5 of the 7 mislabeled domains. Since these domains are malicious, blacklisting them will not cause false positives. The other two domains were benign. One of them had an Alexa rank over $260,000$ and the other above $1,600,000$. To mitigate such false positives, the newly discovered injection domains could be reviewed by analysts before blacklisting. As WebWitness provides the analyst with full details on the traffic collected before the download and the reconstructed download path, this information can make the analyst's verification process significantly less time-consuming.

4.4 MDD - Defense Efficacy & Advantages

Domain name and URL blacklisting are commonly practiced defenses [2]. However, blacklists are only effective if the blacklisted domains remain in use for some period of time after they are detected. The longer-lived a malicious domain, the more useful it is to blacklist it. As discussed in Sections 3.3 and 4.3, WebWitness is able not only to identify the domains from which malware files are downloaded, but also to identify the malicious code injection and exploit domains within drive-by malware download paths. Clearly, these domains are all candidates for blacklisting.

To evaluate the efficacy of blacklisting the code injection domains, we demonstrate the advantages this provides compared to the currently more common approach of blacklisting the exploit and download domains. To this end, we use a set of 88 "complete" injection-based drive-by download paths that we were able to collect from a large academic network. These samples were "complete" paths in the sense that they were manually verified to have an injection, exploit, and malware download node (and related domain).

We evaluate the effect of blocking the different types of drive-by path domains by counting the number of potential victims that would be saved by doing so. Specifically, we define a potential victim as a unique client host visiting a blacklisted domain. Notice that the actual number of hosts that get infected may be smaller than the number of potential victims, because only some of the hosts that visit a malicious domain involved in a drive-by download attack will "successfully" download and run the malware file (e.g., because an anti-virus blocked the malware file from running on the machine). However, we can use the potential victim count to provide a relative comparison on the effectiveness of blacklisting injection versus exploit and malware download domains.

To count the potential victims, we rely on a very large passive DNS (pDNS) database that spans multiple Internet Service Providers (ISPs) and corporate networks. This pDNS dataset stores the historic mappings between domains and IP addresses, and also provides a unique source identifier for each host that queries a given domain name. This allows us to identify all the unique hosts that queried a given domain in a given timeframe (e.g., a given day). For each injection-based drive-by download paths in our set, we compute the potential victims saved by counting the number of unique hosts that query the injection, exploit, and file download domains in the 30 days following the date when we observed and labeled the download event. Figure 4 shows our results, in which day-0 is the day when we detected a malicious download path (the victims counts are aggregated, per day, for all hosts contacting a malicious domain). We can immediately see that the number of potential victims that query the exploit or file download domains rapidly drops as the exploit domain ages. On the other hand, injection domains are longer lived, and blacklisting them would prevent a much larger number of potential victims from being redirected to new (unknown) and frequently churning exploit and file download domains. Blacklisting the injection domain saves almost 6 *times* more potential victims, compared to blacklisting the exploit domain.

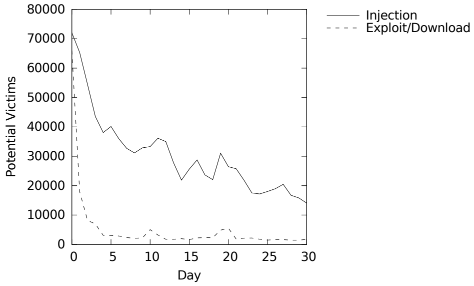

Figure 4: Potential victims saved by blocking the injection versus exploit/download domains on drive-by paths.

4.5 Blacklists & Google Safe Browsing

In this section, we aim to gain additional insights into the advantages that could be provided by our WebWitness' MDD module, compared to existing domain blacklists.

Public Domain Blacklists First, given the entire set of malicious domain names related to drive-by downloads discovered during our study and deployment of WebWitness, we counted how many of these domains appeared in popular public blacklists. We also measured the delay between when we first discovered the domain on a malware download path and when it appeared on a blacklist. This was possible because we repeatedly collected all domain names reported by the following set of public blacklists every day for more than a year: support.clean-mx.de, malwaredomains.com, zeustracker.abuse.ch, phishtank.com and malwaredomainlist.com. Table 6 summarizes our findings.

Table 6: Public Blacklisting Results.

	Uniq. Domains		Days: Detect to Blacklist		
	Observed	Blacklisted	Min.	Med.	Mean
Exploit/Download	152	9	1	20	29
Injection	52	6	20	31	36

As shown in Table 6, from all drive-by download paths that we were able to identify, reconstruct, and label, we collected a total of 52 unique drive-by code injection domains and 152 unique drive-by exploit and malware file download domains. Overall, less than 10% of these domains ever appeared on a public blacklist. As we can see, more exploit/download domains (a total of 9) were blacklisted, compared to the injection domains (only 6). Furthermore, we can see that the minimum time it took for an injection domain to appear in at least one blacklist was 20 days, whereas some exploit domains were blacklisted almost immediately (after only one day).

Because injection domains are typically longer lived than exploit domains, and because the same injection domain is often used throughout the course of a drive-by download campaign to redirect users to different (short-lived) exploit domains, identifying and blocking injection domains has a significant advantage. By helping to quickly identify and blacklist injection domains, WebWitness enables the creation of better defenses against drive-by downloads, thus helping to significantly reduce the number of potential malware victims, as we also demonstrated in the previous Section 4.4.

Google Safe Browsing For the last few weeks of our deployment of WebWitness, we checked the domain names related to the drive-by download paths reconstructed by our system against Google Safe Browsing (GSB) [2]. Specifically, given a malware download path and its malicious domains, we queried GSB on the next day, compared to the day the malware download was observed. Overall, during this final deployment period we observed 34 drive-by download paths. GSB detected a total of 6 malicious domains that were related to only 4 out of the 34 downloads. The domains GSB detected were used to serve drive-by exploits, the malware file themselves, or were related to ads used to lead the victims to a browser exploit. *None of the domains detected by GSB were injection domains*, even though our 34 download paths included 12 unique injection domains.

It is important to notice, however, that while GSB detected malicious domains related to only 4 out of our 34 drive-by download paths, there may be many more malware downloads that WebWitness cannot observe, simply because they are blocked "up front" by GSB. Because WebWitness passively collects malware download traces from the network whenever a malicious executable file download is identified in the traffic, it is very possible that in many cases GSB simply prevented users who were about to visit a drive-by-related domain from loading the malicious content, and therefore from downloading the malware file in the first place. Nonetheless, the fact that WebWitness automatically discovered 30 drive-by download paths that were not known to GSB demonstrates that our system can successfully complement existing defenses.

4.6 Case Studies

4.6.1 Social Engineering

Figure 5 shows the *download path* for an in-the-wild social engineering attack, including the "link" relationships between nodes in the path. The user first performs a search on `www.youtube.com` (A) for a "*facebook private profile viewer*", which is the *root* of the path. Next, the user clicks on the top search result leading to a "*trick*" page on `www.youtube.com` (B), which hosts a video demonstrating a program that supposedly allows the viewing of the private profiles of Facebook users. A textual description under the video provides a link to download a "profile viewer" application through a URL shortener `goo.gl` (C). This shortened URL link redirects the user to `uploading.com` (D), a free file sharing site that prompts the user with a link to start the download. This leads to another `uploading.com` (E) page that thanks the user for downloading the file and opens a new `uploading.com` (F) page that includes an `<iframe>` with source `fs689.uploading.com` (G), from which the executable file is downloaded. The file is labeled as "Trojan Downloader" by some anti-virus scanners.

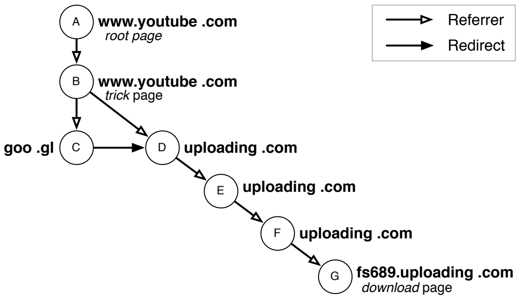

Figure 5: Social engineering download example.

Notice that no exploit appears to be involved in this attack, and that the user (highly likely) had to explicitly click on various links and on the downloaded malware file itself to execute it.

4.6.2 Drive-by

Figure 6 shows the *download path* related to an in-the-wild drive-by download.

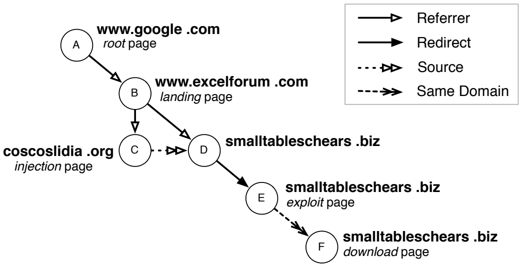

Figure 6: Drive-by download example.

The download path originates from (A) `www.google.com` (the *root* page), where the user entered the search terms "*add years and months together*." The first link in the search results, which the user clicked on, is for a webpage (B) on `www.excelforum[dot]com` (the *landing* page). Sadly, the page the user landed

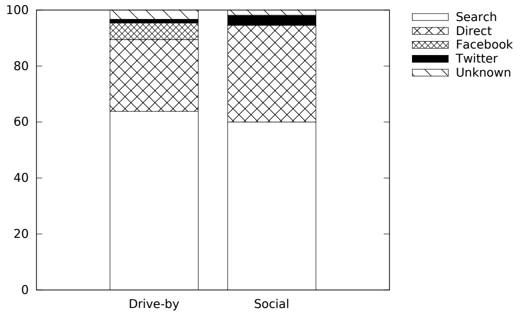

Figure 7: “Root” of malware download paths.

on was compromised several days earlier, resulting in the addition of a `<script>` tag with source at `coscoslidia[dot]org`, which is the *injection* page. The script is automatically retrieved from (C) and executed, forcing an `<iframe>` to be added and rendered. The source of the frame (D) is on the site `smalltableschears[dot]biz`, from which the content is immediately fetched and included in the page. The newly loaded javascript served by (D) then checks for the presence of vulnerable versions of several browser plugins. It quickly matches a version of the installed Adobe Flash Player to a known vulnerability and dynamically adds another `<iframe>` to the page, which pulls a malicious Flash exploit file from (E) on the same `smalltableschears[dot]biz` site (the *exploit* page). The Flash exploit succeeds and the shellcode fetches a malware binary (labeled as ZeroAccess by some AVs) from (F) on the same domain `smalltableschears[dot]biz` (the *download* page).

4.7 “Origin” of Malware Download Paths

Figure 7 shows a breakdown of the drive-by and social engineering “origins” behind the malware downloads. For drive-by downloads, 64% of the download paths started with a search. We noticed that the search query keywords were typically very “normal” (e.g., searching for a new car, social events, or simple tools, as shown in the example in Section 4.6.2), but unfortunately the search results linked to hacked websites that acted as the “entry point” to exploit distribution sites and malware downloads.

For social engineering downloads, about 60% of the web paths started with a search. Search engine queries that eventually led to social engineering attacks tended to be related to less legitimate content. For example, the search queries were often related to free streaming links, pirated movies, or pirated versions of popular expensive software. In these cases, the search results contained links offering content relevant to the search, but the related search result pages would also encourage the user to install malicious software disguised as some required application (e.g., a video codec or a software key generator).

The second most common origin is direct links, whereby a user arrives to a webpage directly (e.g., by clicking on a link within a spam email), rather than through a link from another site. Most of these direct links point to a benign website that is either hacked or displays malicious ads.

Facebook and Twitter represent a relatively infrequent origin for malware downloads (7% and 3% of the cases, respectively). While both Facebook and Twitter usually rely on encrypted (HTTPS) communications, we were able to determine if a download path originated from their sites by noticing that Facebook makes sure that all external requests carry a generic `www.facebook.com` referrer [14]. On the other hand, requests initiated by clicking on a link published on twitter carry a referrer containing a `t.co` shortening URL. During our entire deployment, we only observed one case in which a link from Facebook or Twitter led directly to a drive-by exploit kit. In all other cases, the links led first to a legitimate page that was hacked or that displayed a malicious ad.

For the remaining malicious downloads (less than 3%, overall) we were unable to trace them back to their origin (e.g., due to missing traffic).

During our deployment, we also found that malicious ads are responsible for a significant fraction of the malware downloads in our dataset. Specifically, malicious ads were included in the web path of about 25% of drive-by and 40% of social engineering malware downloads. The malicious ads we observed were typically displayed on relatively unpopular websites. We observed only one example of a malicious ad served on a website with a US Alexa ranking within the top 500.

5 Discussion and System Limitations

Our system only collected data during off-peak hours because it was sharing hardware resources with a production network monitoring system whose functionality could not be disrupted. Thus, our data is just a sample of the malicious downloads that occurred during this period. Also, due to the significant efforts required to analyze complex malware download traces, our evaluation ground truth is limited to a representative sample of the malicious downloads that occurred in the monitored network. However, based on our extensive manual analysis, we believe the samples to be very diverse because of the various exploit kits, exploits, social engineering tricks and malware observed, and therefore representative of the overall set of malware downloads that occurred during our deployment.

One may think that attackers could avoid detection by simply distributing malicious files over encrypted web traffic, using HTTPS. However, it is worth noting that in sensitive networks (e.g., enterprise and government networks) it is now common practice to deploy SSL Man-In-The-Middle (MITM) proxies, which allow for inspecting and recording the content both HTTP and HTTPS traffic (perhaps excluding the traffic towards some whitelisted sides, such as banking applications, etc.). WebWitness could simply work alongside such SSL MITM proxies.

Because the detection of malicious executable files is outside the scope of this paper, we have relied on a "detection oracle" to extract malicious download traces from the network traffic. For the sake of this study, we have chosen to rely on multiple AV scanners. It is well known, though, that AV scanners suffer from false positive and negatives. In addition, the labels assigned by the AV are often not completely meaningful. However, we should consider that using multiple AV scanners reduces the false negatives, and the set of filtering heuristics we discussed in Section 2.2 can mitigate the false positives. In addition, we used re-scanning over a period of a month for each of the downloaded executable files we collected, to further improve our ground truth. Finally, we used the AV labels to filter out adware downloads, because we are mainly interested in the potentially most damaging malware infections. We empirically found that the AV labels usually do a decent job at separating the broad adware and malware classes. Also, we manually reviewed all samples of malware downloads in our dataset, to further mitigate possible mislabeling problems.

Attackers with knowledge of our system may try to evade it by using a purposely crafted attack in attempt to alter some of the features we use in Section 3 to perform path traceback, categorization and for node labeling. Most likely, the attacker will have as a primary goal the evasion of our traceback algorithm. This, for example, could be done by forcing a "disconnect" between the final malware download node and its true predecessors. Such an attack theoretically may be possible, especially in case of drive-by attacks. In such events the browser is compromised and is (in theory) under the full control of the attacker. Now, if the malware download node is isolated in the reconstructed download path, the cause classifier may label the download event a malware update, thus preventing any further processing of the download path (i.e., any attempt to identify the exploit and injection domains).

However, we should also notice that most drive-by downloads are based on what we refer as "commonly exploitable" content in Section 3.3 (e.g., .jar, .swf, or .pdf files that carry an exploit). For such type of drive-by download attacks, the "commonly exploitable" content feature should connect the exploit and the download, if they occur in a small time window. If needed, the time window could be extended by requiring the domain severing the content to be young by checking its "age" before making a connection. Since the exploit must occur before the attacker has control of the browser, it is more difficult to evade.

6 Related Work

Client honeypots actively visit webpages and detect drive-by downloads though observing changes to the system [1, 21, 22, 28, 29] or by analyzing responses for malicious content [3, 10, 24]. These systems tend to have a low false positive rate, but only find malicious websites by visiting them with exploitable browser configurations; also, they have limited range in the quantity of pages they can crawl because they are much slower than static crawlers. Often candidate URLs are selected by filtering content from static crawlers [28, 29, 35], using heuristics to visit parts of the web that are likely more malicious [8] or using search engines to identify webpages that contain content similar to known malicious ones [12].

A number of techniques have been developed to detect drive-by downloads through examining content [10, 11, 15, 32, 34]. Signature based intrusion detection systems, such as Snort [34], passively search network traffic content for patterns of known attacks. Both static [11] and dynamic [10] analysis of JavaScript has been used to detect attacks. The disadvantages of using content is that it is complex and under the control of the attacker. Polymorphic malware and code obfuscation results in missed attacks for signature and static analysis systems, and dynamic analysis can be detected by malware and subverted by altering its execution path [15].

Other systems focus on the redirection chain that leads to drive-by downloads. Stringhini et al [36] create redirection graphs by aggregating redirection chains that end at the same webpage. Features from the redirection graph and visiting users are then used to classify the webpage as malicious or benign. Mekky et al [20] build browsing activity trees using the referrer and redirection headers as well as URLs embedded in the content. Features related to the redirection chain for each tree are extracted and used to classify the activity as malicious or benign. Li et al [17] apply page rank from the dark and bright side of the web to a partially labeled set of redirection chains to separate benign and malicious web paths. They find the majority of malicious paths are directed through traffic distribution systems. Using features from the redirection chain, Surf [18] detects malicious websites found in search engine results due to search poisoning and WarningBird [16] identifies malicious webpages posted on Twitter. These systems focus on the redirection chain and features extracted from it to classify a web activity as benign or malicious. Whereas, WebWitness provides context to malicious downloads by reconstructing the full download path (not just the redirection chain), classifying the cause of the download (drive-by, social, update) and identifying the roles of the domains involved in the attack.

Static blacklists [2] of domains/URLs and domain reputation systems [4, 5] identify malicious websites to prevent users from visiting them. Many of the domains on static blacklists are exploit and download domains that change frequently rendering them less effective. On the other hand, reputation systems only provide a malicious score for a domain and do not indicate their role or give context to an attack. By analyzing the structure of a malicious download, WebWitness can identify the type of attack and the domain roles; providing the highest value domains for blocking and reputation training data.

Recently researchers have proposed executable reputation systems [13,30,38] due the limitations of signature AV [27]. Instead of using content features from the executable content, they focus on properties of the malware distribution infrastructure. These systems can be very effective at identifying malicious downloads. However, they do not provide any context such as how and why the user came to download a malicious executable. Providing download context is the goal of WebWitness not malicious executable detection. We see these systems as complementary to WebWitness and as good candidates to replace our current oracle (signature AV) for malicious executable detection.

Web traffic reconstruction has been studied for example in [9, 25, 39]. WebPatrol [9] uses a client honeypot and a modified web proxy to collect and replay web-based malware scenarios. Unlike WebPatrol, WebWitness is not limited to drive-by downloads invoked through client honeypots and can provide context to drive-by and social engineering attacks on real users observed on live networks. ReSurf [39] uses the referrer header to build graphs of related HTTP transactions to reconstruct web-surfing activities. As discussed in this paper and evaluated in [25], this approach is very limited especially in reconstructing the entire download path of a malicious executable. Lastly, ClickMiner [25] reconstructs user-browser interactions by replaying recorded network traffic through an instrumented browser. Its focus is on the user's behavior that led to a webpage; whereas, WebWitness identifies the cause and structure of an attack that led to a malicious download.

7 Conclusion

We proposed a novel incident investigation system, named WebWitness. Our system targets two main goals: 1) automatically *trace back and label* the chain of events (e.g., visited web pages) preceding malware downloads, to highlight how users reach attack pages on the web; and 2) leverage these automatically labeled in-the-wild malware download paths to better understand current attack trends, and to *develop more effective defenses*.

We deployed WebWitness on a large academic network for a period of 10 months, where we collected and categorized thousands of *live* malware download paths. An analysis of this labeled data allowed us to design a new defense against drive-by downloads that rely on injecting malicious content into (hacked) legitimate web pages. For example, we show that on average by using the results of WebWitness we can decrease the infection rate of drive-by downloads based on malicious content injection by almost *6 times*, compared to existing URL blacklisting approaches.

Vulnerability Disclosure in the Age of Social Media: Exploiting Twitter for Predicting Real-World Exploits

Carl Sabottke Octavian Suciu Tudor Dumitraș
University of Maryland

Abstract

In recent years, the number of software vulnerabilities discovered has grown significantly. This creates a need for prioritizing the response to new disclosures by assessing which vulnerabilities are likely to be exploited and by quickly ruling out the vulnerabilities that are not actually exploited in the real world. We conduct a quantitative and qualitative exploration of the vulnerability-related information disseminated on Twitter. We then describe the design of a Twitter-based exploit detector, and we introduce a threat model specific to our problem. In addition to response prioritization, our detection techniques have applications in risk modeling for cyber-insurance and they highlight the value of information provided by the victims of attacks.

1 Introduction

The number of software vulnerabilities discovered has grown significantly in recent years. For example, 2014 marked the first appearance of a 5 digit CVE, as the CVE database [46], which assigns unique identifiers to vulnerabilities, has adopted a new format that no longer caps the number of CVE IDs at 10,000 per year. Additionally, many vulnerabilities are made public through a *coordinated disclosure process* [18], which specifies a period when information about the vulnerability is kept confidential to allow vendors to create a patch. However, this process results in multi-vendor disclosure schedules that sometimes align, causing a flood of disclosures. For example, 254 vulnerabilities were disclosed on 14 October 2014 across a wide range of vendors including Microsoft, Adobe, and Oracle [16].

To cope with the growing rate of vulnerability discovery, the security community must prioritize the effort to respond to new disclosures by assessing the risk that the vulnerabilities will be exploited. The existing scoring systems that are recommended for this purpose, such as FIRST's Common Vulnerability Scoring System (CVSS) [54], Microsoft's exploitability index [21] and Adobe's priority ratings [19], err on the side of caution by marking many vulnerabilities as likely to be exploited [24]. The situation in the real world is more nuanced. While the disclosure process often produces *proof of concept* exploits, which are publicly available, recent empirical studies reported that only a small fraction of vulnerabilities are exploited *in the real world*, and this fraction has decreased over time [22,47]. At the same time, some vulnerabilities attract significant attention and are quickly exploited; for example, exploits for the Heartbleed bug in OpenSSL were detected 21 hours after the vulnerability's public disclosure [41]. To provide an adequate response on such a short time frame, the security community must quickly determine which vulnerabilities are exploited in the real world, while minimizing false positive detections.

The security vendors, system administrators, and hackers, who discuss vulnerabilities on social media sites like Twitter, constitute rich sources of information, as the participants in coordinated disclosures discuss technical details about exploits and the victims of attacks share their experiences. This paper explores the opportunities for *early exploit detection* using information available on Twitter. We characterize the exploit-related discourse on Twitter, the information posted before vulnerability disclosures, and the users who post this information. We also reexamine a prior experiment on predicting the development of proof-of-concept exploits [36] and find a considerable performance gap. This illuminates the threat landscape evolution over the past decade and the current challenges for early exploit detection.

Building on these insights, we describe techniques for detecting exploits that are active in the real world. Our techniques utilize *supervised machine learning* and ground truth about exploits from ExploitDB [3], OSVDB [9], Microsoft security advisories [21] and the descriptions of Symantec's anti-virus and intrusion-protection signatures [23]. We collect an unsampled corpus of tweets that contain the keyword "CVE," posted between February 2014 and January 2015, and we extract features for training and testing a support vector machine (SVM) classifier. We evaluate the false positive and false negative rates and we assess the detection lead time compared to existing data sets. Because Twitter is an open and free service, we introduce a *threat model*, considering realistic adversaries that can poison both the training and the testing data sets but that may be resource-bound, and we conduct simulations to evaluate the resilience of our detector to such attacks. Finally, we discuss the implications of our results for building security systems without secrets, the applications of early exploit detection and the value of sharing information about successful attacks.

In summary, we make three contributions:

- We characterize the landscape of threats related to information leaks about vulnerabilities before their public disclosure, and we identify features that can be extracted automatically from the Twitter discourse to detect exploits.
- To our knowledge, we describe the first technique for early detection of real-world exploits using social media.
- We introduce a threat model specific to our problem and we evaluate the robustness of our detector to adversarial interference.

Roadmap. In Sections 2 and 3 we formulate the problem of exploit detection and we describe the design of our detector, respectively. Section 4 provides an empirical analysis of the exploit-related information disseminated on Twitter, Section 5 presents our detection results, and Section 6 evaluates attacks against our exploit detectors. Section 7 reviews the related work, and Section 8 discusses the implications of our results.

2 The problem of exploit detection

We consider a *vulnerability* to be a software bug that has security implications and that has been assigned a unique identifier in the CVE database [46]. An *exploit* is a piece of code that can be used by an attacker to subvert the functionality of the vulnerable software. While many researchers have investigated the techniques for creating exploits, the utilization patterns of these exploits provide another interesting dimension to their security implications. We consider *real-world exploits* to be the exploits that are being used in real attacks against hosts and networks worldwide. In contrast, *proof-of-concept (PoC) exploits* are often developed as part of the vulnerability disclosure process and are included in penetration testing suites. We further distinguish between *public PoC exploits*, for which the exploit code is publicly available, and *private PoC exploits*, for which we can find reliable information that the exploit was developed, but it was not released to the public. A PoC exploit may also be a real-world exploit if it is used in attacks.

The existence of a real-world or PoC exploit gives urgency to fixing the corresponding vulnerability, and this knowledge can be utilized for prioritizing remediation actions. We investigate the opportunities for *early detection* of such exploits by using information that is available publicly, but is not included in existing vulnerability databases such as the National Vulnerability Database (NVD) [7] or the Open Sourced Vulnerability Database (OSVDB) [9]. Specifically, we analyze the Twitter stream, which exemplifies the information available from social media feeds. On Twitter, a community of hackers, security vendors and system administrators discuss security vulnerabilities. In some cases, the victims of attacks report new vulnerability exploits. In other cases, information leaks from the *coordinated disclosure* process [18] through which the security community prepares the response to the impending public disclosure of a vulnerability.

The vulnerability-related discourse on Twitter is influenced by trend-setting vulnerabilities, such as Heartbleed (CVE-2014-0160), Shellshock (CVE-2014-6271, CVE-2014-7169, and CVE-2014-6277) or Drupalgeddon (CVE-2014-3704) [41]. Such vulnerabilities are mentioned by many users who otherwise do not provide actionable information on exploits, which introduces a significant amount of noise in the information retrieved from the Twitter stream. Additionally, adversaries may inject fake information into the Twitter stream, in an attempt to poison our detector. Our *goals* in this paper are (i) to identify the good sources of information about exploits and (ii) to assess the opportunities for early detection of exploits in the presence of benign and adversarial noise. Specifically, we investigate techniques for minimizing *false-positive detections*—vulnerabilities that are not actually exploited—which is critical for prioritizing response actions.

Non-goals. We do not consider the detection of *zero-day attacks* [32], which exploit vulnerabilities before their public disclosure; instead, we focus on detecting the use of exploits against known vulnerabilities. Because our aim is to assess the value of publicly available information for exploit detection, we do not evaluate the benefits of incorporating commercial or private data feeds. The design of a complete system for early exploit detection, which likely requires mechanisms beyond the realm of Twitter analytics (e.g., for managing the reputation of data sources to prevent poisoning attacks), is also out of scope for this paper.

2.1 Challenges

To put our contributions in context, we review the three primary challenges for predicting exploits in the absence of adversarial interference: class imbalance, data scarcity, and ground truth biases.

Class imbalance. We aim to train a classifier that produces binary predictions: each vulnerability is classified as either exploited or not exploited. If there are significantly more vulnerabilities in one class than in the other class, this biases the output of supervised machine learning algorithms. Prior research on predicting the existence of proof-of-concept exploits suggests that this bias is not large, as over half of the vulnerabilities disclosed before 2007 had such exploits [36]. However, few vulnerabilities are exploited in the real world and the exploitation ratios tend to decrease over time [47]. In consequence, our data set exhibits a severe class imbalance: we were able to find evidence of real-world exploitation for only 1.3% of vulnerabilities disclosed during our observation period. This class imbalance represents a significant challenge for simultaneously reducing the false positive and false negative detections.

Data scarcity. Prior research efforts on Twitter analytics have been able to extract information from millions of tweets, by focusing on popular topics like movies [27], flu outbreaks [20, 26], or large-scale threats like spam [56]. In contrast, only a small subset of Twitter users discuss vulnerability exploits (approximately 32,000 users), and they do not always mention the CVE numbers in their tweets, which prevents us from identifying the vulnerability discussed. In consequence, 90% of the CVE numbers disclosed during our observation period appear in fewer than 50 tweets. Worse, when considering the known real-world exploits, close to half have fewer than 50 associated tweets. This data scarcity compounds the challenge of class imbalance for reducing false positives and false negatives.

Quality of ground truth. Prior work on Twitter analytics focused on predicting quantities for which good predictors are already available (modulo a time lag): the Hollywood Stock Exchange for movie box-office revenues [27], CDC reports for flu trends [45] and Twitter's internal detectors for highjacked accounts, which trigger account suspensions [56]. These predictors can be used as ground truth for training high-performance classifiers. In contrast, there is no comprehensive data set of vulnerabilities that are exploited in the real world. We employ as ground truth the set of vulnerabilities mentioned in the descriptions of Symantec's anti-virus and intrusion-protection signatures, which is, reportedly, the best available indicator for the exploits included in exploit kits [23, 47]. However, this dataset has coverage biases, since Symantec does not cover all platforms and products uniformly. For example, since Symantec does not provide a security product for Linux, Linux kernel vulnerabilities are less likely to appear in our ground truth dataset than exploits targeting software that runs on the Windows platform.

2.2 Threat model

Research in adversarial machine learning [28, 29], distinguishes between exploratory attacks, which poison the testing data, and causative attacks, which poison both the testing and the training data sets. Because Twitter is an open and free service, causative adversaries are a realistic threat to a system that accepts inputs from all Twitter users. We assume that these adversaries cannot prevent the victims of attacks from tweeting about their observations, but they can inject additional tweets in order to compromise the performance of our classifier. To test the ramifications of these causative attacks, we develop a threat model with three types of adversaries.

Blabbering adversary. Our weakest adversary is not aware of the statistical properties of the training features or labels. This adversary simply sends tweets with random CVEs and random security-related keywords.

Word copycat adversary. A stronger adversary is aware of the features we use for training and has access to our ground truth (which comes from public sources). This adversary uses fraudulent accounts to manipulate the word features and total tweet counts in the training data. However, this adversary is resource constrained and cannot manipulate any user statistics which would require either more expensive or time intensive account acquisition and setup (e.g., creation date, verification, follower and friend counts). The copycat adversary crafts tweets by randomly selecting pairs of non-exploited and exploited vulnerabilities and then sending tweets, so that the word feature distributions between these two classes become nearly identical.

Full copycat adversary. Our strongest adversary has full knowledge of our feature set. Additionally, this adversary has sufficient time and economic resources to purchase or create Twitter accounts with arbitrary user statistics, with the exception of verification and the account creation date. Therefore, the full copycat adversary can use a set of fraudulent Twitter accounts to fully manipulate almost all word and user-based features, which creates scenarios where relatively benign CVEs and real-world exploit CVEs appear to have nearly identical Twitter traffic at an abstracted statistical level.

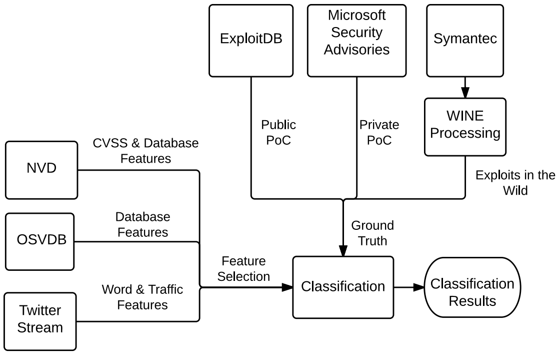

Figure 1: Overview of the system architecture.

3 A Twitter-based exploit detector

We present the design of a Twitter-based exploit detector, using supervised machine learning techniques. Our detector extracts vulnerability-related information from the Twitter stream, and augments it with additional sources of data about vulnerabilities and exploits.

3.1 Data collection

Figure 1 illustrates the architecture of our exploit detector. Twitter is an online social networking service that enables users to send and read short 140-character messages called "tweets", which then become publicly available. For collecting tweets mentioning vulnerabilities, the system monitors occurrences of the "CVE" keyword using Twitter's Streaming API [15]. The policy of the Streaming API implies that a client receives all the tweets matching a keyword as long as the result does not exceed 1% of the entire Twitter hose, when the tweets become samples of the entire matching volume. Because the CVE tweeting volume is not high enough to reach 1% of the hose (as the API signals rate limiting), we conclude that our collection contains all references to CVEs, except during the periods of downtime for our infrastructure.

We collect data over a period of one year, from February 2014 to January 2015. Out of the 1.1 billion tweets collected during this period, 287,717 contain explicit references to CVE IDs. We identify 7,560 distinct CVEs. After filtering out the vulnerabilities disclosed before the start of our observation period, for which we have missed many tweets, we are left with 5,865 CVEs.

To obtain context about the vulnerabilities discussed on Twitter, we query the National Vulnerability Database (NVD) [7] for the CVSS scores, the products affected and additional references about these vulnerabilities. Additionally, we crawl the Open Sourced Vulnerability Database (OSVDB) [9] for a few additional attributes, including the disclosure dates and categories of the vulnerabilities in our study.[1] Our data collection infrastructure consists of Python scripts, and the data is stored using Hadoop Distributed File System. From the raw data collected, we extract multiple features using Apache PIG and Spark, which run on top of a local Hadoop cluster.

Ground truth. We use three sources of ground truth. We identify the set of vulnerabilities *exploited in the real world* by extracting the CVE IDs mentioned in the descriptions of Symantec's anti-virus (AV) signatures [12] and intrusion-protection (IPS) signatures [13]. Prior work has suggested that this approach produces the best available indicator for the vulnerabilities targeted in exploits kits available on the black market [23, 47]. Considering only the vulnerabilities included in our study, this data set contains 77 vulnerabilities targeting products from 31 different vendors. We extract the creation date from the descriptions of AV signatures to estimate the date when the exploits were discovered. Unfortunately, the IPS signatures do not provide this information, so we query Symantec's Worldwide Intelligence Network Environment (WINE) [40] for the dates when these signatures were triggered in the wild. For each real-world exploit, we use the earliest date across these data sources as an estimate for the date when the exploit became known to the security community.

However, as mentioned in Section 2.1, this ground truth does not cover all platforms and products uniformly. Nevertheless, we expect that some software vendors, which have well established procedures for coordinated disclosure, systematically notify security companies of impending vulnerability disclosures to allow them to release detection signatures on the date of disclosure. For example, the members of Microsoft's MAPP program [5] receive vulnerability information in advance of the monthly publication of security advisories. This practice provides defense-in-depth, as system administrators can react to vulnerability disclosures either by deploying the software patches or by updating their AV or IPS signatures. To identify which products are well covered in this data set, we group the exploits by the vendor of the affected product. Out of the 77 real-world exploits, 41 (53%) target products from Microsoft and Adobe, while no other vendor accounts for more than 3% of exploits. This suggests that our ground truth provides the best coverage for vulnerabilities in Microsoft and Adobe products.

We identify the set of vulnerabilities with *public proof-of-concept exploits* by querying ExploitDB [3], a collaborative project that collects vulnerability exploits. We

[1] In the past, OSVDB was called the Open Source Vulnerability Database and released full dumps of their database. Since 2012, OSVDB no longer provides public dumps and actively blocks attempts to crawl the website for most of the information in the database.

identify exploits for 387 vulnerabilities disclosed during our observation period. We use the date when the exploits were added to ExploitDB as an indicator for when the vulnerabilities were exploited.

We also identify the set of vulnerabilities in Microsoft's products for which *private proof-of-concept* exploits have been developed by using the Exploitability Index [21] included in Microsoft security advisories. This index ranges from 0 to 3: 0 for vulnerabilities that are known to be exploited in the real world at the time of release for a security bulletin,[2] and 1 for vulnerabilities that allowed the development of exploits with consistent behavior. Vulnerabilities with scores of 2 and 3 are considered less likely and unlikely to be exploited, respectively. We therefore consider that the vulnerabilities with an exploitability index of 0 or 1 have an private PoC exploit, and we identify 218 such vulnerabilities. 22 of these 218 vulnerabilities are considered real-world exploits in our Symantec ground truth.

3.2 Vulnerability categories

To quantify how these vulnerabilities and exploits are discussed on Twitter, we group them into 7 categories, based on their utility for an attacker: Code Execution, Information Disclosure, Denial of Service, Protection Bypass, Script Injection, Session Hijacking and Spoofing. Although heterogeneous and unstructured, the summary field from NVD entries provides sufficient information for assigning a category to most of the vulnerabilities in the study, using regular expressions comprised of domain vocabulary.

Table 2 and Section 4 show how these categories intersect with POC and real-world exploits. Since vulnerabilities may belong to several categories (a code execution exploit could also be used in a denial of service), the regular expressions are applied in order. If a match is found for one category, the subsequent categories would not be matched.

Aditionally, the Unknown category contains vulnerabilities not matched by the regular expressions and those whose summaries explicitly state that the consequences are unknown or unspecified.

3.3 Classifier feature selection

The features considered in this study can be classified in 4 categories: Twitter Text, Twitter Statistics, CVSS Information and Database Information.

Keyword	MI Wild	MI PoC	Keyword	MI Wild	MI PoC
advisory	0.0007	0.0005	ok	0.0015	0.0002

Table 1: Mutual information provided by the reduced set of keywords with respect to both sources of ground truth data. The "X" marks in the table indicate that the respective words were excluded from the final feature set due to MI below 0.0001 nats.

For the Twitter features, we started with a set of 1000 keywords and 12 additional features based on the distribution of tweets for the CVEs, e.g. the total number of tweets related to the CVE, the average age of the accounts posting about the vulnerability and the number of retweets associated to the vulnerability. For each of these initial features, we compute the mutual information (MI) of the set of feature values X and the class labels $Y \in \{\text{exploited}, \text{not exploited}\}$:

$$MI(Y,X) = \sum_{x \in X} \sum_{y \in Y} p(x,y) \ln \left(\frac{p(x,y)}{p(x)p(y)} \right)$$

Mutual information, expressed in nats, compares the frequencies of values from the joint distribution $p(x,y)$ (i.e. values from X and Y that occur together) with the product of the frequencies from the two distributions $p(x)$ and $p(y)$. MI measures how much knowing X reduces uncertainty about Y, and can single out useful features suggesting that the vulnerability is exploited as well as features suggesting it is not. We prune the initial feature set by excluding all features with mutual information below 0.0001 nats. For numerical features, we estimate probability distributions using a resolution of 50 bins per feature. After this feature selection process, we are left with 38 word features for real-world exploits.

Here, rather than use a wrapper method for feature selection, we use this mutual information-based filter method in order to facilitate the combination of automatic feature selection with intuition-driven manual pruning. For example, keywords that correspond to trend-setting vulnerabilities from 2014, like Heartbleed and Shellshock, exhibit a higher mutual information than many other potential keywords despite their relation to only a small subset of vulnerabilities. Yet, such highly

[2] We do not use this score as an indicator for the existence of real-world exploits because the 0 rating is available only since August 2014, toward the end of our observation period.

specific keywords are undesirable for classification due to their transitory utility. Therefore, in order to reduce susceptibility to concept drift, we manually prune these word features for our classifiers to generate a final set of 31 out of 38 word features (listed in Table 1 with additional keyword intuition described in Section 4.1).

In order to improve performance and increase classifier robustness to potential Twitter-based adversaries acting through account hijacking and Sybil attacks, we also derive features from NVD and OSVDB. We consider all 7 CVSS score components, as well as features that proved useful for predicting proof-of-concept exploits in prior work [36], such as the number of unique references, the presence of the token BUGTRAQ in the NVD references, the vulnerability category from OSVDB and our own vulnerability categories (see Section 3.2). This gives us 17 additional features. The inclusion of these non-Twitter features is useful for boosting the classifier's resilience to adversarial noise. Figure 2 illustrates the most useful features for detecting real-world or PoC exploits, along with the corresponding mutual information.

3.4 Classifier training and evaluation

We train linear support vector machine (SVM) classifiers [35, 38, 39, 43] in a feature space with 67 dimensions that results from our feature selection step (Section 3.3). SVMs seek to determine the maximum margin hyperplane to separate the classes of exploited and non-exploited vulnerabilities. When a hyperplane cannot perfectly separate the positive and negative class samples based on the feature vectors used in training, the basic SVM cost function is modified to include a regularization penalty, C, and non-negative slack variables, ξ_i. By varying C, we explore the trade-off between false negatives and false positives in our classifiers.

We train SVM classifiers using multiple rounds of stratified random sampling. We perform sampling because of the large imbalance in the class sizes between vulnerabilities exploited and vulnerabilities not exploited. Typically, our classifier training consists of 10 random training shuffles where 50% of the available data is used for training and the remaining 50% is used for testing. We use the `scikit-learn` Python package [49] to train our classifiers.

Category	# CVEs	Real-World	PoC	Both
	All Data / Good Coverage			
Code Execution	1249/322	66/39	192/14	28/8
Info Disclosure	1918/59	4/0	69/5	4/0
Denial Of Service	657/17	0/0	16/1	0/0
Protection Bypass	204/34	0/0	3/0	0/0
Script Injection	683/14	0/0	40/0	0/0
Session Hijacking	167/1	0/0	25/0	0/0
Spoofing	55/4	0/0	0/0	0/0
Unknown	981/51	7/0	42/6	5/0
Total	5914/502	77/39	387/26	37/8

Table 2: CVEs Categories and exploits summary. The first sub-column represents the whole dataset, while the second sub-column is restricted to Adobe and Microsoft vulnerabilities, for which our ground truth of real-world exploits provides good coverage.

An important caveat, though, is that our one year of data limits our ability to evaluate concept drift. In most cases, our cross-validation data is temporally intermixed with the training data, since restricting sets of training and testing CVEs to temporally adjacent blocks confounds performance losses due to concept drift with performance losses due to small sample sizes. Furthermore, performance differences between the vulnerability database features of our classifiers and those explored in [36] emphasize the benefit of periodically repeating previous experiments from the security literature in order to properly assess whether the results are subject to long-term concept drift.

Performance metrics. When evaluating our classifiers, we rely on two standard performance metrics: *precision* and *recall*.[3] Recall is equivalent to the true positive rate: Recall $= \frac{TP}{TP+FN}$, where TP is the number of true positive classifications and FN is the number of false negatives. The denominator is the total number of positive samples in the testing data. Precision is defined as: Precision $= \frac{TP}{TP+FP}$ where FP is the total number of false positives identified by the classifier. When optimizing classifier performance based on these criteria, the relative importance of these quantities is dependent on the intended applications of the classifier. If avoiding false negatives is priority, then recall must be high. However, if avoiding false positives is more critical, then precision is the more important metric. Because we envision utilizing our classifier as a tool for prioritizing the response to vulnerability disclosures, we focus on improving the precision rather than the recall.

4 Exploit-related information on Twitter

Table 2 breaks down the vulnerabilities in our study according to the categories described in Section 3.2. 1249 vulnerabilities allowing code execution were disclosed during our observation period. 66 have real-world exploits, and 192 have public proof-of-concept exploits; the intersection of these two sets includes 28 exploits. If we consider only Microsoft and Adobe vulnerabilities, for which we expect that our ground truth has good coverage (see Section 3.1), the table shows that 322 code-

[3] We choose precision and recall because Receiver Operating Characteristic (ROC) curves can present an overly optimistic view of a classifier's performance when dealing with skewed data sets [**?**].

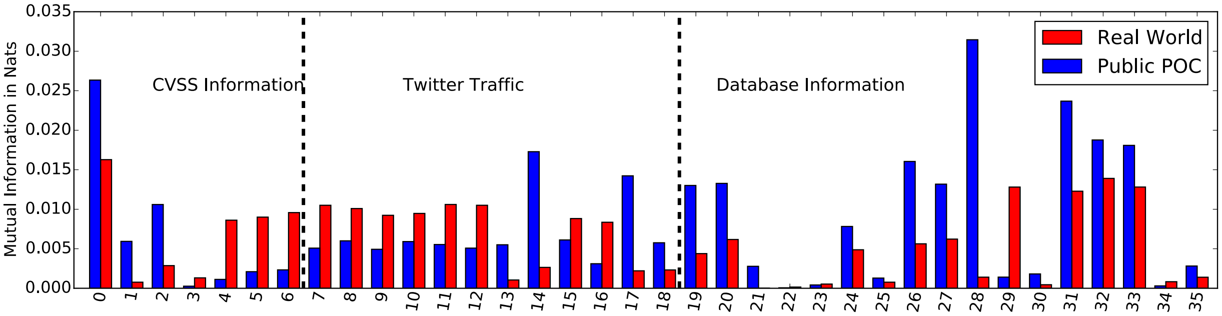

Figure 2: Mutual information between real world and public proof of concept exploits for CVSS, Twitter user statistics, NVD, and OSVDB features. **CVSS Information** - 0: CVSS Score, 1: Access Complexity, 2: Access Vector, 3: Authentication, 4: Availability Impact, 5: Confidentiality Impact, 6: Integrity Impact. **Twitter Traffic** - 7: Number of tweets, 8/9: # users with minimum T followers/friends, 10/11: # retweets/replies, 12: # tweets favorited, 13/14/15: Avg # hashtags/URLs/user mentions per tweet, 16: # verified accounts, 17: Avg age of accounts, 18: Avg # of tweets per account. **Database Information** - 19: # references in NVD, 20: # sources in NVD, 21/22: BUGTRAQ/SECUNIA in NVD sources, 23: allow in NVD summay, 24: NVD last modified date - NVD published date, 25: NVD last modified date - OSVDB disclosed date, 26: Number of tokens in OSVDB title, 27: Current date - NVD last modified date, 28: OSVDB in NVD sources, 29: code in NVD summay, 30: # OSVDB entries, 31: OSVDB Category, 32: Regex Category, 33: First vendor in NVD, 34: # vendors in NVD, 35: # affected products in NVD.

execution vulnerabilities were disclosed, 39 have real-world exploits, 14 have public PoC exploits and 8 have both real-world and public PoC exploits.

Information disclosure is the largest category of vulnerabilities from NVD and it has a large number of PoC exploits, but we find few of these vulnerabilities in our ground truth of real-world exploits (one exception is Heartbleed). Instead, most of the real-world exploits focus on *code execution* vulnerabilities. However, many proof-of-concept exploits for such vulnerabilities do not seem to be utilized in real-world attacks. To understand the factors that drive the differences between real-world and proof-of-concept exploits, we examine the CVSS base metrics, which describe the characteristics of each vulnerability. This analysis reveals that most of the real-world exploits allow *remote* code execution, while some PoC exploits require local host or local network access. Moreover, while some PoC vulnerabilities require authentication before a successful exploit, real-world exploits focus on vulnerabilities that do not require *bypassing authentication* mechanisms. In fact, this is the only type of exploit we found in the segment of our ground truth that has good coverage, suggesting that remote code-execution exploits with no authentication required are strongly favored by real-world attackers. Our ground truth does not provide good coverage of web exploits, which explains the lack of Script Injection, Session Highjacking and Spoofing exploits from our real-world data set.

Surprisingly, we find that, among the remote execution vulnerabilities for which our ground truth provides good coverage, there are *more real-world exploits than public PoC exploits*. This could be explained by the increasing prevalence of obfuscated disclosures, as reflected in NVD vulnerability summaries that mention the possibility of exploitation "via unspecified vectors" (for example, CVE-2014-8439). Such disclosures make it more difficult to create PoC exploits, as the technical information required is not readily available, but they may not thwart determined attackers who have gained experience in hacking the product in question.

4.1 Exploit-related discourse on Twitter

The Twitter discourse is dominated by a few vulnerabilities. Heartbleed (CVE-2014-0160) received the highest attention, with more than 25,000 tweets (8,000 posted in the first day after disclosure). 24 vulnerabilities received more than 1,000 tweets. 16 of these vulnerabilities were exploited: 11 in the real-world, 12 in public proofs of concept and 8 in private proofs of concept. The median number of tweets across all the vulnerabilities in our data set is 14.

The terms that Twitter users employ when discussing exploits also provide interesting insights. Surprisingly, the distribution of the keyword "0day" exhibits a high mutual information with public proof-of-concept exploits, but not with real-world exploits. This could be explained by confusion over the definition of the term *zero-day vulnerability*: many Twitter users understand this to mean simply a new vulnerability, rather than a vulnerability that was exploited in real-world attacks before its public disclosure [32]. Conversely, the distribution of the keyword "patch" has high mutual information only with the real-world exploits, because a common reason for posting tweets about vulnerabilities is to alert other users and point them to advisories for updating vulnerable software versions after exploits are detected in the wild. Certain words like “exploit” or “advisory” are useful for detecting both real-world and PoC exploits.

4.2 Information posted before disclosure

For the vulnerabilities in our data set, Figure 3 compares the dates of the earliest tweets mentioning the corresponding CVE numbers with the public disclosure dates for these vulnerabilities. Using the disclosure date recorded in OSVDB, we identify 47 vulnerabilities that were mentioned in the Twitter stream before their public disclosure. We investigate these cases manually to determine the sources of this information. 11 of these cases represent misspelled CVE IDs (e.g. users mentioning 6172 but talking about 6271 – Shellshock), and we are unable to determine the root cause for 5 additional cases owing to the lack of sufficient information. The remaining cases can be classified into 3 general categories of information leaks:

Disagreements about the planned disclosure date. The vendor of the vulnerable software sometimes posts links to a security bulletin ahead of the public disclosure date. These cases are typically benign, as the security advisories provide instructions for patching the vulnerability. A more dangerous situation occurs when the party who discovers the vulnerability and the vendor disagree about the disclosure schedule, resulting in the publication of vulnerability details a few days before a patch is made available [6, 14, 16, 17]. We have found 13 cases of disagreements about the disclosure date.

Coordination of the response to vulnerabilities discovered in open-source software. The developers of open-source software sometimes coordinate their response to new vulnerabilities through social media, e.g. mailing lists, blogs and Twitter. An example for this behavior is a tweet about a `wget` patch for CVE-2014-4877 posted by the patch developer, followed by retweets and advice to update the binaries. If the public discussion starts before a patch is completed, then this is potentially dangerous. However, in the 5 such cases we identified, the patching recommendations were first posted on Twitter and followed by an increased retweet volume.

Leaks from the coordinated disclosure process. In some cases, the participants in the coordinated disclosure process leak information before disclosure. For example, security researchers may tweet about having confirmed that a vulnerability is exploitable, along with the software affected. This is the most dangerous situation, as attackers may then contact the researcher with offers to purchase the exploit, before the vendor is able to release a patch. We have identified 13 such cases.

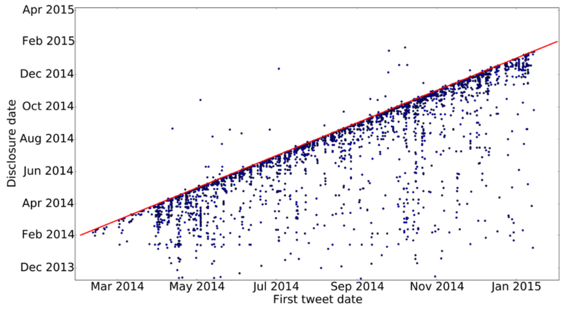

Figure 3: Comparison of the disclosure dates with the dates when the first tweets are posted for all the vulnerabilities in our dataset. Plotted in red is the identity line where the two dates coincide.

4.3 Users with information-rich tweets

The tweets we have collected were posted by approximately 32,000 unique users, but the messages posted by these users are not equally informative. Therefore, we quantify utility on a per user basis by computing the ratio of CVE tweets related to real-world exploits as well as the fraction of unique real-world exploits that a given user tweets about. We rank user utility based on the harmonic mean of these two quantities. This ranking penalizes users that tweet about many CVEs indiscriminately (e.g. a security news bot) as well as the thousands of users that only tweet about the most popular vulnerabilities (e.g. Shellshock and Heartbleed). We create a whitelist with the top 20% most informative users, and we use this whitelist in our experiments in the following sections as a means of isolating our classifier from potential adversarial attacks. Top ranked whitelist users include computer repair servicemen posting about the latest viruses discovered in their shops and security researchers and enthusiasts sharing information about the latest blog and news postings related to vulnerabilities and exploits.

Figure 4 provides an example of how the information about vulnerabilities and exploits propagates on Twitter amongst all users. The “Futex” bug, which enables unauthorized root access on Linux systems, was disclosed on June 6 as CVE-2014-3153. After identifying users who posted messages that had retweets counting for at least 1% of the total tweet counts for this vulnerability and applying a thresholding based on the number of retweets,

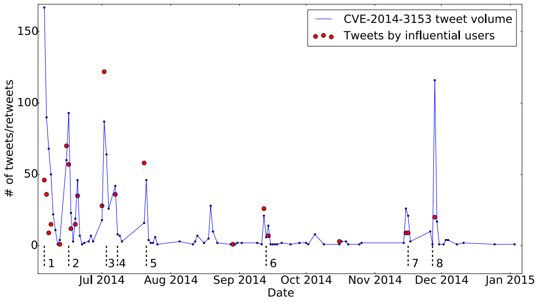

Figure 4: Tweet volume for CVE-2014-3153 and tweets from the most influential users. These influential tweets shape the volume of Twitter posts about the vulnerability. The 8 marks represent important events in the vulnerability's lifecycle: 1 - disclosure, 2 - Android exploit called Towelroot is reported and exploitation attempts are detected in the wild, 3,4,5 - new technical details emerge, including the Towelroot code, 6 - new mobile phones continue to be vulnerable to this exploit, 7 - advisory about the vulnerability is posted, 8 - exploit is included in ExploitDB.

we identify 20 influential tweets that shaped the volume of Twitter messages. These tweets correspond to 8 important milestones in the vulnerability's lifecycle, as marked in the figure.

While CVE-2014-3153 is known to be exploited in the wild, it is not included in our ground truth for real-world exploits, which does not cover the Linux platform. This example illustrates that monitoring a subset of users can yield most of the vulnerability- and exploit-related information available on Twitter. However, over reliance on a small number of user accounts, even with manual analysis, can increase susceptibility to data manipulation via adversarial account hijacking.

5 Detection of proof-of-concept and real-world exploits

To provide a baseline for our ability to classify exploits, we first examine the performance of a classifier that uses only the CVSS score, which is currently recommended as the reference assessment method for software security [50]. We use the total CVSS score and the exploitability subscore as a means of establishing baseline classifier performances. The exploitability subscore is calculated as a combination of the CVSS access vector, access complexity, and authentication components. Both the total score and exploitability subscore range from 0-10. By varying a threshold across the full range of values for each score, we can generate putative labels where vulnerabilities with scores above the threshold are marked as "real-world exploits" and vulnerabilities below the threshold are labeled as "not exploited". Unsurprisingly, since CVSS is designed as a high recall system which errs on the side of caution for vulnerability severity, the maximum possible precision for this baseline classifier is less than 9%. Figure 5 shows the recall and precision values for both total CVSS score thresholds and CVSS exploitability subscore thresholds.

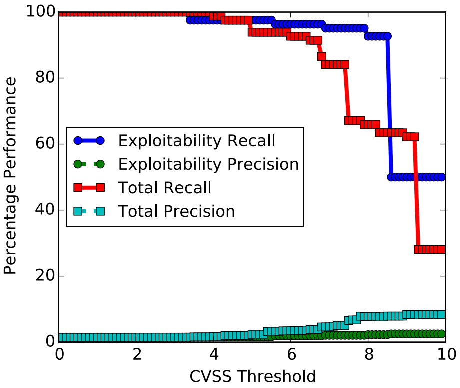

Figure 5: Precision and recall for classifying real world exploits with CVSS score thresholds.

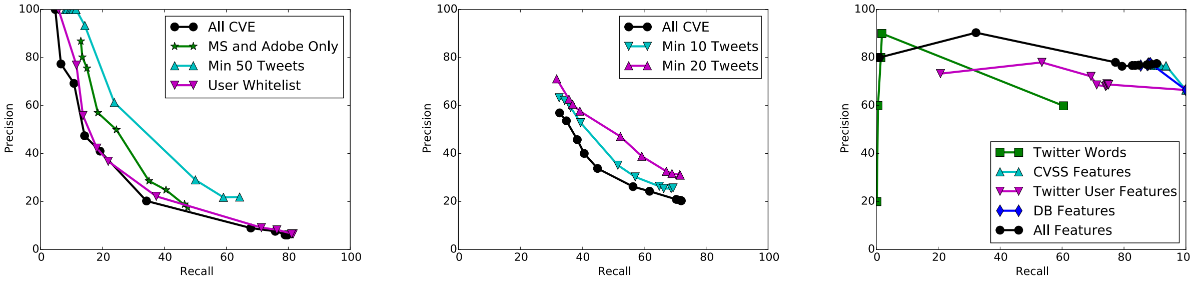
Thus, this high recall, low precision vulnerability score is not useful by itself for real-world exploit identification, and boosting precision is a key area for improvement.

Classifiers for real-world exploits. Classifiers for real-world exploits have to deal with a severe class imbalance: we have found evidence of real-world exploitation for only 1.3% of the vulnerabilities disclosed during our observation period. To improve the classification precision, we train linear SVM classifiers on a combination of CVSS metadata features, features extracted from security-related tweets, and features extracted from NVD and OSVDB (see Figure 2). We tune these classifiers by varying the regularization parameter *C*, and we illustrate the precision and recall achieved. Values shown are for cross-validation testing averaged across 10 stratified random shuffles. Figure 6a shows the average cross-validated precision and recall that are simultaneously acheivable with our Twitter-enhanced feature set. These classifiers can achieve higher precision than a baseline classifier that uses only the CVSS score, but there is still a tradeoff between precision and recall. We can tune the classifier with regularization to decrease the number of false positives (increasing precision), but this comes at the cost of a larger number of false negatives (decreasing recall).



(a) Real-world exploits.

(b) Public proof-of-concept exploits.

(c) Private proof-of-concept exploits for vulnerabilities in Microsoft products.

Figure 6: Precision and recall of our classifiers.

This result partially reflects an additional challenge for our classifier: the fact that our ground truth is imperfect, as Symantec does not have products for all the platforms that are targeted in attacks. If our Twitter-based classifier predicts that a vulnerability is exploited and the exploit exists, but is absent from the Symantec signatures, we will count this instance as a false positive, penalizing the reported precision. To assess the magnitude of this problem, we restrict the training and evaluation of the classifier to the 477 vulnerabilities in Microsoft and Adobe products, which are likely to have a good coverage in our ground truth for real-world exploits (see Section 3.1). 41 of these 477 vulnerabilities are identified as real-world exploits in our ground truth. For comparison, we include the performance of this classifier in Figure 6a. Improving the quality of the ground truth allows us to bolster the values of precision and recall which are simultaneously achievable, while still enabling classification precision an order of magnitude larger than a baseline CVSS score-based classifier. Additionally, while restricting the training of our classifier to a whitelist made up of the top 20% most informative Twitter users (as described in Section 4.3) does not enhance classifier performance, it does allow us to achieve a precision comparable to the previous experiments (Figure 6a). This is helpful for preventing an adversary from poisoning our classifier, as discussed in Section 6.

These results illustrate the current potential and limitations for predicting real-world exploits using publicly-available information. Further improvements in the classification performance may be achieved through a broader effort for sharing information about exploits active in the wild, in order to assemble a high-coverage ground truth for training of classifiers.

Classifiers for proof-of-concept exploits. We explore two classification problems: predicting *public proof-of-concept exploits*, for which the exploit code is publicly available, and predicting *private proof-of-concept exploits*, for which we can find reliable information that the exploit was developed, but it was not released to the public. We consider these problems separately, as they have different security implications and the Twitter users are likely to discuss them in distinct ways.

First, we train a classifier to predict the availability of exploits in ExploitDB [3], the largest archive of *public* exploits. This is similar to the experiment reported by Bozorgi et al. in [36], except that our feature set is slightly different—in particular, we extract word features from Twitter messages, rather than from the textual descriptions of the vulnerabilities. However, we include the most useful features for predicting proof-of-concept exploits, as reported in [36]. Additionally, Bozorgi et al. determined the availability of proof-of-concept exploits using information from OSVDB [9], which is typically populated using references to ExploitDB but may also include vulnerabilities for which the exploit is rumored or private (approximately 17% of their exploit data set). After training a classifier with the information extracted about the vulnerabilities disclosed between 1991–2007, they achieved a precision of 87.5%.

Surprisingly, we are not able to reproduce their performance results, as seen in Figure 6b, when analyzing the vulnerabilities that appear in ExploitDB in 2014. The figure also illustrates the performance of a classifier trained with exclusion threshold for CVEs that lack sufficient quantities of tweets. These volume thresholds improve performance, but not dramatically.[4] In part, this is due to our smaller data set compared to [36], made up of vulnerabilities disclosed during one year rather than a 16-year period. Moreover, our ground truth for public proof-of-concept exploits also exhibits a high class im-

[4] In this case, we do not restrict the exploits to specific vendors, as ExploitDB will incorporate any exploit submitted.

balance: only 6.2% of the vulnerabilities disclosed during our observation period have exploits available in ExploitDB. This is in stark contrast to the prior work, where more than half of vulnerabilities had proof of concept exploits.

This result provides an interesting insight into the evolution of the threat landscape: today, proof-of-concept exploits are less centralized than in 2007, and ExploitDB does not have total coverage of public proof-of-concept exploits. We have found several tweets with links to PoC exploits, published on blogs or mailing lists, that were missing from ExploitDB (we further analyze these instances in Section 4). This suggests that information about public exploits is increasingly dispersed among social media sources, rather than being included in a centralized database like ExploitDB,[5] which represents a hurdle for prioritizing the response to vulnerability disclosures.

To address this concern, we explore the potential for predicting the existence of *private* proof-of-concept exploits by considering only the vulnerabilities disclosed in Microsoft products and by using Microsoft's Exploitability Index to derive our ground truth. Figure 6c illustrates the performance of a classifier trained with a conservative ground truth in which we treat vulnerabilities with scores of 1 or less as exploits. This classifier achieves precision and recall higher than 80%, even when only relying on database feature subsets. Unlike in our prior experiments, for the Microsoft Exploitability Index the classes are more balanced: 67% of the vulnerabilities (218 out of 327) are labeled as having a private proof-of-concept exploit. However, only 8% of the Microsoft vulnerabilities in our dataset are contained within our real-world exploit ground truth. Thus, by using a conservative ground truth that labels many vulnerabilities as exploits we can achieve high precision and recall, but this classifier performance does not readily translate to real-world exploit prediction.

Contribution of various feature groups to the classifier performance. To understand how our features contribute to the performance of our classifiers, in Figure 7 we compare the precision and recall of our real-world exploit classifier when using different subgroups of features. In particular, incorporating Twitter data into the classifiers allows for improving the precision beyond the levels of precision achievable with data that is currently available publicly in vulnerability databases. Both user features and word features generated based on tweets are capable of bolstering classifier precision in comparison to CVSS and features extracted from NVD and OSVDB. Consequently, the analysis of social media streams like Twitter is useful for boosting identification of exploits active in the real-world.

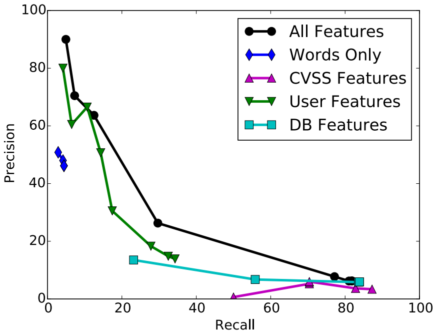


Figure 7: Precision and recall for classification of real world exploits with different feature subsets. Twitter features allow higher-precision classification of real-world exploits.

5.1 Early detection of exploits

In this section we ask the question: *How soon can we detect exploits active in the real world by monitoring the Twitter stream?* Without rapid detecton capabilities that leverage the real-time data availability inherent to social media platforms, a Twiter-based vulnerability classifier has little practical value. While the first tweets about a vulnerability precede the creation of IPS or AV signatures by a median time of 10 days, these first tweets are typically not informative enough to determine that the vulnerability is likely exploited. We therefore simulate a scenario where our classifier for real-world exploits is used in an online manner, in order to identify the dates when the output of the classifier changes from "not exploited" to "exploited" for each vulnerability in our ground truth.

We draw 10 stratified random samples, each with 50% coverage of "exploited" and "not exploited" vulnerabilities, and we train a separate linear SVM classifier with each one of these samples ($C = 0.0003$). We start testing each of our 10 classifiers with a feature set that does not include features extracted from tweets, to simulate the activation of the online classifier. We then continue to test the ensemble of classifiers incrementally, by adding one tweet at a time to the testing set. We update the aggregated prediction using a moving average with a window of 1000 tweets. Figure 8a highlights the tradeoff between precision and early detection for a range of aggregated SVM prediction thresholds. Notably, though, large precision sacrifices do not necessarily lead to large

[5] Indeed, OSVDB no longer seems to provide the exploitation availability flag.

gains for the speed of detection. Therefore, we choose an aggregated prediction threshold of 0.95, which achieves 45% precision and a median lead prediction time of two days before the first Symantec AV or WINE IPS signature dates. Figure 8b shows how our classifier detection lags behind first tweet appearances. The solid blue line shows the cumulative distribution function (CDF) for the number of days difference between the first tweet appearance for a CVE and the first Symantec AV or IPS attack signature. The green dashed line shows the CDF for the day difference between 45% precision classification and the signature creation. Negative day differences indicate that Twitter events occur before the creation of the attack signature. In approximately 20% of cases, early detection is impossible because the first tweet for a CVE occurs after an attack signature has been created. For the remaining vulnerabilities, Twitter data provides valuable insights into the likelihood of exploitation.

Figure 8c illustrates early detection for the case of Heartbleed (CVE-2014-1060). The green line indicates the first appearance of the vulnerability in ExploitDB, and the red line indicates the date when a Symantec attack signature was published. The dashed black line represents the earliest time when our online classifier is able to detect this vulnerability as a real-world exploit at 45% precision. Our Twitter-based classifier provides an "exploited" output 3 hours after the first tweet appears related to this CVE on April 7, 2014. Heartbleed exploit traffic was detected 21 hours after the vulnerability's public disclosure [41]. Heartbleed appeared in ExploitDB on the day after disclosure (April 8, 2014), and Symantec published the creation of an attack signature on April 9, 2014. Additionally, by accepting lower levels of precision, our Twitter-based classifiers can achieve even faster exploit detection. For example, with classifier precision set to approximately 25%, Heartbleed can be detected as an exploit within 10 minutes of its first appearance on Twitter.

6 Attacks against the exploit detectors

The public nature of Twitter data necessitates considering classification problems not only in an ideal environment, but also in an environment where adversaries may seek to poison the classifiers. In causative adversarial machine learning (AML) attacks, the adversaries make efforts to have a direct influence by corrupting and altering the training data [28, 29, 31].

With Twitter data, learning the statistics of the training data is as simple as collecting tweets with either the REST or Streaming APIs. Features that are likely to be used in classification can then be extracted and evaluated using criteria such as correlation, entropy, or mutual information, when ground truth data is publicly available. In this regard, the most conservative assumption for security is that an adversary has complete knowledge of a Twitter-based classifier's training data as well as knowledge of the feature set.

When we assume an adversary works to create both false negatives and false positives (an availability AML security violation), practical implementation of a basic causative AML attack on Twitter data is relatively straightforward. Because of the popularity of spam on Twitter, websites such as `buyaccs.com` cheaply sell large volumes of fraudulent Twitter accounts. For example, on February 16, 2015 on buyaccs.com, the baseline price for 1000 AOL email-based Twitter accounts was $17 with approximately 15,000 accounts available for purchase. This makes it relatively cheap (less than $300 as a base cost) to conduct an attack in which a large number of users tweet fraudulent messages containing CVEs and keywords, which are likely to be used in a Twitter-based classifier as features. Such an attacker has two main limitations. The first limitation is that, while the attacker can add an extremely large number of tweets to the Twitter stream via a large number of different accounts, the attacker has no straightforward mechanism for removing legitimate, potentially informative tweets from the dataset. The second limitation is that additional costs must be incurred if an attacker's fraudulent accounts are to avoid identification. Cheap Twitter accounts purchased in bulk have low friend counts and low follower counts. A user profile-based preprocessing stage of analysis could easily eliminate such accounts from the dataset if an adversary attempts to attack a Twitter classification scheme in such a rudimentary manner. Therefore, to help make fraudulent accounts seem more legitimate and less readily detectable, an adversary must also establish realistic user statistics for these accounts.

Here, we analyze the robustness of our Twitter-based classifiers when facing three distinct causative attack strategies. The first attack strategy is to launch a causative attack without any knowledge of the training data or ground truth. This *blabbering adversary* essentially amounts to injecting noise into the system. The second attack strategy corresponds to the *word-copycat adversary*, who does not create a sophisticated network between the fraudulent accounts and only manipulates word features and the total tweet count for each CVE. This attacker sends malicious tweets, so that the word statistics for tweets about non-exploited and exploited CVEs appear identical at a user-naive level of abstraction. The third, most powerful adversary we consider is the *full-copycat adversary*. This adversary manipulates the user statistics (friend, follower, and status counts) of a large number of fraudulent accounts as well as the text content of these CVE-related tweets to launch a more sophisticated Sybil attack. The only user statis-

Figure 8: Early detection of real-world vulnerability exploits.

tics which we assume this full copycat adversary cannot arbitrarily manipulate are account verification status and account creation date, since modifying these features would require account hijacking. The goal of this adversary is for non-exploited and exploited CVEs to appear as statistically identical as possible on Twitter at a user-anonymized level of abstraction.

For all strategies, we assume that the attacker has purchased a large number of fraudulent accounts. Fewer than 1,000 out of the more than 32,000 Twitter users in our CVE tweet dataset send more than 20 CVE-related tweets in a year, and only 75 accounts send 200 or more CVE-related tweets. Therefore, if an attacker wishes to avoid tweet volume-based blacklisting, then each account cannot send a high number of CVE-related tweets. Consequently, if the attacker sets a volume threshold of 20-50 CVE tweets per account, then 15,000 purchased accounts would enable the attacker to send 300,000-750,000 adversarial tweets.

The blabbering adversary, even when sending 1 million fraudulent tweets, is not able to force the precision of our exploit detector below 50%. This suggests that Twitter-based classifiers can be relatively robust to this type of random noise-based attack (black circles in Fig. 9). When dealing with the word-copycat adversary (green squares in Fig. 9), performance asymptotically degrades to 30% precision. The full-copycat adversary can cause the precision to drop to approximately 20% by sending over 300,000 tweets from fraudulent accounts. The full-copycat adversary represents a practical upper bound for the precision loss that a realistic attacker can inflict on our system. Here, performance remains above baseline levels even for our strongest Sybil attacker due to our use of non-Twitter features to increase classifier robustness. Nevertheless, in order to recover performance, implementing a Twitter-based vulnerability classifier in a realistic setting is likely to require curation of whitelists and blacklists for informative and adversarial users. As shown in figure 6a, restricting the classifier to only consider the top 20% of users with the most relevant tweets about real-world exploits causes no performance degradation and fortifies the classifier against low tier adversarial threats.

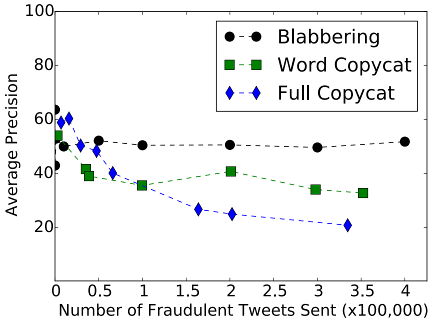

Figure 9: Average linear SVM precision when training and testing data are poisoned by the three types of adversaries from our threat model.

7 Related work

Previous work by Allodi et al. has highlighted multiple deficiencies in CVSS version 2 as a metric for predicting whether or not a vulnerability will be exploited in the wild [24], specifically because predicting the small fraction of vulnerabilities exploited in the wild is not one of the design goals of CVSS. By analyzing vulnerabilities in exploit kits, work by Allodi et al. has also established that Symantec threat signatures are an effective source of information for determining which vulnerabilities are exploited in the real world, even if the coverage is not complete for all systems [23].

The closest work to our own is Bozorgi et al., who applied linear support vector machines to vulnerability and exploit metadata in order predict the development of proof-of-concept exploits [36]. However, the existence of a POC exploit does not necessarily mean that an exploit will be leveraged for attacks in the wild, and real world attacks occur in only of a small fraction of the cases for which a vulnerability has a proof of concept exploit. [25,47]. In contrast, we aim to detect exploits that are active in the real world. Hence, our analysis expands on this prior work [36] by focusing classifier training on real world exploit data rather than POC exploit data and by targeting social media data as a key source of features for distinguishing real world exploits from vulnerabilities that are not exploited in the real world.

In prior analysis of Twitter data, success has been found in a wide variety of applications including earthquake detection [53], epidemiology [26, 37], and the stock market [34, 58]. In the security domain, much attention has been focused on detecting Twitter spam accounts [57] and detecting malicious uses of Twitter aimed at gaining political influence [30, 52, 55]. The goals of these works is distinct from our task of predicting whether or not vulnerabilities are exploited in the wild. Nevertheless, a practical implementation of our vulnerability classification methodology would require the detection of fraudulent tweets and spam accounts to prevent poisoning attacks.

8 Discussion

Security in Twitter analytics. Twitter data is publicly available, and new users are free to join and start sending messages. In consequence, we cannot obfuscate or hide the features we use in our machine learning system. Even if we had not disclosed the features we found most useful for our problem, an adversary can collect Twitter data, as well as the data sets we use for ground truth (which are also public), and determine the most information rich features within the training data in the the same way we do. Our exploit detector is an example of a *security system without secrets*, where the integrity of the system does not depend on the secrecy of its design or of the features it uses for learning. Instead, the security properties of our system derive from the fact that the adversary can inject new messages in the Twitter stream, but cannot remove any messages sent by the other users. Our threat model and our experimental results provide practical bounds for the damage the adversary can inflict on such a system. This damage can be reduced further by incorporating techniques for identifying adversarial Twitter accounts, for example by assigning a reputation score to each account [44,48,51].

Applications of early exploit detection. Our results suggest that, the information contained in security-related tweets is an important source for timely security-related information. Twitter-based classifiers can be employed to guide the prioritization of response actions after vulnerability disclosures, especially for organizations with strict policies for testing patches prior to enterprise-wide deployment, which makes patching a resource-intensive effort. Another potential application is modeling the risk associated with vulnerabilities, for example by combining the likelihood of real-world exploitation, produced by our system, with additional metrics for vulnerability assessment, such as the CVSS severity scores or the odds that the vulnerable software is exploitable given its deployment context (e.g. whether it is attached to a publicly-accessible network). Such models are key for the emerging area of cyber-insurance [33], and they would benefit from an evidence-based approach for estimating the likelihood of real-world exploitation.

Implications for information sharing efforts. Our results highlight the current challenges for the early detection of exploits, in particular the fact that the existing sources of information for exploits active in the wild do not cover all the platforms that are targeted by attackers. The discussions on security-related mailing lists, such as Bugtraq [10], Full Disclosure [4] and oss-security [8], focus on disclosing vulnerabilities and publishing exploits, rather than on reporting attacks in the wild. This makes it difficult for security researchers to assemble a high-quality ground truth for training supervised machine learning algorithms. At the same time, we illustrate the potential of this approach. In particular,our whitelist identifies 4,335 users who post information-rich messages about exploits. We also show that the classification performance can be improved significantly by utilizing a ground truth with better coverage. We therefore encourage the victims of attacks to share relevant technical information, perhaps through recent information-sharing platforms such as Facebook's ThreatExchange [42] or the Defense Industrial Base voluntary information sharing program [1].

9 Conclusions

We conduct a quantitative and qualitative exploration of information available on Twitter that provides early warnings for the existence of real-world exploits. Among the products for which we have reliable ground truth, we identify more vulnerabilities that are *exploited in* *the real-world* than vulnerabilities for which *proof-of-concept exploits* are available publicly. We also identify a group of 4,335 users who post information-rich messages about real-world exploits. We review several unique challenges for the exploit detection problem, including the skewed nature of vulnerability datasets, the frequent scarcity of data available at initial disclosure times and the low coverage of real world exploits in the ground truth data sets that are publicly available. We characterize the threat of information leaks from the coordinated disclosure process, and we identify features that are useful for detecting exploits.

Based on these insights, we design and evaluate a detector for real-world exploits utilizing features extracted from Twitter data (e.g., specific words, number of retweets and replies, information about the users posting these messages). Our system has fewer false positives than a CVSS-based detector, boosting the detection precision by *one order of magnitude*, and can detect exploits a median of *2 days ahead of existing data sets*. We also introduce a threat model with three types of adversaries seeking to poison our exploit detector, and, through simulation, we present practical bounds for the damage they can inflict on a Twitter-based exploit detector.

Acknowledgments

We thank Tanvir Arafin for assistance with our early data collection efforts. We also thank the anonymous reviewers, Ben Ransford (our shepherd), Jimmy Lin, Jonathan Katz and Michelle Mazurek for feedback on this research. This research was supported by the Maryland Procurement Office, under contract H98230-14-C-0127 and by the National Science Foundation, which provided cluster resources under grant CNS-1405688 and graduate student support with GRF 2014161339.

Abstract

Malware sandboxes are automated dynamic analysis systems that execute programs in a controlled environment. Within the large volumes of samples submitted every day to these services, some submissions appear to be different from others, and show interesting characteristics. For example, we observed that malware samples involved in famous targeted attacks – like the Regin APT framework or the recently disclosed malwares from the Equation Group – were submitted to our sandbox months or even years before they were detected in the wild. In other cases, the malware developers themselves interact with public sandboxes to test their creations or to develop a new evasion technique. We refer to similar cases as *malware developments*.

In this paper, we propose a novel methodology to automatically identify *malware development* cases from the samples submitted to a malware analysis sandbox. The results of our experiments show that, by combining dynamic and static analysis with features based on the file submission, it is possible to achieve a good accuracy in automatically identifying cases of *malware development*. Our goal is to raise awareness on this problem and on the importance of looking at these samples from an intelligence and threat prevention point of view.

1 Introduction

Malware sandboxes are automated dynamic analysis tools that execute samples in an isolated and instrumented environment. Security researchers use them to quickly collect information about the behavior of suspicious samples, typically in terms of their execution traces and API calls. While customized sandboxes are often installed in the premises of security companies, some sandboxes are available as public online services, as it is the case for Malwr [13], Anubis [10], ThreatExpert [14], VirusTotal [16], and many others [5, 18, 4, 6, 15, 1, 3]

The main advantage of these systems is the fact that the analysis is completely automated and easily parallelizable, thus providing a way to cope with the overwhelming number of new samples that are collected every day. However, due to this extreme parallelization, an incredible amount of reports are generated every day. This makes the task of distinguishing new and important malware from the background noise of polymorphic and uninteresting samples very challenging.

In particular, two important and distinct observations motivate our work. First, it is relatively common that malware samples used to carry out famous targeted attacks were collected by antivirus companies or public sandboxes long before the attacks were publicly discovered [25]. For instance, the binaries responsible for operation Aurora, Red October, Regin, and even some of the new one part of the Equation Group were submitted to the sandbox we used in our experiments several months before the respective attacks appeared in the news [11, 40, 17, 50, 45, 35]. The reasons behind this phenomenon are not always clear. It is possible that the files were automatically collected as part of an automated network or host-based protection system. Or maybe a security analyst noticed something anomalous on a computer and wanted to double-check if a suspicious file exhibited a potentially malicious behavior. It is even possible that the malware developers themselves submitted an early copy of their work to verify whether it triggered any alert on the sandbox system. Whatever the reason, the important point is that no one paid attention to those files until it was too late.

The second observation motivating our study is the constant arm race between the researchers that put continuous effort to randomize their analysis environments, and the criminals that try to fingerprint those systems to avoid being detected. As a consequence of this hidden battle, malware and packers often include evasion techniques for popular sandboxes [19] and updated information about the internal sandbox details are regularly posted on public websites [2]. These examples prove that there must be a constant interaction between malware developers and popular public malware analysis services. This interaction is driven by the need to collect updated information as well as to make sure that new malware creation would go undetected. Even though detecting this interaction might be very difficult, we believe it would provide valuable information for malware triage.

Up to the present, malware analysis services have collected large volumes of data. This data has been used both to enhance analysis techniques [23, 46] and to extrapolate trends and statistics about the evolution of malware families [24]. Unfortunately, to the best of our knowledge, these datasets have never been used to systematically study malware development and support malware intelligence on a large scale. The only public exception is a research recently conducted by looking at VirusTotal to track the activity of specific high-profile hacking groups involved in APT campaigns [52, 27].

In this paper, we approach this objective by applying data-mining and machine learning techniques to study the data collected by Anubis Sandbox [10], a popular malware dynamic analysis service. At the time we performed our analysis, the dataset contained the analysis reports for over 30 millions unique samples. Our main goal is to automatically detect if miscreants submit their samples during the malware development phase and, if this is the case, to acquire more insights about the dynamics of malware development. By analyzing the metadata associated to the sample submissions, it might be possible to determine the software provenance and implement an early-warning system to flag suspicious submission behaviors.

It is important to understand that our objective is not to develop a full-fledged system, but instead to explore a new direction and to show that by combining metadata with static and dynamic features it is possible to successfully detect many examples of malware development submitted to public sandboxes. In fact, our simple prototype was able to automatically identify thousands of development cases, including botnets, keyloggers, backdoors, and over a thousand unique trojan applications.

2 Overview and Terminology

There are several reasons why criminals may want to interact with an online malware sandbox. It could be just for curiosity, in order to better understand the analysis environment and estimate its capabilities. Another reason could be to try to escape from the sandbox isolation to perform some malicious activity, such as scanning a network or attacking another machine. Finally, criminals may also want to submit samples for testing purposes, to make sure that a certain evasion technique works as expected in the sandbox environment, or that a certain malware prototype does not raise any alarm.

In this paper, we focus on the detection of what we call *malware development*. We use the term *"development"* in a broad sense, to include anything that is submitted by the author of the file itself. In many cases the author has access to the source code of the program – either because she wrote it herself or because she acquired it from someone else. However, this is not always the case, e.g., when the author of a sample uses a builder tool to automatically generate a binary according to a number of optional configurations (see Section 6 for a practical example of this scenario). Moreover, to keep things simple, we also use the word *"malware"* as a generic term to model any suspicious program. This definition includes traditional malicious samples, but also attack tools, packers, and small probes written with the only goal of exfiltrating information about the sandbox internals.

Our main goal is to automatically detect suspicious submissions that are likely related to malware development or to a misuse of the public sandbox. We also want to use the collected information for malware intelligence. In this context, *intelligence* means a process, supported by data analysis, that helps an analyst to infer the motivation, intent, and possibly the identity of the attacker.

Our analysis consists of five different phases. In the first phase, we filter out the samples that are not interesting for our analysis. Since the rest of the analysis is quite time-consuming, any sample that cannot be related to malware development or that we cannot process with our current prototype is discarded at this phase. In the second phase, we cluster the remaining samples based on their binary similarity. Samples in each cluster are then compared using a more fine-grained static analysis technique. Afterwards, we collect six sets of features, based respectively on static characteristics of the submitted files, on the results of the dynamic execution of the samples in the cluster, and on the metadata associated to the samples submissions. This features are finally provided to a classifier that we previously trained to identify the *malware development* clusters.

3 Data reduction

The first phase of our study has the objective of reducing the amount of data by filtering out all the samples that are not relevant for our analysis. We assume that a certain file could be a candidate for malware development only if two conditions are met. First, the sample must have been submitted to the public sandbox *before* it was observed in the wild. Second, it has to be part of a *manual* submission done by an individual user – and not, for example, originating from a batch submission of a security company or from an automated malware collection or protection system.

We started by filtering out the large number of batch submissions Anubis Sandbox receives from several researchers, security labs, companies, universities and registered users that regularly submit large bulks of binaries. As summarized in Table 1, with this step we managed to reduce the data from 32 million to around 6.6 million binaries. These samples have been collected by Anubis Sandbox from 2006 to 2013.

Then, to isolate the new files that were never observed in the wild, we applied a two-step approach. First, we removed those submissions that, while performed by single users, were already part of a previous batch submission. This reduced the size of the dataset to half a million samples. In the second step, we removed the files that were uploaded to the sandbox *after* they were observed by two very large external data sources: Symantec's Worldwide Intelligence Network (WINE), and VirusTotal.

After removing corrupted or not executable files (e.g, Linux binaries submitted to the Microsoft Windows sandbox), we remained with 184,548 files that match our initial definition of candidates for malware development. Before sending them to the following stages of our analysis, we applied one more filter to remove the packed applications. The rationale behind this choice is very simple. As explained in Section 4, the majority of our features work also on packed binaries, and, therefore, some potential malware development can be identified also in this category. However, it would be very hard for us to verify our results without having access to the decompiled code of the application. Therefore, in this paper we decided to focus on unpacked binaries, for which it is possible to double-check the findings of our system. The packed executables were identified by leveraging the SigBuster [37] signatures.

Table 1 summarizes the number of binaries that are filtered out after each step. The filtering phase reduced the data to be analyzed from over 32 millions to just above 121,000 candidate files, submitted by a total of 68,250 distinct IP addresses. In the rest of this section we describe in more details the nature and role of the Symantec and VirusTotal external sources.

Symantec Filter

Symantec Worldwide Intelligence Network Environment (WINE) is a platform that allows researchers to perform data intensive analysis on a wide range of cyber security relevant datasets, collected from over a hundred million hosts [28]. The data provided by WINE is very valuable for the research community, because these hosts are computers that are actively used by real users which are potential victims of various cyber threats. WINE adopts a 1:16 sampling on this large-scale data such that all types of complex experiments can be held at scale.

Dataset	Submissions
Initial Dataset	32,294,094
Submitted by regular users	6,660,022
Not already part of large submissions	522,699
Previously unknown by Symantec	420,750
Previously unknown by VirusTotal	214,321
Proper executable files	184,548
Final (not packed binaries)	121,856

Table 1: Number of submissions present in our dataset at each data reduction step.

To filter out from our analysis the binaries that are not good candidates to belong to malware development, we used two WINE datasets: the binary reputation and the AntiVirus telemetry datasets. The binary reputation dataset contains information about all of the executables (both malicious and benign) downloaded by Symantec customers over a period of approximately 5 years. To preserve the user privacy, this data is collected only from the users that gave explicit consent for it. At the time we performed our study, the binary reputation dataset included reports for over 400 millions of distinct binaries. On the other hand, the AntiVirus telemetry dataset records only the detections of known files that triggered the Norton Antivirus Engine on the users' machines.

The use of binary reputation helps us locating the exact point in time in which a binary was first disseminated in the wild. The AntiVirus telemetry data provided instead the first time the security company deployed a signature to detect the malware. We combined these datasets to remove those files that had already been observed by Symantec either before the submission to Anubis Sandbox, or within 24 hours from the time they were first submitted to the sandbox.

VirusTotal Filter

VirusTotal is a public service that provides virus scan results and additional information about hundreds of millions of analyzed files. In particular, it incorporates the detection results of over 50 different AntiVirus engines – thus providing a reliable estimation of whether a file is benign or malicious. Please note that we fetched the VirusTotal results for each file in our dataset several months (and in some cases even years) after the file was first submitted. This ensures that the AV signatures were up to date, and files were not misclassified just because they belonged to a new or emerging malware family.

Among all the information VirusTotal provides about binaries, the most important piece of information we incorporate in our study is the first submission time of a certain file to the service. We believe that by combining the timestamps obtained from the VirusTotal and Symantec datasets, we achieved an acceptable approximation of the first time a certain malicious file was observed in the wild.

4 Sample Analysis

If a sample survived the data reduction phase, it means that (with a certain approximation due to the coverage of Symantec and Virustotal datasets) it had never been observed in the wild before it was submitted to the online malware analysis sandbox. Although this might be a good indicator, it is still not sufficient to flag the submission as part of a potential malware development. In fact, there could be other possible explanations for this phenomenon, such as the fact that the binary was just a new metamorphic variation of an already known malware family.

Therefore, to reduce the risk of mis-classification, in this paper we consider a candidate for possible development only when we can observe at least two samples that clearly show the changes introduced by the author in the software. In the rest of this section we describe how we find these groups of samples by clustering similar submissions together based on the sample similarity.

4.1 Sample Clustering

In the last decade, the problem of malware clustering has been widely studied and various solutions have been proposed [31, 33, 51, 32]. Existing approaches typically use behavioral features to group together samples that likely belong to the same family, even when the binaries are quite different. Our work does not aim at proposing a new clustering method for malware. In fact, our goal is quite different and requires to group files together only when they are very similar (we are looking for small changes between two versions of the same sample) and not when they just belong to the same family. Therefore, we leverage a clustering algorithm that simply groups samples together based on their binary similarity (as computed by *ssdeep* [38]) and on a set of features we extract from the submission metadata.

Moreover, we decided to put together similar binaries into the same cluster only if they were submitted to our sandbox in a well defined time window. Again, the assumption is that when a malware author is working on a new program, the different samples would be submitted to the online sandbox in a short timeframe. Therefore, to cluster similar binaries we compute the binary similarities among all the samples submitted in a sliding window of seven days. We then shift the sliding window ahead of one day and repeat this step. We employ this sliding window approach in order (1) to limit the complexity of the computation and the total number of binary comparisons, and (2) to ensure that only the binaries that are similar and have been submitted within one week from each other are clustered together. We also experimented with other window sizes (between 2 and 15 days) but while we noticed a significant reduction of clusters for shorter thresholds, we did not observed any advantage in increasing it over one week.

Similarities among binaries are computed using the *ssdeep* [38] tool which is designed to detect similarities on binary data. *ssdeep* provides a light-weight solution for comparing a large-number of files by relying solely on similarity digests that can be easily stored in a database. As we already discarded packed binaries in the data reduction phase, we are confident that the similarity score computed by *ssdeep* is a very reliable way to group together binaries that share similar code snippets. After computing the similarity metrics, we executed a simple agglomerative clustering algorithm to group the binaries for which the similarity score is greater than 70%. Note that this step is executed separately for each time window, but it preserves transitivity between binaries in different sliding windows. For example, if file *A* is similar to *B* inside *window1*, and *B* is similar to file *C* inside the next sliding window, at the end of the process *A*, *B* and *C* will be grouped into the same cluster. As a result, a single cluster can model a malware development spanning also several months.

Starting from the initial number of binaries, we identified 5972 clusters containing an average of 4.5 elements each.

Inter-Cluster Relationships

The *ssdeep* algorithm summarizes the similarity using an index between 0 (completely different) and 100 (perfect match). Our clustering algorithm groups together samples for which the difference between the fuzzy hashes is greater than the 70% threshold. This threshold was chosen according to previous experiments [38], which concluded that 70% similarity is enough to guarantee a probability of misclassification close to zero.

However, if the malware author makes very large changes on a new version of his program, our approach may not be able to find the association between the two versions. Moreover, the final version of a malware development could be compiled with different options, making a byte-level similarity too imprecise. To mitigate these side effects, after the initial clustering step, we perform a refinement on its output by adding inter-clusters edges whenever two samples in the same time window share the same submission origin (i.e., either from the same IP address or using the same email address for the registration). These are "weak" connections that do not model a real similarity between samples, and therefore they are more prone to false positives. As a consequence, our system does not use them when performing its automated analysis to report suspicious clusters. However, as explained in Section 6, these extra connections can be very useful during the analysis of a suspicious cluster to gain a more complete picture of a malware development.

After executing this refinement step, we were able to link to our clusters an additional 10,811 previously isolated binaries. This procedure also connected several clusters together, to form 225 macro groups of clusters.

4.2 Intra-cluster Analysis

Once our system had clustered the binaries that likely belong to the same malware development, we investigate each cluster to extract more information about its characteristics. In particular, we perform a number of code-based analysis routines to understand if the samples in the same cluster share similar code-based features.

Code Normalization

Code normalization is a technique that is widely used to transform binary code to a canonical form [26]. In our study, we normalize the assembly code such that the differences between two binaries can be determined more accurately. Under the assumption that two consecutive variations of the same program are likely compiled with the same tool chain and the same options, code normalization can be very useful to remove the noise introduced by small variations between two binaries.

There are several approaches that have been proposed to normalize assembly code [36, 49, 34]. Some of them normalize just the operands, some the mnemonics, and some normalize both. In this paper, we chose to normalize only the operands so that we can preserve the semantics of the instructions. In particular, we implemented a set of IDA Pro plugins to identify all the functions in the code and then replace, for each instruction, each operand with a corresponding placeholder tag: `reg` for registers, `mem` for memory locations , `val` for constant values, `near` for near call offsets, and `ref` for references to memory locations. These IDA scripts were run in batch mode to pre-process all the samples in our clusters.

Programming Languages

The second step in our intra-cluster analysis phase consists in trying to identify the programming language used to develop the samples. The programming language can provide some hints about the type of development. For example, scripting languages are often used to develop tools or probes designed to exfiltrate information from the sandbox. Moreover, it is likely that a malware author would use the same programming language for all the intermediate versions of the same malware. Therefore, if a cluster includes samples of a malware development, all samples should typically share the same programming language. Exceptions, as the one explained in Section 6, may point to interesting cases.

To detect the programming language of a binary we implemented a simple set of heuristics that incorporate the information extracted by three tools: `PEiD`, the `pefile` python library, and the Linux `strings` command. First, we use `pefile` to parse the Import Address Table (IAT) and obtain the list of libraries that are linked to the binary. Then, we search for programming language specific keywords on the extracted list. For example, the "VB" keyword in the library name is a good indicator of using Visual Basic, and including `mscoree.dll` in the code can be linked to the usage of Microsoft `.NET`. In the second step of our analysis, we analyze the strings and the output of `PEiD` to detect compiler specific keywords (e.g., `type_info` and RTTI produced by C++ compilers, or "Delphi" strings generated by the homonymous language).

With these simple heuristics, we identified the programming language of 14,022 samples. The most represented languages are Visual Basic (49%), C (21%), Delphi (18%), Visual Basic .Net (7%), and C++ (3%). The large number of Visual Basic binaries could be a consequence of the fact that a large number of available tools that automatically create generic malware programs adopt this language.

Fine-grained Sample Similarity

In this last phase, we look in more detail at the similarity among the samples in the same cluster. In particular, we are interested to know why two binaries show a certain similarity: Did the author add a new function to the code? Did she modify a branch condition, or remove a basic block? Or maybe the code is exactly the same, and the difference is limited to some data items (such as a domain name, or a file path).

To answer these questions, we first extract the timeline of each cluster, i.e., the sequence in which each sample was submitted to the sandbox in chronological order. Moving along the timeline, we compare each couple of samples using a number of static analysis plugins we developed for IDA Pro.

The analysis starts by computing and comparing the *call graph* of the two samples. In this phase we compare the normalized code of each function, to check which functions of the second binary were present unchanged in the first binary. The output is a list of additional function that were not present in the original file, plus a list of functions that were likely modified by the author – i.e., those function that share the same position in the call graph but whose code does not perfectly match. However, at this level of granularity it is hard to say if something was modified in the function or if the author just removed the function and added another with the same callee.

Therefore, in these cases, we "zoom" into the function and repeat our analysis, this time comparing their *control flow graphs* (CFGs). Using a similar graph-based approach, this time we look for differences at the basic block level. If the two CFGs are too different, we conclude that the two functions are not one the evolution of the other. Otherwise, we automatically locate the different basic blocks and we generate a similarity measure that summarize the percentage of basic blocks that are shared by the two functions.

4.3 Feature Extraction

Based on the analysis described in the previous sections, our system automatically extracts a set of 48 attributes that we believe are relevant to study the dynamics of malware development.

This was done in two phases. First, we enriched each sample with 25 individual features, divided in six categories (see the Appendix for a complete list of individual features). The first class includes self-explanatory file features (such as its name and size). The Timestamps features identify when the sample was likely created, when it was submitted to Anubis Sandbox, and when it was later observed in the wild. While the creation time of the binary (extracted from the PE headers) could be manually faked by the author, we observed that this is seldom the case in practice, in particular when the author submits a probe or an intermediate version of a program. In fact, in these cases we often observed samples in which the compilation time precedes the submission time by only few minutes.

The third category of features contain the output of the VirusTotal analysis on the sample, including the set of labels associated by all AntiVirus software and the number of AVs that flag the sample as malicious. We then collect a number of features related to the user who submitted the sample. Since the samples are submitted using a web browser, we were able to extract information regarding the browser name and version, the language accepted by the system (sometime useful to identify the nationality of the user) and the IP from which the client was connecting from. Two features in this set require more explanation. The email address is an optional field that can be specified when submitting a sample to the sandbox web interface. The proxy flag is instead an attempt to identify if the submitter is using an anonymization service. We created a list of IP addresses related to these services and we flagged the submissions in which the IP address of the submitter appears in the blacklist. In the Binary features set we record the output of the fine-grained binary analysis scripts, including the number of sections and functions, the function coverage, and the metadata extracted by the PE files. Finally, in the last feature category we summarize the results of the sandbox behavioral report, such as the execution time, potential runtime errors, use of evasion techniques, and a number of boolean flags that represent which behavior was observed at runtime (e.g., HTTP traffic, TCP scans, etc.)

In the second phase of our analysis we extended the previous features from a single sample to the cluster that contains it. Table 2 shows the final list of aggregated attributes, most of which are obvious extensions of the values of each sample in the cluster. Some deserve instead a better explanation. For instance, the cluster `shape` (A3) describes how the samples are connected in the cluster: in a tightly connected group, in a chain in which each node is only similar to the next one, or in a mixed shape including a core group and a small tail. The `Functions diff` (B13) summarized how many functions have been modified in average between one sample and the next one. `Dev time` (B25) tells us how far apart in time each samples were submitted to the sandbox, and `Connect Back` (B24) counts how many samples in the cluster open a TCP connection toward the same /24 subnetwork from which the sample was submitted. This is a very common behavior for probes, as well as for testing the data exfiltration component of a malicious program.

Finally, some features such as the number of crashes (C8) and the average VT detection (D4) are not very interesting per se, but they become more relevant when compared with the number of samples in the cluster. For example, imagine a cluster containing three very similar files. Two of them run without errors, while the third one crashes. Or two of them are not detected by AV signatures, but one is flagged as malware by most of the existing antivirus software.

While we are aware of the fact that each feature could be easily evaded by a motivated attacker, as described in Section 6 the combinations of all them is usually sufficient to identify a large number of development clusters. Again, our goal is to show the feasibility of this approach and draw attention to a new problem, and not to propose its definitive solution.

A: Cluster Features	
A.1 Cluster_id	The ID of the cluster
A.2 Num Elements	The number of samples in the cluster
A.3 Shape	An approximation of the cluster shape (GROUP—MIX—CHAIN)
B: Samples Features	
B.1-4 Filesize stats	Min, Max, Avg, and Variance of the samples filesize
B.5-8 Sections stats	Min, Max, Avg, and Variance of the number of sections
B.9-12 Functions stats	Min, Max, Avg, and Variance of the number of functions
B.13 Functions diff	Average number of different functions
B.14 Sections diff	Average number of different sections
B.15 Changes location	One of: Data, Code, Both, None
B.16 Prog Languages	List of programming languages used during the development
B.17 Filename Edit Distance	The Average edit distance of the samples's filenames
B.18 Avg Text Coverage	Avg text coverage of the .text sections
B.19-22 CTS Time	Min, Max, Avg, and Variance of the difference between compile and the submission time
B.23 Compile time Flags	Booleans to flag `NULL` or constant compile times
B.24 Connect back	True if any file in the cluster contacts back the submitter's /24 network
B.25 Dev time	Average time between each submission (in seconds)
C: Sandbox Features	
C.1 Sandbox Only	Numer of samples seen only by the sandbox (and not from external sources)
C.2 Short Exec	Number of samples terminating the analysis in less than 60s
C.4-6 Exec Time	Min, Max, and Avg execution time of the samples within the sandbox
C.7 Net Activity	The number of samples with network activity
C.7 Time Window	Time difference between first and last sample in the cluster (in days)
C.8 Num Crashes	Number of samples crashing during their execution inside the sandbox
D: Antivirus Features	
D.1-3 Malicious Events	Min, Max, Avg numbers of behavioral flags exibited by the samples
D.4-5 VT detection	Average and Variance of VirusTotal detection of the samples in the cluster
D.6 VT Confidence	Confidence of the VirusTotal score
D.7 Min VT detection	The score for the sample with the minimum VirusTotal Detection
D.8 Max VT detection	The score for the sample with the maximum VirusTotal Detection
D.9 AV Labels	All the AV labels for the identified pieces of malware in the cluster
E: Submitter Features	
E.1 Num IPs	Number of unique IP addresses used by the submitter
E.2 Num E-Mails	Number of e-mail addresses used by the submitter
E.3 Accept Languages	Accepted Languages from the submitter's browser

Table 2: List of Features associated to each cluster

	AUC	Det. Rate	False Pos.
Full data	0.999	98.7%	0%
10-folds Cross-Validation	0.988	97.4%	3.7%
70% Percentage Split	0.998	100%	11.1%

5 Machine Learning

Machine learning provides a very powerful set of techniques to conduct automated data analysis. As the goal of this paper is to automatically distinguishing malware developments from other submissions, we tested with a number of machine learning techniques applied to the set of features we presented in detail in the previous section.

Among the large number of machine learning algorithms we have tested our training data with, we have obtained the best results by using the logistic model tree (LMT). LMT combines the logistic regression and decision tree classifiers by building a decision tree whose leaves have linear regression models [41].

Training Set

The most essential phase of machine learning is the training phase where the algorithm learns how to distinguish the characteristics of different classes. The success of the training phase strictly depends on a carefully prepared labeled data. If the labeled data is not prepared carefully, the outcome of machine learning can be misleading. To avoid this problem, we manually labeled a number of clusters that were randomly chosen between the ones created at the end of our analysis phase. Manual labeling was carried out by an expert that performed a manual static analysis of the binaries to identify the type and objective of each modification. With this manual effort, we flagged 91 clusters as non-development and 66 as development. To estimate the accuracy of the LMT classifier, we conducted a 10-fold cross validation and a 70% percentage split evaluation on the training data.

Feature Selection

In the previous section, we have presented a comprehensive set of features that we believe can be related to the evolution of samples and to distinguish malware developments from ordinary malware samples. However, not all the features contribute in the same way to the final classification, and some works well only when used in combination with other classes.

To find the subset of features that achieves the optimal classification accuracy while helping us to obtain the list of features that contribute the most to it, we leveraged a number of features selection algorithms that are widely used in machine learning literature: Chi-Square, Gain Ratio and Relief-F attribute evaluation. Chi-square attribute evaluation computes the chi-square statistics of each feature with respect to the class, which in our case is the fact of being a malware development or not. The Gain Ratio evaluation, on the other hand, evaluates the effect of the feature by measuring its gain ratio. Finally, the Relief-F attribute evaluation methodology assigns particular weights to each feature according to how much they are successful to distinguish the classes from each other. This weight computation is based on the comparison of the probabilities of two nearest neighbors having the same class and the same feature value.

While the order slightly differs, the ten most effective features for the accuracy of the classifier for all three feature selection algorithms are the same. As also the common sense suggests, the features we extract from the binary similarity and the analysis of the samples are the most successful. For example, the connect back feature that checks if the sample connects back to the same IP address of the submitter, the average edit distance of the filenames of the samples, the binary function similarity, and the sample compile time features are constantly ranked on the top of the list. The submitter features and the sandbox features are following the sample features in the list. All of the features except the number of sandbox evasions, the VirusTotal results, and the features we extracted from the differences on the file sizes in the clusters had a contribution to the accuracy. After removing those features, we performed a number of experiments on the training set to visualize the contribution of the different feature sub-sets to the classification accuracy. Figure 1 shows (in log-scale) the impact of each class and combination of classes. Among all the classes the samples-based features produced the best combination of detection and false positive rates (i.e. 88.2% detection rate with 7.4% false positives). In particular, the ones based on the static and dynamic analysis of the binaries seem to be the core of the detection ability of the system. Interestingly, the cluster-based features alone are the worst between all sets, but they increase the accuracy of the final results when combined with other features.

The results of the final classifier are reported in Table 3: 97.4% detection with of 3.7% false positives, according to 10-folds cross validation experiment. Note that we decided to tune the classifier to favor detection over false positives, since the goal of our system is only to tag suspicious submissions that would still need to be manually verified by a malware analyst.

6 Results

Our prototype implementation was able to collect substantial evidences related to a large number of malware developments.

In total, our system flagged as potential development 3038 clusters over a six years period. While this number was too large for us to perform a manual verification of each case, if such a system would be deployed we estimate between two and three alerts generated per day. Therefore, we believe our tool could be used as part of an early warning mechanism to automatically collect information about suspicious submissions and report them to human experts for further investigation.

In addition to the 157 clusters already manually labeled to prepare the training set for the machine learning component, we also manually verified 20 random clusters automatically flagged as suspicious by our system. Although according to the 10-fold cross validation experiments the false positive rate is 3.7%, we have not found any false positives on the clusters we randomly selected for our manual validation.

Our system automatically detected the development of a diversified group of real-world malware, ranging from generic trojans to advanced rootkits. To better understand the distribution of the different malware families, we verified the AV labels assigned to each reported cluster. According to them, 1474 clusters were classified as malicious, out of which our system detected the development of 45 botnets, 1082 trojans, 83 backdoors, 4 keyloggers, 65 worms, and 21 malware development tools (note that each development contained several different samples modeling intermediate steps). A large fraction

of the clusters that were not identified by the AV signatures contained the development of probes, i.e., small programs whose goal is only to collect and transmit information about the system where they run. Finally, some clusters also contained the development or testing of offensive tools, such as packers and binders.

6.1 Targeted Attacks Campaigns

Before looking at some of the malware development cases detected by our system, we wanted to verify our initial hypothesis that even very sophisticated malware used in targeted attacks are often submitted to public sandboxes months before the real attacks are discovered. For this reason, we created a list of hashes of known and famous APT campaigns, such as the ones used in operation Aurora and Red October. In total, we collected 1271 MD5s belonging to twelve different campaigns. As summarized in Table 4, in all cases we found at least one sample in our database before the campaign was publicly discovered (*Early Submission* column). For example, for Red October the first sample was submitted in February 2012, while the campaign was later detected in October

2012. The sample of Regin was collected a record 44 months before the public discovery.

Finally, we checked from whom those samples were submitted to the system. Interestingly, several samples were first submitted by large US universities. A possible explanation is that those samples were automatically collected as part of a network-based monitoring infrastructure maintained by security researchers. Other were instead first submitted by individual users (for whom we do not have much information) from several different countries, including US, France, Germany, UK, and Romania. Even more interesting, some were first submitted from DSL home Internet connections. However, we cannot claim that we observed the development phase of these large and popular targeted attacks campaigns as in all cases the samples were already observed in the wild (even though undetected and no one was publicly aware of their existence) before they were submitted to our sandbox. It is important to note that for this experiment we considered the entire dataset, without applying any filtering and clustering strategy. In fact, in this case we did not want to spot the *development* of the APT samples, but simply the fact that those samples were submitted and available to researchers long before they were publicly discovered.

We believe the sad message to take away from this experiment is that all those samples went unnoticed. As a community, there is a need for some kind of early warning system to report suspicious samples to security researches. This could prevent these threats from flying under the radar and could save months (or even years) of damage to the companies targeted by these attacks.

6.2 Case studies

In the rest of this section we describe in more details three development scenarios. While our system identified many more interesting cases, due to space limitation we believe the following brief overview provides a valuable insight on the different ways in which attackers use (and misuse) public sandboxes. Moreover, it also shows how a security analyst can use the information collected by our system to investigate each case, and reconstruct both the author behavior and his final goal.

In the first example, the malware author introduced an anti-sandbox functionality to a Trojan application. In this case the analyst gathers intelligence information about the modus operandi of the attacker and about all the development phases.

In the second scenario, we describe a step by step development in which the attacker tries to collect information from the sandbox. This information is later used to detect the environment and prevent the execution of a future malware in the sandbox. In the last example, we show how an attacker uses the sandbox as a testbed to verify the behavior of the malware. In this case, the author generated the binary using one of the many dedicated builder applications that can be downloaded from the Internet or bought on the black market.

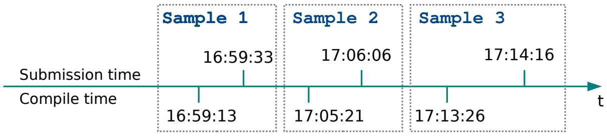

Figure 2: Anti-sandbox check - Timeline

Example I: Anti-sandbox Malware

The cluster related to this example contains three samples. The timeline (summarized in Figure 2) already suggests a possible development. In fact, the difference between the `submission` time and the `compile` time is very small.

A quick look at the static features of the cluster shows that the three samples are very similar, and share the same strings as well as the same imphash (the *import hash* [20, 21] recently introduced also by VirusTotal). However, the first sample is composed of 21 functions, while the last two samples have 22 functions. Our report also shows how the first and the second samples differ for two functions: the author modified the function `start`, and introduced a new function `CloseHandle`. This information (so far extracted completely automatically by our system) is a good starting point for a closer analysis.

We opened the two executables in IDA Pro, and quickly identified the two aforementioned functions (snippet in Figure 3). It was immediately clear that the `start` function was modified to add an additional basic block and a call to the new `CloseHandle` function. The new basic block uses the `rdtsc` x86 instruction to read the value of the Timestamp Counter Register (TSC), which contains the number of CPU cycles since the last reset. The same snippet of assembly is called two times to check the time difference. After the first `rdtsc` instruction there is a call to `CloseHandle`, using the timestamp as handler (probably an invalid handler). These two well known tricks are here combined to detect the Anubis Sandbox environment – due to the delay introduced by its checks during program execution. The Anubis Sandbox's core is slower in looking up the handlers table, and this time discrepancy is the key to detect the analysis environment. In this case the difference has to be less than `0E0000h`, or the program would immediately terminate by calling the `ExitProcess` function.

The last sample in the cluster was submitted only to tune the threshold and for this reason there were no important differences with the second sample. The *control*

Figure 3: Anti-sandbox check - Start function comparison

flow graph analysis performed automatically by our system report a very high similarity between the first two samples, in line with the little modifications we found in the disassembled code. Finally, the behavioral features extracted by our system confirm our hypothesis: the first sample was executed until the analysis timeout, but the execution of the second one terminated after only five seconds.

The behavior described so far suggest malicious intents. This is also confirmed by other cluster metadata. For instance, while the first sample in the cluster was unknown to VirusTotal, the last one was clearly identified as a common `Trojan` application. This suggests that the original sample, without the timing check, has never been used in the wild. Once more, the fact that all three samples have been submitted days before the trojan was first observed in the wild strongly supports the fact that the person who submitted them was indeed the malware author.

Example II: Testing a Trojan Dropper

The second cluster we want to describe is composed of five samples. Our report indicates that the first four are written in Delphi and the last one is written in Visual Basic. This is already a strange fact, since the two programming languages are quite different and it is unlikely that they could generate similar binaries.

In this case the cluster timeline does not provide useful information as all the Delphi samples share exactly the same compilation time: 20th of June, 1992. Only the Visual Basic sample had a compilation time consistent with the submission. On the contrary, the submission times provide an interesting perspective. All the samples have been submitted in few hours and this might indicate a possible development. In addition, there are two IP addresses involved: one for the four Delphi samples and one for the final Visual Basic version. The static features of the first four samples show very little differences, suggesting that these are likely just small variations of the same program. In average, they share 169 out of 172 functions and 7 out of 8 PE sections. By inspecting the changes, we notice that the attacker was adding some threads synchronization code to a function responsible for injecting code into a different process. The *control flow graph* similarity reported by our tool was over 98%, confirming the small differences we observed between each versions. Once the author was happy with the result, she submitted one more sample, this time completely different from the previous ones. Despite the obvious differences in most of the static analysis features, the fuzzyhash similarity with sample 4 was 100%. A rapid analysis showed that this perfect match was due to the fact that the Visual Basic application literally embedded the entire binary of the fourth Delphi program. In addition, the behavior report confirmed that, once executed, the Visual Basic Trojan dropped the embedded executable that was later injected inside a target process. None of the Antivirus software used by VirusTotal recognized the first four samples as malicious. However, the last one was flagged by 37 out of 50 AVs as a *trojan dropper* malware.

It is important to stress that a clear advantage of our system is that it was able to automatically reconstruct the entire picture despite the fact that not all samples were submitted from the same IP address (even though all located in the same geographical area). Moreover, we were able to propagate certain metadata extracted by our system (for example the username of the author extracted from the binary compiled with Visual Studio) from one sample to the others in which that information was missing. This ability to retrieve and propagate metadata between different samples can be very useful during an investigation.

Another very interesting aspect of this malware development is the fact that after the process injection, the program used a well known dynamic DNS service (`no-ip`) to resolve a domain name. The IP address returned by the DNS query pointed exactly to the same machine that was used by the author to submit the sample. This suggests that the attacker was indeed testing his attack before releasing it, and this information could be used to locate the attacker machine.

We identified a similar *connect-back* behavior in other 1817 clusters. We also noticed how most of these clusters contain samples generated by known trojan *builders*, like Bifrost [8] or PoisonIvy [9]. While this may seem to prove that these are mostly unsophisticated attacks, FireEye [22] recently observed how the Xtremerat builder [7] (which appeared in 28 of our clusters) was used to prepare samples used in several targeted attacks.

Example III: Probe Development

In this last example we show an attacker fingerprinting the analysis environment and how, at the end, she manages to create her own successful antisandbox check. The cluster consists of two samples, both submitted from France in a time span of 23 hours by the same IP address. The two samples have the same size, the same number of functions (164), and of sections (4). There is only one function (`_start`) and two sections (`.text` and `.rdata`) presenting some differences. The two programs perform the same actions, they create an empty text file and then they retrieve the file attributes through the API `GetFileAttributes`. The only differences are on the API version they use (`GetFileAttributesA` or `GetFileAttributesW`) and on the file name to open.

At a first look, this cluster did not seem very interesting. However the inter-cluster connections pointed to other six loosely correlated samples submitted by the same author in the same week. As explained in Section 4, these files have not been included in the core cluster because the binary similarity was below our threshold. In this case, these samples were all designed either to collect information or to test anti-virtualization/emulation tricks. For instance, one binary implemented all the known techniques based on `idt`, `gdt` and `ldt` to detect a virtual machine monitor [48, 47, 42]. Another one simply retrieved the computer name, and another one was designed to detect the presence of inline hooking. Putting all the pieces together, it is clear that the author was preparing a number of probes to assess various aspects of the sandbox environment.

This example shows how valuable the inter-clusters edges can be to better understand and link together different submissions that, while different between each other at a binary level, are likely part of the same organized "campaign".

6.3 Malware Samples in the Wild

As we already mentioned at the beginning of the section, out of 3038 clusters reported as malware development candidates by our machine learning classifier, 1474 (48%) contained binaries that were detected by the antivirus signatures as malicious (according to VirusTotal).

A total of 228 of the files contained in these clusters were later detected in the wild by the Symantec's antivirus engine. The average time between the submission to our sandbox and the time the malware was observed in the wild was 135 days – i.e., it took between four and five months for the antivirus company to develop a signature and for the file to appear on the end-users machines. Interestingly, some of these binaries were later detected on more than 1000 different computers in 13 different countries all around the world (obviously a lower bound, based on the alerts triggered on a subset of the Symantec's customers). This proves that, while these may not be very sophisticated malware, they certainly have a negative impact on thousands of normal users.

7 Limitations

We are aware of the fact that once this research is published, malware authors can react and take countermeasures to sidestep this type of analysis systems. For instance, they may decide to use "private" malware checkers, and avoid interacting with public sandboxes altogether. First of all, this is a problem that applies to many analysis techniques ranging from botnet detection, to intrusion prevention, to malware analysis. Despite that, we believe that it is important to describe our findings so that other researchers can work in this area and propose more robust methodologies in the future.

Moreover, as we mentioned in the introduction, after we completed our study someone noticed that some known malware development groups were testing their creation on VirusTotal [52, 27]. This confirms that what we have found is not an isolated case but a widespread phenomenon that also affects other online analysis systems. Second, now that the interaction between malware developers and public sandboxes is not a secret anymore, there is no reason that prevents us from publishing our findings as well.

We are aware of the fact that our methodology is not perfect, that it can be evaded, and that cannot catch all development cases. However, we believe the key message of the paper is that malware authors are abusing public sandboxes to test their code, and at the moment we do not need a very sophisticated analysis to find them. Since this is the first paper that tries to identify these cases, we found that our approach was already sufficient to detect thousands of them. Certainly more research is needed in this area to develop more precise monitoring and early warning system to analyze the large amounts of data automatically collected by public services on a daily basis.

8 Related Work

While there has been an extensive amount of research on malware analysis and detection, very few works in the literature have studied the datasets collected by public malware dynamic analysis sandboxes. The most comprehensive study in this direction was conducted by Bayer et al. [24]. The authors looked at two years of Anubis [10] reports and they provided several statistics about malware evolution and about the prevalent types of malicious behaviors observed in their dataset.

Lindorfer et al. [43] conducted the first study in the area of malware development by studying the evolution over time of eleven known malware families. In particular, the authors documented the malware updating process and the changes in the code for a number of different versions of each family. In our study we look at the malware development process from a different angle. Instead of studying different versions of the same well known malware, we try to detect, on a large scale, the authors of the malware at the moment in which they interact with the sandbox itself. In a different paper, Lindorfer et al. [44] proposed a technique to detect environment sensitive malware. The idea is to execute each malware sample multiple times on several sandboxes equipped with different monitoring implementations and then compare the normalized reports to detect behavior discrepancies.

A similar research area studies the phylogeny [30] of malware by using approaches taken from the biology field. Even if partially related to our work, in our study we were not interested in understanding the relationship between different species of malware, but only to detect suspicious submissions that may be part of a malware development activity.

In a paper closer to our work, Jang et al. [34] studied how to infer the software evolution looking at program binaries. In particular, the authors used both static and dynamic analysis features to recover the software lineage. While Jang's paper focused mostly on benign programs, some experiments were also conducted on 114 malicious software with known lineage extracted from the Cyber Genome Project [12]. Compared to our work, the authors used a smaller set of static and dynamic features especially designed to infer the software lineage (e.g., the fact that a linear development is characterized by a monotonically increasing file size). Instead, we use a richer set of features to be able to distinguish malware developments from variations of the same samples collected on the wild and not submitted by the author. While our approaches share some similarities, the goals are clearly different.

Other approaches have been proposed in the literature to detect similarities among binaries. Flake [29] proposed a technique to analyze binaries as graphs of graphs, and we have been inspired by his work for the *control flow analysis* described in Section 4. Kruegel et al. [39] proposed a similar technique in which they analyzed the control flow graphs of a number of worms and they used a graph coloring technique to cope with the graph-isomorphism problem.

Finally, one step of our technique required to cluster together similar malware samples. There are several papers in the area of malware clustering [31, 33, 51, 32]. However, their goal is to cluster together samples belonging to the same malware family as fastest as possible and with the highest accuracy. This is a crucial task for all the Antivirus companies. However, our goal is different as we are interested in clustering samples based only on binary similarity and we do not have any interest in clustering together members of the same family based on their behavior.

9 Conclusion

Public dynamic analysis sandboxes collect thousands of new malware samples every day. Most of these submissions belong to well known malware families, or are benign files that do not pose any relevant security threat. However, hidden in this large amount of collected data, few samples have something special that distinguishes them from the rest. In this paper, we discussed the importance of looking at these samples from an intelligence and threat prevention point of view.

We show that several binaries used in the most famous targeted attack campaigns had been submitted to our sandbox months before the attack was first reported. Moreover, we propose a first attempt to mine the database of a popular sandbox, looking for signs of malware development. Our experiments show promising results. We were able to automatically identify thousands of developments, and to show how the authors modify their programs to test their functionalities or to evade detections from known sandboxes. Around 1,500 of them were real malware developments – some of which have been later observed on thousands of infected machines around the world.

A Individual Sample Features

A: File Features	
A.1 Filename	The original name of the file submitted by the user
A.2 File size	The size of the file
A.3 MD5	Simple hash used for lookup in other data sources
A.4 Fuzzy Hashes	Using SSDeep algorithm
B: Timestamps	
B.1 Submission time	Time in which the sample was submitted to Anubis Sandbox
B.2 Compile time	Time in which the binary was compiled
B.3 Symantec first	Time the sample was first observed in the wild by Symantec
B.4 VirusTotal first	Time in which the binary was first submitted to VirusTotal
C: AV Features	
C.1 AV-Detection	Number of AV that flag the samples as malicious (according to VirusTotal)
C.2 AV-Labels	List of AV labels associated to the sample (according to VirusTotal)
D: User-based Features	
D.1 User Agent	User agent of the browser used to submit the sample
D.2 Languages	Languages accepted by the user browser (according to the `accept-language` HTTP header)
D.3 IP	IP address of the user who submitted the file
D.4 IP Geolocation	Geolocation of the user IP address
D.5 Email address	Optional email address specified when the sample was submitted
D.6 Proxy	Boolean value used to identify submission through popular anonymization proxies
E: Binary Features	
E.1 N.Sections	Number of sections in the PE file
E.2 N.Fuctions	Number of functions identified by the disassembly
E.3 Code Coverage	Fraction of `.text` segment covered by the identified functions
E.4 Programming Language	Programming language used to develop the binary
E.5 Metadata	Filenames and username extracted from the PE file
F: Behavioral Features	
F.1 Duration	Duration in seconds of the analysis
F.2 Errors	Error raised during the analysis
F.3 Evasion	Known anti-sandbox techniques detected by the sandbox itself
F.4 Behavior Bitstring	Sequence of 24 boolean flags that characterize the behavior of the sample. (`has_popups`, `has_udp_traffic`, `has_http`, `has_tcp_address_scan`, `modified_registry_keys`, ...)

Table 5: List of Individual Features associated to each sample

Supplement to the Proceedings of the
22nd USENIX Security Symposium

August 14–16, 2013
Washington, D.C.

Message from the 22nd USENIX Security Symposium Program Chair and USENIX Executive Director

In this supplement to the Proceedings of the 22nd USENIX Security Symposium, we are pleased to announce the publication of the paper, "Dismantling Megamos Crypto: Wirelessly Lockpicking a Vehicle Immobilizer," by Roel Verdult, Flavio D. Garcia, and Baris Ege. This paper, which was accepted by the USENIX Security '13 Program Committee, was withdrawn from publication by its authors in response to the imposition of an injunction by the High Court of Justice in the United Kingdom prohibiting the authors, their institutions, and anyone who assists them, from publishing key sections of the paper. We now join the authors in their delight that USENIX may now publish their paper in this supplement to the original Proceedings. Verdult and Garcia will present the paper in a special evening session during the 24th USENIX Security Symposium. Although two years have passed, this work remains important and relevant to our community.

Sam King, *USENIX Security '13 Program Chair*
Casey Henderson, *USENIX Executive Director*

Dismantling Megamos Crypto: Wirelessly Lockpicking a Vehicle Immobilizer

Abstract

The Megamos Crypto transponder is used in one of the most widely deployed electronic vehicle immobilizers. It is used among others in most Audi, Fiat, Honda, Volkswagen and Volvo cars. Such an immobilizer is an anti-theft device which prevents the engine of the vehicle from starting when the corresponding transponder is not present. This transponder is a passive RFID tag which is embedded in the key of the vehicle.

In this paper we have reverse-engineered all proprietary security mechanisms of the transponder, including the cipher and the authentication protocol which we publish here in full detail. This article reveals several weaknesses in the design of the cipher, the authentication protocol and also in their implementation. We exploit these weaknesses in three practical attacks that recover the 96-bit transponder secret key. These three attacks only require wireless communication with the system. Our first attack exploits weaknesses in the cipher design and in the authentication protocol. We show that having access to only two eavesdropped authentication traces is enough to recover the 96-bit secret key with a computational complexity of 2^{56} cipher ticks (equivalent to 2^{49} encryptions). Our second attack exploits a weakness in the key-update mechanism of the transponder. This attack recovers the secret key after 3×2^{16} authentication attempts with the transponder and negligible computational complexity. We have executed this attack in practice on several vehicles. We were able to recover the key and start the engine with a transponder emulating device. Executing this attack from beginning to end takes only 30 minutes. Our third attack exploits the fact that some car manufacturers set weak cryptographic keys in their vehicles. We propose a time-memory trade-off which recovers such a weak key after a few minutes of computation on a standard laptop.

1 Introduction

Electronic vehicle immobilizers have been very effective at reducing car theft. Such an immobilizer is an electronic device that prevents the engine of the vehicle from starting when the corresponding transponder is not present. This transponder is a low-frequency RFID chip which is typically embedded in the vehicle's key. When the driver starts the vehicle, the car authenticates the transponder before starting the engine, thus preventing hot-wiring. In newer vehicles the mechanical ignition key has often been removed and replaced by a start button, see Figure 1(a). In such vehicles the immobilizer transponder is the only anti-theft mechanism that prevents a hijacker from driving away.

A distinction needs to be made between the vehicle immobilizer and the remotely operated central locking system. The latter is battery powered, operates at an ultra-high frequency (UHF), and only activates when the user pushes a button on the remote to (un)lock the doors of the vehicle. Figure 1(b) shows a disassembled car key where it is possible to see the passive Megamos Crypto transponder and also the battery powered remote of the central locking system.

The Megamos Crypto transponder is the first cryptographic immobilizer transponder manufactured by [19] and is currently one of the most widely used. The manufacturer claims to have sold more than 100 million immobilizer chips including Megamos Crypto transponders [22]. Figure 2 shows a list of vehicles that use or have used Megamos Crypto at least for some version/year. As it can be seen from this list, many Audi, Fiat, Honda, Volkswagen and Volvo cars used Megamos Crypto transponders at the time of this research (fall 2012).

The transponder uses a 96-bit secret key and a proprietary cipher in order to authenticate to the vehicle. Furthermore, a 32-bit PIN code is needed in order to be able to write on the memory of the transponder. The con-

crete details regarding the cipher design and authentication protocol are kept secret by the manufacturer and little is currently known about them.

From our collaboration with the local police it was made clear to us that sometimes cars are being stolen and nobody can explain how. They strongly suspect the use of so-called ‘car diagnostic’ devices. Such a device uses all kind of custom and proprietary techniques to bypass the immobilizer and start a car without a genuine key. This motivated us to evaluate the security of vehicle immobilizer transponders. There are known attacks for three of the four widely used immobilizer transponders, namely DST40, Keeloq and Hitag2. Although, at the time of this research, little was known about the security of the Megamos Crypto transponder.

1.1 Our contribution

In this paper we have fully reverse-engineered all cryptographic mechanisms of Megamos Crypto which we publish here in full detail. For this we used IDA Pro[1] to decompile the software package that comes with the Tango Programmer[2].

Furthermore, we have identified several weaknesses in Megamos Crypto which we exploit in three attacks. Our first attack consists of a cryptanalysis of the cipher and the authentication protocol. Our second and third attack not only look at the cipher but also at the way in which it is implemented and poorly configured by the automotive industry.

Our first attack, which comprises *all* vehicles using Megamos Crypto, exploits the following weaknesses.

- The transponder lacks a pseudo-random number generator, which makes the authentication protocol vulnerable to replay attacks.

Make	Models

Figure 2: Vehicles that used Megamos Crypto for some version/year [39]. Boldface and year indicate specific vehicles we experimented with.

- The internal state of the cipher consists of only 56 bits, which is much smaller than the 96-bit secret key.
- The cipher state successor function can be inverted, given an internal state and the corresponding bit of cipher-text it is possible to compute the predecessor state.
- The last steps of the authentication protocol

[1] https://www.hex-rays.com/products/ida/

[2] http://www.scorpio-lk.com

provides and adversary with 15-bits of known-plaintext.

We present two versions of this attack. First we introduce a simple (but more computationally intensive) attack that recovers the secret key of the transponder with a computational complexity of 2^{56} encryptions. Then we optimize this attack, reducing its computational complexity to 2^{49} by using a time-memory trade-off. For this trade-off, a 12 terabyte lookup table needs to be pre-computed. This optimized version of the attack takes advantage of the fact that some of the cipher components can be run quite autonomously.

Our second attack exploits the following weaknesses.

- Currently, the memory of many Megamos Crypto transponders in the field is either unlocked or locked with a publicly known default PIN code [17]. This means that anybody has write access to the memory of the transponder. This also holds for the secret key bits.
- The 96-bit secret key is written to the transponder in blocks of 16 bits instead of being an atomic operation.

This attack recovers the 96-bit secret key of such a transponder within 30 minutes. This time is necessary to perform 3×2^{16} authentication attempts to the transponder and then recover the key with negligible computational complexity. We have executed this attack in practice and recovered the secret key of several cars from various makes and models. Having recovered the key we were able to emulate the transponder and start the vehicles.

Our third attack is based on the following observation. Many of the keys that we recovered using the previous attack had very low entropy and exhibit a well defined pattern, i.e., the first 32 bits of the key are all zeros. This attack consists of a time-memory trade-off that exploits this weakness to recover the secret key, within a few minutes, from two authentication traces. This attack requires storage of a 1.5 terabyte rainbow table.

We propose a simple but effective mitigating measure against our second attack. This only involves setting a few bits on the memory of the transponder and can be done by anyone (even the car owners themselves) with a compatible RFID reader.

Finally, we have developed an open source library for custom and proprietary RFID communication schemes that operate at an frequency of 125 kHz. We used this library to provide eavesdropping, emulation and reader support for Megamos Crypto transponders with the Proxmark III device[3]. The reader functionality allows the user to send simple commands like read and write to the transponder. In particular, this library can be used to set the memory lock bit and a random PIN code as a mitigation for our second attack, as described in Section 8.

1.2 Related work

In the last decades, semiconductor companies introduced several proprietary algorithms specifically for immobilizer security. Their security often depends on the secrecy of the algorithm. When their inner-workings are uncovered, it is often only a matter of weeks before the first attack is published. There are several examples in the literature that address the insecurity of proprietary algorithms. The most prominent ones are those breaking A5/1 [31], DECT [45, 47], GMR [18], WEP [24] and also many RFID systems like the MIFARE Classic [16, 26, 29, 46], CryptoRF [30] and iClass [27, 28].

Besides Megamos Crypto, there are only three other major immobilizer products being used. The DST transponder which was reverse-engineered and attacked by Bono et.al. in [9]; KeeLoq was first attacked by Bogdanov in [6] and later this attack was improved in [12, 36, 38]; Hitag2 was anonymously published in [60] and later attacked in [8, 13, 35, 52, 53, 57, 58].

With respect to vehicle security, Koscher et. al. attracted a lot of attention from the scientific community when they demonstrated how to compromise the board computer of a modern car [11, 40]. They were able to remotely exploit and control many car features such as tracking the car via GPS and adjust the speeding of the car. In 2011, Francillon et. al. [25] showed that with fairly standard equipment it is possible to mount a relay-attack on all keyless-entry systems that are currently deployed in modern cars.

The scientific community proposed several alternatives [43, 44, 59, 61, 62] to replace the weak proprietary ciphers and protocols. There are several commercial vehicle immobilizer transponders that makes use of standard cryptography, like AES [14]. Examples include the Hitag Pro transponder from NXP Semiconductors and ATA5795 transponder from Atmel. To the best of our knowledge, only Atmel made an open protocol design [1] and published it for scientific scrutiny. The security of their design was analyzed by Tillich et. al. in [54].

2 Technical background

This section briefly describes what a vehicle immobilizer is and how it is used by the automotive industry. Then we describe the hardware setup we use for our experiments. Finally we introduce the notation used throughout the paper.

2.1 Immobilizer

To prevent a hijacker from hot-wiring a vehicle, car manufacturers incorporated an electronic car immobilizer as

[3] http://www.proxmark.org/

an extra security mechanism. In some countries, having such an immobilizer is enforced by law. For example, according to European Commission directive (95/56/EC) it is mandatory that all cars sold in the EU from 1995 are fitted with an electronic immobilizer. Similar regulations apply to other countries like Australia, New Zealand (AS/NZS 4601:1999) and Canada (CAN/ULC S338-98). Although in the US it is not required by law, according to the independent organization Insurance Institute for Highway Safety (IIHS), 86 percent of all new passenger cars sold in the US had an engine immobilizer installed [55].

An electronic car immobilizer consists of three main components: a small transponder chip which is embedded in (the plastic part of) the car key, see Figure 1(b); an antenna coil which is located in the dashboard of the vehicle, typically around the ignition barrel; and the immobilizer unit that prevents the vehicle from starting the engine when the transponder is absent.

The immobilizer unit communicates through the antenna coil and enumerates all transponders that are in proximity of field. The transponder identifies itself and waits for further instructions. The immobilizer challenges the transponder and authenticates itself first. On a successful authentication of the immobilizer unit, the transponder sends back its own cryptographic response. Only when this response is correct, the immobilizer unit enables the engine to start.

The immobilizer unit is directly connected to the internal board computer of the car, also referred to as Electrical Control Unit (ECU). To prevent hot-wiring a car, the ECU blocks fuel-injection, disables spark-plugs and deactivates the ignition circuit if the transponder fails to authenticate.

2.2 Hardware setup

We used the Proxmark III to eavesdrop and communicate with the car and transponder. This is a generic RFID protocol analysis tool [56] that supports raw data sampling at a frequency of 125 kHz. We implemented a custom firmware and FPGA design that supports the modulation and encoding schemes of Megamos Crypto transponders. The design samples generic analog-digital converter (ADC) values and interpret them in real-time in the micro-controller. We have implemented commands to eavesdrop, read and emulate a transponder. Our library is able to decode field and transponder modulation simultaneously and is very precise in timing.

Figure 3: Proxmark 3

2.3 Notation

Throughout this paper we use the following mathematical notation. Let $\mathbb{F}_2 = \{\mathtt{0},\mathtt{1}\}$ be the set of Booleans. The symbol $\oplus$ denotes exclusive-or (XOR), $\mathtt{0}^n$ denotes a bitstring of n zero-bits. ε denotes the empty bitstring. Given two bitstrings x and y, xy denotes their concatenation. Sometimes we write this concatenation explicitly with $x \cdot y$ to improve readability. $\overline{x}$ denotes the bitwise complement of x. Given a bitstring $x \in \mathbb{F}_2^k$, we write x_i to denote the i-th bit of x. For example, given the bitstring $x = \mathtt{0x03} = \mathtt{00000011} \in \mathbb{F}_2^8$, $x_0 = 0$ and $x_6 = x_7 = 1$.

3 Megamos Crypto

This section describes Megamos Crypto in detail. We first describe the Megamos Crypto functionality, memory structure, and communication protocols, this comes from the product datasheet [21] and the application note [23]. Then we briefly describe how we reverse-engineered the cryptographic algorithms and protocols used in Megamos Crypto. Finally, we describe these algorithms and protocols in detail.

3.1 Memory

There are two types of Megamos Crypto transponders, in automotive industry often referred to as Magic I (V4070) [20] and Magic II (EM4170) [21]. The EM4170 transponder is the newer version and it has 16 memory blocks of 16-bit words. The contents of these memory blocks are depicted in Figure 4. The older version (V4070) supports exactly the same read and write operations and cryptographic algorithms, but it only has 10 memory blocks. The blocks 10 to 15, which store 64 bits of additional user memory and a 32-bit PIN code are simply not readable. The EM4170 transponder uses the same communication and is therefore backwards compatible with the V4070 transponder. Note that in some cars the new revision is deployed as replacement for the V4070 without making use of, or even initializing the additional user memory blocks and PIN code. The whole memory is divided in three sections with different access rights, see Figure 4.

The transponder identifier *id* is always read-only. The write access over the other memory blocks is determined by the value of the lock-bit l_0. Just as specified, the value of lock-bit l_1 does not have any influence the memory access conditions. Similarly, a successful or failed authentication has no effect on the access conditions.

- When $l_0 = 0$, all memory blocks (except *id*) of a Megamos Crypto transponder are still writable. The key k, PIN code *pin* are write-only and the user memory *um* blocks (which includes the lock-bits l) are read-write. However, after a successful write in block 1, the new value of l_0 determines the access condition for future write operations.

- When $l_0 = 1$, all writing is disabled. However, it does not affect the read access conditions. This means that the key k, PIN code pin can not be read out and the user memory um becomes read-only. Because the lock-bits l are stored in a user memory block they can always be read out.

The EM4170 allows to set the lock-bit l_0 back to zero using a PIN code pin. A valid PIN code resets the access conditions and enables again writing of k, pin, um and l. The PIN code has to be known or overwritten to the transponder before it is locked, otherwise an exhaustive search of the PIN code is required.

Block	Content	Denoted by
0	user memory	$um_0 \dots um_{15}$
1	user memory, lock bits	$um_{16} \dots um_{29} l_0 l_1$
2	device identification	$id_0 \dots id_{15}$
3	device identification	$id_{16} \dots id_{31}$
4	crypto key	$k_0 \dots k_{15}$
5	crypto key	$k_{16} \dots k_{31}$
6	crypto key	$k_{32} \dots k_{47}$
7	crypto key	$k_{48} \dots k_{63}$
8	crypto key	$k_{64} \dots k_{79}$
9	crypto key	$k_{80} \dots k_{95}$
10	pin code	$pin_0 \dots pin_{15}$
11	pin code	$pin_{16} \dots pin_{31}$
12	user memory	$um_{30} \dots um_{45}$
13	user memory	$um_{46} \dots um_{61}$

15	user memory	$um_{78} \dots um_{93}$

░ read-only
▒ write-only
□ read-write

Figure 4: Megamos Crypto transponder memory layout

3.2 Functionality and communication

The Megamos Crypto transponder supports four different operations: `read`, `write`, `reset` and `authenticate`.

- `read` operations are performed by three different commands, each returns multiple blocks. The transponder returns the concatenation of these blocks in one bitstring. The three available bitstrings are $id_{31} \dots id_0$, $l_1 l_0 um_{29} \dots um_0$ and $um_{93} \dots um_{30}$.
- `write` stores a 16-bit memory block in the memory of the transponder. The arguments for this command are the block number and the data. After receiving the command, the transponder stores the data in memory if the access conditions allow the requested write operation.
- `reset` takes the id and 32-bit PIN code as an argument. If the PIN code matches the value that is stored in pin, then the lock-bit l_0 is reset, see Section 3.1 for more details about l_0.
- `authenticate` takes three arguments. The first one is a 56-bit car nonce n_C. The second argument is a bitstring of 7 zero bits. The datasheet [21] refers to them as "divergency bits". It seems that these bit-periods are used to initialize the cipher. In Section 3.6 we show that the authentication protocol exactly skips 7 cipher steps before it starts generating output. The third argument is a 28-bit authenticator from the car a_C. If successful, the transponder responds with its 20-bit authenticator a_T.

When the driver turns on the ignition, several back-and-forward messages between the car and transponder are exchanged. It starts with the car reading out the transponder memory blocks that contains the identity, user memory and lock-bits. Next, the car tries to authenticate using the shared secret key k. If the authentication fails, the car retries around 20 times before it reports on the dashboard that the immobilizer failed to authenticate the transponder. Figure 5 shows an eavesdropped trace of a German car that initializes and authenticates a Megamos Crypto transponder.

To the best of our knowledge, there is no publicly available document that describes the structure of Megamos Crypto cipher. However, a simplified representation of the authentication protocol is presented in the EM4170 application note [23] as shown in Figure 6. It does not specify any details beyond the transmitted messages and the checks which the car and transponder must perform. The car authenticates by sending a nonce $n_C = Random$ and the corresponding authenticator $a_C = f(Rnd, K)$. When the car successfully authenticated itself, the Megamos Crypto transponder sends the transponder authenticator $a_T = g(Rnd, f, K)$ back to car.

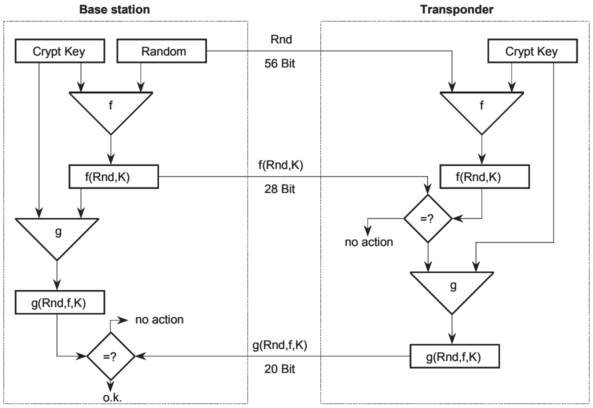

Figure 6: Authentication procedure excerpt from [23]

For communication the Megamos Crypto transponder uses a low frequency wave of 125 kHz and applies amplitude shift keying (ASK) modulation by putting a small resistance on the electro magnetic field. It utilizes a cus-

Origin	Message	Description
Car	`3`	Read identifier
Transponder	`A9 08 4D EC`	Identfier $id_{31} \dots id_0$
Car	`5`	Read user memory and lock-bits
Transponder	`80 00 95 13`	First user memory $l_1 l_0 um_{29} \dots um_0$
Car	`F`	Read large user memory (EM4170)
Transponder	`AA AA AA AA AA AA AA AA`	Second user memory $um_{93} \dots um_{30}$
Car	`6 | 3F FE 1F B6 CC 51 3F |` 0^7 `| F3 55 F1 A`	Authentication, $n_{C_{55}} \dots n_{C_0}$, 0^7, a_C
Transponder	`60 9D 6`	Car authenticated successful, send back a_T

Figure 5: Eavesdropped Megamos Crypto authentication using the 96-bit key `000000000000010405050905`. The structure of the secret key of the car suggests that it has an entropy of only 24 bits.

tom encoding scheme for status bits and a Manchester encoding scheme for transmitting data bits. The Megamos Crypto immobilizer unit signals the transponder to receive a command by dropping the field two consecutive times in a small time interval. Then it drops the field a few microseconds to modulate a zero and leaves the field on to modulate a one.

This way of modulation introduces the side-effect that the immobilizer unit and the transponder could get out-of-sync. When the immobilizer unit sends a bitstring of contiguous ones, there are no field drops for almost 15 milliseconds. The manufacturer realized this was a problem, but instead of proposing an alternative communication scheme they suggest to choose random numbers with more zeros's than ones and especially avoid sequential ones [23]. From a security perspective it sounds like a bad idea to suggest to system integrators that they should effectively drop entropy from the used random numbers.

To get a fair estimate of communication timings we did some experiments. With our hardware setup we were able to reach the highest communication speed with the transponder that is possible according to the datasheet. It allows us to read out the identifier *id* in less than 14 milliseconds and successfully authenticate within 34 milliseconds. These timings confirm that an adversary can wirelessly pickpocket the identifier and all its user memory in less than a second from a distance of one inch. Standing close to a victim for only a fraction of a second enables the adversary to gather the transponder identifier. When this identifier is emulated to the corresponding car, it is possible to gather partial authentication traces. Because the transponder lacks a random generator, this partial traces can later be used to retrieve the responses from the transponder which extends them to successful authentication traces. With a number of successful authentication traces it is possible to recover the secret key as described in Section 5.

3.3 Reverse-engineering the cipher

Recent articles point out the lack of security [11, 40, 41] in modern cars. The software in existing cars is designed with safety in mind, but is still immature in terms of security. Legacy protocols and technologies are often vulnerable to a number of remote and local exploits.

Most car keys need to be preprogrammed, which is also referred to as pre-coded, before they can be associated to a car. During this initialization phase the user memory blocks are filled with manufacturer specific data to prevent mixing of keys. This step adds no security, it just restricts the usage of keys that were meant a specific car make or model.

There are several car locksmith tools[4][5][6] in the after market that can initialize or change such transponder data. Such tools fully support the modulation/encoding schemes and communication protocol of the Megamos Crypto transponder. They implement some publicly available functionality like the `read`, `write` and `reset` commands. However, they do not implement the authentication protocol. To perform a successful authentication, knowledge of the Megamos Crypto cipher is necessary to compute the authentication messages a_C and a_T.

More advanced car diagnostic tools like AVDI[7] and Tango Programmer[8] offer functionality that goes beyond "legitimate" usage. These devices are able to dump the board-computer memory, recover the dealer code, and add a new blank transponder to the car. For this the tools do not require a genuine key to be present but they do need physical access to the can bus.

These diagnostic tools use the Megamos Crypto authentication functionality to speed up the process of adding new transponders to the car. For this, the tool needs the Megamos Crypto algorithm to compute valid

authentication attempts. We would like to emphasize that non of these tools is able to recover the secret key of a transponder or perform any kind of cryptanalysis. In fact, within the legitimate automotive industry Megamos Crypto is believed to be unclonable.

The software package that comes with the Tango Programmer implements all cryptographic operations of the transponder including the Megamos Crypto cipher. We have analyzed the software thoroughly and extracted the algorithm from it.

Since the application implements several counter measures against reverse-engineering, this task was not trivial at all. It is highly protected with an executable obfuscator that runs a custom virtual machine, as described in [51], and a number of advanced anti-debugging tricks to avoid exposure of its inner workings. To perform our security evaluation of the Megamos Crypto cipher we bypassed all these measures and reverse engineered the cipher in a semi-automatic way by observing the memory state changes and guessing the intermediate cryptographic calculations.

Furthermore, we observed every Megamos Crypto related function call from the program instructions memory segment. When the program counter entered a suspicious memory segment, we invoked our clean-up routine that automatically grouped and dropped all unnecessary instructions (unconditional re-routings, sequential operations on the same variables, random non-influential calculations). After analysing this at run-time, the actual working of the algorithm was quickly deduced from the optimized and simplified persistent instruction set.

3.4 Cipher

This section describes the Megamos Crypto cipher in detail. The cipher consists of five main components: a Galois Linear Feedback Shift Register, a non-linear Feedback Shift Register, and three 7-bit registers. A schematic representation of the cipher is depicted in Figure 7.

Definition 3.1 (Cipher state)**.** *A Megamos Crypto* cipher state $s = \langle g,h,l,m,r \rangle$ *is an element of* $\mathbb{F}_2^{57}$ *consisting of the following five components:*

1. *the* Galois LFSR $g = (g_0 \dots g_{22}) \in \mathbb{F}_2^{23}$*;*
2. *the* non-linear FSR $h = (h_0 \dots h_{12}) \in \mathbb{F}_2^{13}$*;*
3. *the* first output register $l = (l_0 \dots l_6) \in \mathbb{F}_2^{7}$*;*
4. *the* second output register $m = (m_0 \dots m_6) \in \mathbb{F}_2^{7}$*;*
5. *the* third output register $r = (r_0 \dots r_6) \in \mathbb{F}_2^{7}$.

The following definitions describe the successor or feedback functions for each of these components.

Definition 3.2. *The successor function for the Galois linear feedback shift register* $G\colon \mathbb{F}_2^{23} \times \mathbb{F}_2 \times \mathbb{F}_2 \to \mathbb{F}_2^{23}$ *is defined as*

$$\begin{aligned} G(g_0 \dots g_{22}, i, j) = {} & (j \oplus g_{22}) g_0 g_1 g_2 (g_3 \oplus g_{22})(g_4 \oplus i) \\ & (g_5 \oplus g_{22})(g_6 \oplus g_{22}) g_7 \cdots g_{12} (g_{13} \oplus g_{22}) g_{14} g_{15} \\ & (g_{16} \oplus g_{22}) g_{17} \cdots g_{21} \end{aligned}$$

We also overload the function G *to multiple-bit input string* $G\colon \mathbb{F}_2^{23} \times \mathbb{F}_2 \times \mathbb{F}_2^{n+1} \to \mathbb{F}_2^{23}$ *as*

$$G(g, i, j_0 \dots j_n) = G(G(g, i, j_1 \dots j_n), i, j_0)$$

Definition 3.3. *The successor function for the non-linear feedback shift register* $H\colon \mathbb{F}_2^{13} \to \mathbb{F}_2^{13}$ *is defined as*

$$H(h_0 \dots h_{12}) = ((h_1 \wedge h_8) \oplus (h_9 \wedge h_{11}) \oplus \overline{h_{12}}) h_0 \dots h_{11}$$

Definition 3.4. *The feedback function for the first output register* $f_l\colon \mathbb{F}_2^{6} \to \mathbb{F}_2$ *is defined as*

$$\begin{aligned} f_l(x_0 \dots x_5) = {} & (\overline{x_0} \wedge \overline{x_2} \wedge x_3) \vee (x_2 \wedge x_4 \wedge \overline{x_5}) \vee \\ & (x_5 \wedge x_1 \wedge \overline{x_3}) \vee (x_0 \wedge \overline{x_1} \wedge \overline{x_4}). \end{aligned}$$

Definition 3.5. *The feedback function for the second output register* $f_m\colon \mathbb{F}_2^{6} \to \mathbb{F}_2$ *is defined as*

$$\begin{aligned} f_m(x_0 \dots x_5) = {} & (\overline{x_4} \wedge x_1 \wedge \overline{x_2}) \vee (x_5 \wedge \overline{x_1} \wedge x_3) \vee \\ & (x_0 \wedge x_2 \wedge \overline{x_3}) \vee (x_4 \wedge \overline{x_5} \wedge \overline{x_0}). \end{aligned}$$

Definition 3.6. *The feedback function for the third output register* $f_r\colon \mathbb{F}_2^{6} \to \mathbb{F}_2$ *is defined as*

$$\begin{aligned} f_r(x_0 \dots x_5) = {} & (x_5 \wedge \overline{x_0} \wedge \overline{x_2}) \vee (\overline{x_5} \wedge x_3 \wedge x_1) \vee \\ & (x_2 \wedge \overline{x_3} \wedge \overline{x_4}) \vee (x_0 \wedge x_4 \wedge \overline{x_1}). \end{aligned}$$

With every clock tick the cipher steps to its successor state and it (potentially) outputs one bit of keystream. The following precisely defines the successor state and the output of the cipher.

Definition 3.7 (Successor state)**.** *Let* $s = \langle g,h,l,m,r \rangle$ *be a cipher state and* $i \in \mathbb{F}_2$ *be an input bit. Then, the* successor cipher state $s' = \langle g',h',l',m',r' \rangle$ *is defined as*

$$\begin{aligned} g' &:= G(g, i, l_1 \oplus m_6 \oplus h_2 \oplus h_8 \oplus h_{12}) \\ h' &:= H(h) \\ l' &:= a l_0 \dots l_5 \\ m' &:= b m_0 \dots m_5 \\ r' &:= c r_0 \dots r_5 \end{aligned}$$

where

$$\begin{aligned} a &= f_l(g_0 g_4 g_6 g_{13} g_{18} h_3) \oplus g_{22} \oplus r_2 \oplus r_6 \\ b &= f_m(g_1 g_5 g_{10} g_{15} h_0 h_7) \oplus l_0 \oplus l_3 \oplus l_6 \\ c &= f_r(g_2 (g_3 \oplus i) g_9 g_{14} g_{16} h_1) \oplus m_0 \oplus m_3 \oplus m_6 \end{aligned}$$

We define the successor function suc: $\mathbb{F}_2^{57} \times \mathbb{F}_2 \to \mathbb{F}_2^{57}$ *which takes a state* s *and an input* $i \in \mathbb{F}_2$ *and outputs the successor state* s'*. We overload the function* suc *on multiple-bit input which takes a state* s *and an input* $i \in \mathbb{F}_2^{n+1}$ *as*

$$\begin{aligned} \mathrm{suc}(s, i_0 \dots i_n) &= \mathrm{suc}(s', i_n) \\ \textit{where } s' &= \mathrm{suc}(s, i_0 \dots i_{n-1}) \end{aligned}$$

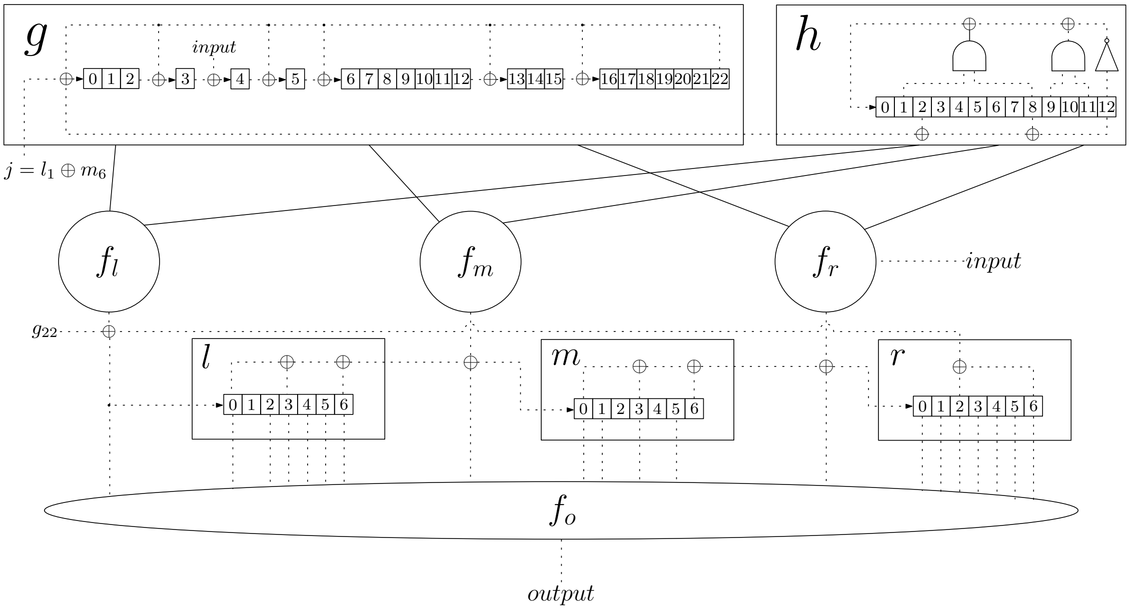

Figure 7: Schematic representation of the cipher

Definition 3.8. *The non-linear output filter function $f_o \colon \mathbb{F}_2^{20} \to \mathbb{F}_2$ has been deliberately omitted in this paper.*

Definition 3.9 (Output)**.** *Define the function output: $\mathbb{F}_2^{57} \times \mathbb{F}_2 \to \mathbb{F}_2$ which takes as input an internal state $s = \langle g,h,l,m,r \rangle$ and an input $i \in \mathbb{F}_2$ and returns the bit*

$$f_o(abcl_0l_2l_3l_4l_5l_6m_0m_1m_3m_5r_0r_1r_2r_3r_4r_5r_6)$$

where

$$a = f_l(g_0g_4g_6g_{13}g_{18}h_3) \oplus g_{22} \oplus r_2 \oplus r_6$$
$$b = f_m(g_1g_5g_{10}g_{15}h_0h_7) \oplus l_0 \oplus l_3 \oplus l_6$$
$$c = f_r(g_2(g_3 \oplus i)g_9g_{14}g_{16}h_1) \oplus m_0 \oplus m_3 \oplus m_6$$

We also overload the function output on multiple-bit input which takes a state s and an input $i \in \mathbb{F}_2^{n+1}$ as

$$output(s, i_0 \dots i_n) = output(s, i_0) \cdot output(s', i_1 \dots i_n)$$
$$\text{where } s' = \mathrm{suc}(s, i_0).$$

3.5 Cipher initialization

The following sequence of definitions describe how the cipher is initialized.

Definition 3.10. *Let init: $\mathbb{F}_2^{23} \times \mathbb{F}_2^{n+1} \to \mathbb{F}_2^{n+24}$ be defined as*

$$init(g, \varepsilon) := g$$
$$init(g, x_0 \dots x_n) := init(G(g, 0, x_n), x_0 \dots x_{n-1}) \cdot g_{22}$$

Definition 3.11. *Let $p \in \mathbb{F}_2^{56}, q \in \mathbb{F}_2^{44}$ and $t \in \mathbb{F}_2^{43}$ be defined as*

$$p := n_{C_0} \dots n_{C_{55}} + k_{40} \dots k_{95} \mod 2^{56}$$
$$q := (p_2 \dots p_{45}) \oplus (p_8 \dots p_{51}) \oplus (p_{12} \dots p_{55})$$
$$t := init(q_{20} \dots q_{42}, q_0 \dots q_{19})$$

Then, the initial cipher state *$s_0 = \langle g,h,l,m,r \rangle$ is defined as*

$$g := t_0 \dots t_{22}$$
$$h := 0p_0 \dots p_{11}$$
$$l := t_{23} \dots t_{29}$$
$$m := t_{30} \dots t_{36}$$
$$r := t_{37} \dots t_{42}q_{43}$$

3.6 Authentication protocol

This section describes the authentication protocol between a Megamos Crypto transponder and the vehicle immobilizer. This protocol is depicted in Figure 8. An annotated example trace is shown in Figure 5.

Definition 3.12. *Given a key $k = k_0 \dots k_{95} \in \mathbb{F}_2^{96}$ and an initial state s_0 as defined in Definition 3.11, the internal state of the cipher at step i is defined as*

$$s_i := \mathrm{suc}(s_{i-1}, k_{40-i}) \qquad \forall i \in [1 \dots 40]$$
$$s_{i+41} := \mathrm{suc}(s_{i+40}, 0) \qquad \forall i \in \mathbb{N}$$

During authentication, the immobilizer starts by sending an authenticate command to the transponder. This command includes a 56-bit nonce n_C and the 28 bits a_C output by the cipher from state s_7. Then, the transponder responds with the next 20 output bits a_T, i.e., produced from state s_{35}.

4 Cipher Properties

This section describes several properties of the Megamos Crypto cipher which will be later used in the attacks.

4.1 Rollback

Given a cipher state it is possible to recover its previous state when this exists. Rolling-back the cipher is non-trivial due to the non-linear operations in the suc function. Next we describe precisely how to rollback the cipher to recover a predecessor state.

We start by rolling-back registers g and h. This computation is straightforward as described in the following definitions.

Definition 4.1. *The predecessor function for the non-linear feedback shift register $H^{-1}\colon \mathbb{F}_2^{13} \to \mathbb{F}_2^{13}$ is defined as*

$$H^{-1}(h_0 \dots h_{12}) = h_1 \dots h_{11}((h_2 \wedge h_9) \oplus (h_{10} \wedge h_{12}) \oplus \overline{h_0})$$

Definition 4.2. *The predecessor function for the Galois linear feedback shift register $G^{-1}\colon \mathbb{F}_2^{23} \times \mathbb{F}_2 \times \mathbb{F}_2 \to \mathbb{F}_2^{23}$ is defined as*

$$G^{-1}(g_0 \dots g_{22}, i, j) = g_1 g_2 (g_3 \oplus b)(g_4 \oplus i)(g_5 \oplus b)(g_6 \oplus b)$$
$$g_7 \dots g_{12}(g_{13} \oplus b) g_{14} g_{15} (g_{16} \oplus b) g_{17} \dots g_{22} b$$

where $b = g_0 \oplus j$

Next we describe how to rollback registers l, m and r. A difficulty in doing that arises from the fact that m_6 in the predecessor state is not determined. To circumvent this issue, we need to first guess the bit m_6 and then check whether this guess is consistent with the rest of the state. For 18.75% of the states this condition is not met for neither $m_6 = 0$ nor $m_6 = 1$, which means that the state has no predecessor. For 62.5% of the states there is only one value of m_6 satisfying this condition, which means that they have only one predecessor state. Finally, 18.75% of the states have two possible predecessor states, one for $m_6 = 0$ and one for $m_6 = 1$. In this case both states have to be considered as potentially being the predecessor state. Given the fact that the average probability of having two predecessors equals the probability of having none the list of candidate predecessor states remains of a constant size.

A precise description of how to compute a predecessor state follows.

Definition 4.3 (Predecessor state)**.** *Let $s' = \langle g', h', l', m', r' \rangle$ be a cipher state and $i \in \mathbb{F}_2$ be an input bit. Then, $s = \langle g, h, l, m, r \rangle$ is a* predecessor cipher state *of s' if it satisfies*

$$h = H^{-1}(h')$$
$$g = G^{-1}(g', i, h_{12} \oplus h_8 \oplus h_2 \oplus l'_2 \oplus m_6)$$
$$l = l'_1 \dots l'_6 (m'_0 \oplus f_m(g_1 g_5 g_{10} g_{15} h_0 h_7 h) \oplus l'_4 \oplus l'_1)$$
$$m_6 = r'_0 \oplus f_r(g_2 (g_3 \oplus i) g_9 g_{14} g_{16} h_1) \oplus m'_4 \oplus m'_1$$
$$m = m'_1 \dots m'_6 m_6$$
$$r = r'_1 \dots r'_6 (l'_0 \oplus f_l(g_0 g_4 g_6 g_{13} g_{18} h_3) \oplus r'_3 \oplus g_{22}).$$

4.2 Undoing cipher initialization

In this section we show that the cipher initialization procedure can be reverted. This means that given an initial state it is possible to recover the part of the secret key that was used for initialization. The following describes exactly how this can be achieved. We first introduce some auxiliary functions.

Definition 4.4. *Let $init^{-1}\colon \mathbb{F}_2^{23} \times \mathbb{F}_2^{n+1} \to \mathbb{F}_2^{n+1}$ be defined as*

$$init^{-1}(g, x_0) := g$$
$$init^{-1}(g, x_0 \dots x_n) := b \cdot init^{-1}(G^{-1}(g, 0, b), x_1 \dots x_n)$$
$$\text{where } b = g_0 \oplus x_0$$

Definition 4.5. *Let $Q^{-1}\colon \mathbb{F}_2^{n+12} \to \mathbb{F}_2^n$ be defined as*

$$Q^{-1}(p_0 \dots p_{11}) := \varepsilon$$
$$Q^{-1}(p_0 \dots p_n) := (p_2 \oplus p_8 \oplus p_{12}) \cdot Q^{-1}(p_1 \dots p_n)$$

Proposition 4.6. *Given an initial state $s_0 = \langle g, h, l, m, r \rangle$ it is possible to compute secret key bits $k_{40} \dots k_{95}$.*

The computation of the key bits is as follows.

$$t := g \cdot l \cdot m \cdot r$$
$$q := init^{-1}(t_0 \dots t_{22}, t_{23} \dots t_{42}) \cdot t_{43}$$
$$p := h \cdot Q^{-1}(h \cdot q)$$
$$k_{40} \dots k_{95} := p - n_C \mod 2^{56}.$$

4.3 Entropy of the non-linear feedback shift register

First and foremost, the initialization of the 13-bit non-linear feedback shift register (NLFSR) h is far from ideal. The NLFSR is initialized with only 12 bits by an almost linear function of the random nonce and the secret key. Adding upon the fact that, naturally, as the NLFSR h is not affected by other registers and the input, it is trivial to compute all successor states for a given h. Therefore, the search space for the 13-bit h register drops down to 2^{12}. Moreover, careful observation of the n_C value on the communication channel can leak information on whether the same value has been previously used for initializing h. For instance if the first 13 bits of n_C is the same for two different authentication attempts, depending on the rest of the bits, the attacker can conclude with a certain confidence that the same state is used for initializing h. This weakness can be later exploited in a differential attack.

5 Cryptanalysis of Megamos Crypto

This section describes a cryptanalysis of the Megamos Crypto cipher. We first introduce a simple cryptanalysis which is easier-to-grasp and recovers the 96-bit secret key with a computational complexity of 2^{56}. Then, in Section 5.1 we reduce its computational complexity down to 2^{48}.

This analysis requires two successful authentication traces $T = \langle n_C, output(s_7, k_{32} \ldots k_5), output(s_{35}, k_4 \ldots k_0 \cdot 0^{15})\rangle$ and $T' = \langle n'_C, output(s'_7, k_{32} \ldots k_5), output(s'_{35}, k_4 \ldots k_0 \cdot 0^{15})\rangle$. Discarding from all internal states $s_{40} \in \mathbb{F}_2^{56}$ those guesses which produce different 15 output bits than the trace T which leaves $2^{56-15} = 2^{41}$ candidate states for s_{40}. Rolling the cipher backwards for each candidate up to state s_7, as shown in Section 4.1, leaves—on average—the same number of candidate states for s_7, namely 2^{41}. Each step requires guessing one input bit k_i but at the same time the output provides one bit of information. Note that this determines a guess for key bits $k_0 \ldots k_{32}$. Rolling further the cipher backwards up to state s_0 requires guessing of $k_{33} \ldots k_{39}$ while no output bits are produced. This brings the number of candidate states for s_0 to $2^{41+7} = 2^{48}$. For each candidate s_0, the remaining key bits $k_{40} \ldots k_{95}$ can be recovered by undoing the initialization of the cipher as described in Section 4.2. This produces 2^{48} candidate keys $k_0 \ldots k_{95}$. On average, there is only one candidate secret key $k_0 \ldots k_{95}$ that together with n'_C produces the trace T'. This is because there are only 2^{48} candidates keys and 48 bits of information on the trace.

Time complexity on average, the aforementioned algorithm has a computational complexity of approximately 2^{56} encryptions. We have simulated an FPGA implementation of the algorithm on a Xilinx ISE 10.1 for synthesis and place & route. The results show that our implementation of a Megamos Crypto core covers approximately 1% of the Xilinx Spartan 3-1000 FPGA, the exact same chip that is employed in the COPACOBANA [42]. The maximum frequency that the core can run at is 160.33 MHz, which means we can test a single bit output in 6.237ns. Given this performance and area figures, a rough estimation suggests we can fit at least 50 Megamos Crypto cores in a Spartan 3-1000 FPGA. Considering that there are 120 such FPGA in a COPACOBANA, and since we can run them at 160.33MHz, we can run approximately $2^{39.8}$ tests per second. After every cycle, half of the candidate states are discarded, which means that a search takes less than two days on a COPACOBANA.

5.1 Reducing the computational complexity

Most of the computational complexity of the cryptanalysis described in Section 5 comes from iterating over all 2^{56} internal states s_{40}. In the following analysis we lower this complexity to 2^{48} by splitting the cipher state into two and using a time-memory trade-off. The main idea behind this optimization is to exploit the fact that components g and h are quite independent from components l, m and r. In fact, at each cipher step, there is only one bit of information from l, m, r which affects g, h, namely $l_1 \oplus m_6$. Conversely, there are only three bits of information from g, h that have an influence on components l, m, r.

In order reduce the complexity of the cryptanalysis an adversary $\mathscr{A}$ proceeds as follows.

1. Pre-computation: only once, and for each 2^{12} possible values of h, the adversary computes a table T_h as follows. For each $g \in \mathbb{F}_2^{23}$ and $j \in \mathbb{F}_2^{8}$ the adversary runs cipher components g and h one step forward. For this, $\mathscr{A}$ uses j_0 as a guess for $l_1 \oplus m_6$. At this stage $\mathscr{A}$ computes $f_0 := f_l(\cdot) f_m(\cdot) f_r(\cdot)$. From the resulting g and h, $\mathscr{A}$ repeats this procedure another 7 times, using j_i as a guess at step i and computing a three bit value f_i. At the end, she creates an entry in the table T_h of the form $< f_0 \ldots f_7, j_0 \ldots j_7, g >$. When the table is completed $\mathscr{A}$ sorts the table (on f, j).
2. As before $\mathscr{A}$ first eavesdrops one authentication trace between a legitimate transponder and an immobilizer. Thus $\mathscr{A}$ learns n_C, $output(s_7, k_{32} \ldots k_5)$ and $output(s_{35}, k_4 \ldots k_0 \cdot 0^{15})$.
3. Choose h.
4. Next the adversary will try to recover state s_{40}. For each $l, m, r \in \mathbb{F}_2^7$ the adversary runs these components 8 steps forward. At each step i she needs to guess 3 bits $f_i := f_l(\cdot) f_m(\cdot) f_r(\cdot)$ but she will be able to immediately discard half of these guesses as they will not produce the correct output bit $output(s_{40+i}, 0)$. At each step $\mathscr{A}$ will also compute $j_i : l_1 \oplus m_6$. At the end $\mathscr{A}$ has $2^{21+16} = 2^{37}$ bitstrings of the form $< f_0 \ldots f_7, j_0 \ldots j_7, l, m, r >$.
5. For each of these bitstrings $\mathscr{A}$ performs a lookup on $f_0 \ldots f_7, j_0 \ldots j_7$ in the table T_h and recovers g. On average, half of these lookups will not have a match in T_h. In that case the candidate state is discarded, leaving only 2^{36} full candidate states.
6. Each of these candidate states are then rolled forward another 7 steps. Only $2^{36-7} = 2^{29}$ of these states will produce the correct $output(s_{48}, 0^7)$ bits and the rest are discarded.

7. For each of these 2^{29} states the adversary proceeds as in Section 5, undoing the initialization and checking against a second trace.

Time and resource complexity

- Pre-computation: for building the tables T_h the adversary needs to run components g and h of the cipher 8 steps. This has a computational complexity of $2^{23+12+3} = 2^{38}$ cipher steps. The generated tables can be conveniently stored in memory using a structure for compression like $/n/f_0/f_1/\dots/f_7/j/$`g.dat`. Storing all these tables require 12 terabyte of memory.
- As before, this cryptanalysis requires two successful authentication traces to recover the secret key. The most time intensive operation of this analysis is performing the 2^{37} lookups in the table for each of the 2^{12} values of h, i.e., 2^{49} table lookups.

The time-memory trade-off proposed in this section requires many indirect memory lookups and is therefore difficult to mount in practice with ordinary consumer hardware.

6 Partial Key-Update Attack

As it was described in Section 3.2, when the transponder is not locked, the Megamos Crypto transponder does not require authentication in order to write to memory. This makes it vulnerable to a trivial denial of service attack. An adversary just needs to flip one bit of the secret key of the transponder to disable it.

Besides this obvious weakness, there is another weakness regarding the way in which the secret key is written to the transponder. The secret key of Megamos Crypto is 96 bits long. As described in Section 3.1, these 96 bits are stored in 6 memory blocks of 16 bits each (blocks 4 to 9), see Figure 4. It is only possible to write one block at a time to the transponder. This constitutes a serious weakness since a secure key-update must be an atomic operation.

Next, we mount an attack which exploits this weakness to recover the secret key. For this attack we assume that an adversary $\mathscr{A}$ is able communicate with the car and transponder. She proceeds as follows.

1. The adversary first eavesdrops a successful authentication trace, obtaining n_C and a_C from the car.
2. Then, for $k = 0$ to $2^{16} - 1$ the adversary writes k on memory block 4 of the transponder, where key bits $k_0 \dots k_{15}$ are stored. After each write command $\mathscr{A}$ initiates an authentication attempt with the transponder, replaying n_C and a_C (remember that the transponder does not challenge the car). For one value of k the transponder will accept a_C and give an answer. Then $\mathscr{A}$ knows that $k_0 \dots k_{15} = k$.
3. The adversary proceeds similarly for blocks $5 \dots 9$ thus recovering the complete secret key.

Attack complexity this attack requires 6×2^{16} key-updates and the same amount of authentication attempts. This takes approximately 25 minutes for each block which adds up to a total of two and a half hours.

6.1 Optimizing the attack

The above attack is very powerful, in the worst case, the attacker needs to update the key on the transponder and make an authentication attempt 2^{16} times. However, the same attack can be applied with only one key-update and 2^{16} authentication attempts, by choosing carefully the value of n_C. The optimized attack can be mounted as follows:

1. As before, the adversary first eavesdrops a successful authentication trace, obtaining n_C, a_C and a_T.
2. then, she writes `0x0000` on memory block 9 which contains key bits $k_{80} \dots k_{95}$.
3. The adversary then increments the observed n_C value and attempts an authentication for each
$$n_C + inc \pmod{2^{56}}, \text{ where } 0 \leq inc < 2^{16}.$$
4. Repeating step 3) at most 2^{16} times, the transponder will accept one a_C value for a particular increment value inc and give an answer. Then $\mathscr{A}$ knows that $k_{80} \dots k_{95} = inc$.
5. The adversary proceeds similarly for blocks 8 and 7. At this point the adversary has recovered key bits $k_{48} \dots k_{95}$.
6. Next, the adversary guesses 15 key bits $k_{33} \dots k_{47}$.
7. Having $k_{33} \dots k_{95}$ the adversary is now able to initialize the cipher, obtain the initial state s_0 and run it forward up to state s_7. At this point the adversary has 2^{15} candidates for state s_7.
8. For each of these candidates, she runs the cipher forward 33 steps up to state s_{40}. While running the cipher forward the adversary is able to determine input bits $k_{32} \dots k_0$ by comparing the output bits to a_C and a_T from the trace.
9. Then, forward each candidate state at s_{40} to s_{55} and produce another 15 output bits to test on, although this time, with the known input of 15 zero bits. On average only one candidate survives this test. The adversary has now recovered the complete key.

Attack complexity This attack requires only one successful authentication trace. In total, we need to write three times on the memory of the transponder and perform 3×2^{16} authentications with the transponder. This can be done within 30 minutes using a Proxmark III. The computational complexity of the last three steps is 2^{15} encryptions which takes less than a second on a laptop.

7 Weak-Key Attack

During our experiments we executed the previous attack on several cars of different make and model. Many of the keys we recovered were of the form $k_0 = \cdots = k_{31} = 0$ and more or less random looking bits for $k_{32} \dots k_{96}$ (although we have found keys where only ten of the 96 bits were ones). In the remainder of this paper we call such a key *weak*. Figure 9 shows some examples of weak keys we found during our experiments (on the vehicles indicated in Figure 2). To avoid naming concrete car models we use $A, B, C \dots$ to represent car makes. We write numbers $X.1, X.2, X.3 \dots$ to represent different car models of make X.

Car	Secret key
$A.1$	00000000**d**8 **b**3**9**6**7**c**5**a**3**c**3**b**2**9
$A.2$	00000000**d**9 **b**7**9**d**7**a**5**b**3**c**3**b**2**8
$B.1$	00000000**0**0 **0**0**0**1**0**4**0**5**0**5**0**9**0**5

Figure 9: Recovered keys from our own cars. Besides the evident 32 leading zero bits, every second nibble seems to encode a manufacturer dependant value, which further reduces the entropy of the key.

Apparently, the automotive industry has decided to use only 64 bits of the secret key, probably due to compatibility issues with legacy immobilizer systems. If a Megamos Crypto transponder uses such a weak key it is possible to recover this key quickly, even when the memory of the transponder is locked with a PIN code. To be concrete, a weak secret key with the bits $k_0 \dots k_{31}$ fixed by the car manufacturer allows an adversary know the input bits of the cipher states $s_8 \dots s_{55}$.

With known input to the cipher at states $s_8 \dots s_{55}$, it is possible to pre-compute and sort on a 47 contiguous output bits for each internal state at s_8. However, such a table with 2^{56} entries requires a huge amount of storage. There are many time-memory tradeoff methods proposed in the literature over the last decades [2–5, 10, 33, 34, 49]. For example, a rainbow table shrinks the storage significantly, while requiring only a modest amount of computation for a lookup.

Concretely, in order to mount such an attack, an adversary $\mathscr{A}$ proceeds as follows.

1. Pre-computation: only once, the adversary computes the following rainbow table. First, she chooses n random permutations $R_0 \dots R_{n-1}$ of $\mathbb{F}_2^{56} \to \mathbb{F}_2^{56}$ which she uses as reduction functions (colors). To compute a chain, the intermediate states are generated by

$$s_{i+1} = R_j(output(s_i, 0^{56})).$$

The chain begins with the first reduction function R_0. When a distinguished point (i.e., a state with a specific pattern like a prefix of z zero bits) is reached then the next reduction function R_{j+1} is used, in order to prevent chain merges. The chain is completed once a distinguished point is reached while using the last reduction function R_{n-1}, see Figure 10. The start and end values of each chain are stored in the rainbow table which is sorted on end values.

$$\boxed{\begin{array}{ccccc} sp_0 \overset{R_0(\cdot)}{\leadsto} d_1 \overset{R_1(\cdot)}{\leadsto} & \dots & \overset{R_{n-2}(\cdot)}{\leadsto} d_{n-1} \overset{R_{n-1}(\cdot)}{\leadsto} d_n = ep_0 \\ \vdots & & \vdots \\ sp_m \overset{R_0(\cdot)}{\leadsto} d'_1 \overset{R_1(\cdot)}{\leadsto} & \dots & \overset{R_{n-2}(\cdot)}{\leadsto} d'_{n-1} \overset{R_{n-1}(\cdot)}{\leadsto} d'_n = ep_m \end{array}}$$

Figure 10: Construction of the rainbow table

2. As before $\mathscr{A}$ first eavesdrops one authentication trace between a legitimate transponder and an immobilizer. Thus $\mathscr{A}$ learns the car nonce n_C and 47 output bits $o_0 \dots o_{46} = output(s_7, k_{32} \dots k_5) \cdot output(s_{35}, k_4 \dots k_0 \cdot 0^{15})$.
3. For each value of $u_0 \dots u_8 \in \mathbb{F}_2^9$ and each reduction function R_j the adversary looks up $o_0 \dots o_{46} u_0 \dots u_8$ in the Rainbow table. In order to look up such a value she sets it as a state and runs the chain until the last distinguished point is reached at the last reduction function. Then, it performs n lookups in the rainbow table (one for each reduction function) to find the corresponding end point ep.
4. When the end point is found then the corresponding start point sp is used to find the previous internal state which generates $o_0 \dots o_{46} u_0 \dots u_8$ as output. Since we guessed the last 9 bits $u_0 \dots u_8$, we should consider this as a candidate state.
5. Then, the adversary rolls back each of those states seven steps, guessing the input $k_{32} \dots k_{39}$. This produces 2^8 candidate states for s_0. As before, for each candidate s_0 she undoes the initialization of the cipher and recovers the remaining key bits $k_{40} \dots k_{95}$. These need to be tested with another trace.
6. If the test is passed then we have recovered the secret key. Otherwise the next $u_0 \dots u_8$ should be considered at step 3).

Attack complexity This attack requires two successful authentication traces. This attack allows for a trade-off between memory and computational complexity. The longer the chains the smaller the table gets but more computation is needed for each lookup. Just to give an impression of the feasibility of the attack we consider the following configuration. Take z to be 10 bits, therefore our distinguished states have 10 zero bits followed by other 46 bits. We also take $64 = 2^6$ random permutations $R_0 \ldots R_{63}$. Then, following the computations of Oechslin [49], we get that the size of the rainbow table is $(2^{56})^{\frac{2}{3}} \approx 2^{37}$ entries of 12 bytes which is 1.5 TB. Regarding its computational complexity, we need to compute at step 3) 2^9 candidates for which we compute, for all 2^6 reduction functions and for all offsets, the end point. Since a chain has length at most 2^{16}, this takes at most $2^9 \times 2^6 \times 2^6 \times 2^{16} = 2^{37}$ encryptions. This can be computed within a few minutes on a laptop.

For building the rainbow table (needed only once), computation of the chains is sped up considerably by using FPGAs. Recently Kalenderi et. al. showed in [37] that a single FPGA (similar to the ones used in the COPACOBANA) computes chains 2824 times faster than a single 3GHz processor. They computed rainbow tables for the A5/1 cipher, which is reasonably similar to the Megamos Crypto cipher. Although the internal state of A5/1 is with 64 bits considerably larger than the 56 bits of Megamos Crypto, they are both designed for hardware implementation and both embed a non-linear component that causes some internal states to merge. Their experimental setup generates 345 chains for A5/1 in 830 milliseconds, which is roughly $\frac{345}{0.830} \approx 415$ chains per second. If we compute an estimate with respect to the difference in complexity, the COPACOBANA with a 120 FPGA-array can compute $415 \times (2^8)^{\frac{1}{3}} \times 120 \approx 2^{18.3}$ chains per second. That means it takes only $2^{37-18.3} \approx 2^{18.7}$ seconds, which is less than 5 days, to build the complete rainbow table.

8 Practical considerations and mitigation

Our attacks require close range wireless communication with both the immobilizer unit and the transponder. It is not hard to imagine real-life situations like valet parking or car rental where an adversary has access to both for a period of time. It is also possible to foresee a setup with two perpetrators, one interacting with the car and one wirelessly pickpocketing the car key from the victims pocket.

As mitigating measure, car manufacturers should set uniformly generated secret keys and for the devices which are not locked yet, set PIN codes and write-lock their memory after initialization. This obvious measures would prevent a denial of service attack, our partial key-update attack from Section 6 and our weak-key attack from Section 7.

Car owners can protect their own vehicles against a denial of service and the partial key-update attack, described in Section 6. These attacks only work if the adversary has write access to the memory of the transponder, which means that the lock-bit l_0 is set to zero. It is possible for a user to test for this property with any compatible RFID reader, like the Proxmark III, using our communication library. If $l_0 = 0$, then you should set the lock-bit l_0 to one. It is possible to set this bit without knowing the secret key or the PIN code. When dealing with the more recent version of the Megamos Crypto transponder (EM4170), users should also update the PIN code to a random bit-string before locking the transponder.

On the positive side, our first (cryptographic) attack is more computationally intensive than the attacks from Section 6 and 7 which makes it important to take the aforementioned mitigating measures in order to prevent the more inexpensive attacks. Unfortunately, our first attack is also hard to mitigate when the adversary has access to the car and the transponder (e.g., Valet and car rental). It seems infeasible to prevent an adversary from gathering two authentication traces. Furthermore, this attack exploits weaknesses in the core of the cipher's design (e.g., the size of the internal state). It would require a complete redesign of the cipher to fix these weaknesses. To that purpose, lightweight ciphers like Grain [32], Present [7] and KATAN [15] have been proposed in the literature and could be considered as suitable replacements for Megamos Crypto. Also, immobilizer products implementing AES are currently available in the market.

9 Conclusions

The implications of the attacks presented in this paper are especially serious for those vehicles with keyless ignition. At some point the mechanical key was removed from the vehicle but the cryptographic mechanisms were not strengthened to compensate.

We want to emphasize that it is important for the automotive industry to migrate from weak proprietary ciphers like this to community-reviewed ciphers such as AES [14] and use it according to the guidelines. For a few years already, there are contactless smart cards on the market [48, 50] which implement AES and have a fairly good pseudo-random number generator. It is surprising that the automotive industry is reluctant to migrate to such transponders considering the cost difference of a better chip ($\leq$ 1 USD) in relation to the prices of high-end car models ($\geq 50{,}000$ USD). Since most car keys are actually fairly big, the transponder design does not really have to comply with the (legacy) constraints of minimal size.

Following the principle of responsible disclosure, we have notified the manufacturer of our findings back in November 2012. Since then we have an open communication channel with them. We understand that measures have been taken to prevent the weak-key and partial key-update attacks when the transponder was improperly configured.
